**Relations.**—This artery is superficial throughout its entire extent, being covered, in front, by the integument, the superficial and deep fasciae; the bicipital fascia separates it opposite the elbow from the median basilic vein; the median nerve crosses it at its middle; behind, it is separated from the long head of the Triceps by the musculo-spiral nerve and superior profunda artery. It then lies upon the inner head of the Triceps, next upon the insertion of the Coraco-brachialis, and lastly on the Brachialis anticus; by its outer side, it is in relation with the commencement of the median nerve and the Coraco-brachialis and Biceps muscles, which overlap the artery to a considerable extent; by its inner side, its upper half is in relation with the internal cutaneous and ulnar nerves, its lower half with the median nerve. The basilic vein lies on the inner side of the artery, but is separated from it in the lower part of the arm by the deep fascia. The brachial artery is accompanied by
two vena comites, which lie in close contact with the artery, being connected together at intervals by short transverse communicating branches.

**Plan of the Relations of the Brachial Artery.**

Brachialis anticus.

**Surgical Anatomy of the Bend of the Elbow.**

At the bend of the elbow the brachial artery sinks deeply into a triangular interval, the antecubital space, the base of which is directed upward, and may be represented by a line connecting the two condyles of the humerus; the sides are bounded, externally, by the inner edge of the Supinator longus; internally, by the outer margin of the Pronator radii teres; its floor is formed by the Brachialis anticus and Supinator brevis. This space contains the brachial artery with its accompanying veins, the radial and ulnar arteries, the median and musculo-spiral nerves, and the tendon of the Biceps. The brachial artery occupies the middle line of this space, and divides opposite the neck of the radius into the radial and ulnar arteries; it is covered, in front, by the integument, the superficial fascia, and the median basilic vein, the vein being separated from direct contact with the artery by the bicipital fascia. Behind, it lies on the Brachialis anticus, which separates it from the elbow-joint. The median nerve lies on the inner side of the artery, close to it above, but separated from it below by the coronoid origin of the Pronator radii teres. The tendon of the Biceps lies to the outer side of the space, and the musculo-spiral nerve still more externally, situated upon the Supinator brevis and partly concealed by the Supinator longus.

**Peculiarities of the Brachial Artery as Regards its Course.**—The brachial artery, accompanied by the median nerve, may leave the inner border of the Biceps and descend toward the inner condyle of the humerus, where it usually curves round a prominence of bone, the supracondylar process. From this process, in most subjects, a fibrous arch is thrown over the artery. The vessel then inclines outward, beneath or through the substance of the Pronator radii teres muscle, to the bend of the elbow. The variation bears considerable analogy to the normal condition of the artery in some of the carnivora; it has been referred to in the description of the humerus (page 181).

**As Regards its Division.**—Occasionally, the artery is divided for a short distance at its upper part into two trunks, which are united above and below. A similar peculiarity occurs in the main vessel of the lower limb.

The point of bifurcation may be above or below the usual point, the former condition being by far the more frequent. Out of 481 examinations recorded by Mr. Quain, some made on the right and some on the left side of the body, in 386 the artery bifurcated in its normal position. In one case only was the place of division lower than usual, being two or three inches below the elbow-joint. "In 94 cases out of 481, or about 1 in 5½, there were two arteries instead of one in some part or in the whole of the arm."
THE BLOOD-VASCULAR SYSTEM

There appears, however, to be no correspondence between the arteries of the two arms with respect to their irregular division; for in 61 bodies it occurred on one side only in 43; on both sides, in different positions, in 13; on both sides, in the same position, in 3.

The point of bifurcation takes place at different parts of the arm, being most frequent in the upper part, less so in the lower part, and least so in the middle, the most usual point for the application of a ligature; under any of these circumstances two large arteries would be found in the arm instead of one. The most frequent (in three out of four) of these peculiarities is the high origin of the radial. That artery often arises from the inner side of the brachial, and runs parallel with the main trunk to the elbow, where it crosses it, lying beneath the fascia; or it may perforate the fascia and pass over the artery immediately beneath the integument.

The ulnar sometimes arises from the brachial high up, and accompanies that vessel to the lower part of the arm, and descends toward the inner condyle. In the forearm it generally lies beneath the deep fascia, superficial to the flexor muscles; occasionally between the integument and deep fascia, and very rarely beneath the flexor muscles.

The interosseous artery sometimes arises from the upper part of the brachial or axillary; as it passes down the arm it lies behind the main trunk, and at the bend of the elbow regains its usual position.

In some cases of high origin of the radial the remaining trunk (ulnar interosseous) occasionally passes, together with the median nerve, along the inner margin of the arm to the inner condyle, and then passing from within outward, beneath or through the Pronator radii teres, regains its usual position at the bend of the elbow.

Occasionally the two arteries representing the brachial are connected at the bend of the elbow by a short transverse branch, and are even sometimes reunited.

Sometimes, long slender vessels, *vasa aberrantia*, connect the brachial or axillary arteries with one of the arteries of the forearm or a branch from them. These vessels usually join the radial.

**Varieties in Muscular Relations.**—The brachial artery is occasionally concealed in some part of its course by muscular or tendinous slips derived from the Coraco-brachialis, Biceps, Brachialis anticus, and Pronator radii teres muscles.

**Surface Marking.**—The direction of the brachial artery is marked by a line drawn along the inner edge of the Biceps from the junction of the anterior and middle thirds of the axillary outlet to the middle of the front of the elbow-joint.

**Surgical Anatomy.**—Compression of the brachial artery is required in cases of amputation and some other operations in the arm and forearm; and it will be observed that it may be effected in almost any part of the course of the artery. If pressure is made in the upper part of the limb, it should be directed from within outward; and if in the lower part, from before backward, as the artery lies on the inner side of the humerus above and in front of the humerus below. The most favorable situation is about the middle of the arm, where it lies on the tendon of the Coraco-brachialis on the inner flat side of the humerus.

The application of a ligature to the brachial artery may be required in case of wound of the vessel and in some cases of wound of the palmar arch. It is also sometimes necessary in cases of aneurism of the brachial, the radial, ulnar, or interosseous arteries. The artery may be secured in any part of its course. The chief guides in determining its position are the surface markings produced by the inner margin of the Coraco-brachialis and Biceps, the known course of the vessel, and its pulsation, which should be carefully felt for before any operation is performed, as the vessel occasionally deviates from its usual position in the arm. In whatever situation the operation is performed, great care is necessary, on account of the extreme thinness of the parts covering the artery and the intimate connection which the vessel has throughout its whole course with important nerves and veins. Sometimes a thin layer of muscular fibre is met with concealing the artery; if such is the case, it must be cut across in order to expose the vessel.

In the upper third of the arm the artery may be exposed in the following manner: The patient being placed supine upon a table, the affected limb should be raised from the side and the hand supinated. An incision about two inches in length should be made on the inner side of the Coraco-brachialis muscle, and the subjacent fascia cautiously divided, so as to avoid wounding the internal cutaneous nerve or basilic vein, which sometimes runs on the surface of the artery as high as the axillary. The fascia having been divided, it should be remembered that the ulnar and internal cutaneous nerves lie on the inner side of the artery, the median on the outer side, the latter nerve being occasionally superficial to the artery in this situation, and that the venous comites are also in relation with the vessel, one on either side. These being carefully separated, the aneurism needle should be passed round the artery from the inner to the outer side.

If two arteries are present in the arm in consequence of a high division, they are usually placed side by side: and if they are exposed in an operation, the surgeon should endeavor to

1 See Struther’s Anatomical and Physiological Observations.
ascertain, by alternately pressing on each vessel, which of the two communicates with the wound or aneurism, when a ligature may be applied accordingly; or if pulsation or hemorrhage ceases only when both vessels are compressed, both vessels may be tied, as it may be concluded that the two communicate above the seat of disease or are reunited.

It should also be remembered that two arteries may be present in the arm in a case of high division, and that one of these may be found along the inner intermuscular septum, in a line toward the inner condyle of the humerus, or in the usual position of the brachial, but deeply placed beneath the common trunk: a knowledge of these facts will suggest the precautions necessary in every case, and indicate the measures to be adopted when anomalies are met with.

In the middle of the arm the brachial artery may be exposed by making an incision along the inner margin of the Biceps muscle. The forearm being bent so as to relax the muscle, it should be drawn slightly aside, and, the fascia being carefully divided, the median nerve will be exposed lying upon the artery (sometimes beneath); this being drawn inward and the muscle outward, the artery should be separated from its accompanying veins and secured. In this situation the inferior profunda may be mistaken for the main trunk, especially if enlarged, from the collateral circulation having become established; this may be avoided by directing the incision externally toward the Biceps, rather than inward or backward toward the Triceps.

The lower part of the brachial artery is of interest in a surgical point of view, on account of the relation which it bears to the veins most commonly opened in venesection. Of these vessels, the median basilic is the largest and most prominent, and, consequently, the one usually selected for the operation. It should be remembered that this vein runs parallel with the brachial artery, from which it is separated by the bicipital fascia, and that care should be taken in opening the vein not to carry the incision too deeply, so as to endanger the artery.

Collateral Circulation.—After the application of a ligature to the brachial artery in the upper third of the arm, the circulation is carried on by branches from the circumflex and subscapular arteries, anastomosing with ascending branches from the superior profunda. If the brachial is tied below the origin of the profunda arteries, the circulation is maintained by the branches of the profunda, anastomosing with the recurrent radial, ulnar, and interosseous arteries. In two cases described by Mr. South,1 in which the brachial artery had been tied some time previously, in one "a long portion of the artery had been obliterated, and the vessels are descending on either side from above the obliteration, to be received into others which ascend in a similar manner from below it. In the other the obliteration is less extensive, and a single curved artery about as big as a crow-quin passes from the upper to the lower open part of the artery."

Branches.—The branches of the brachial artery are—the

The Superior Profunda Artery (a. profunda brachii) arises from the inner and back part of the brachial, just below the lower border of the Teres major, and passes backward to the interval between the outer and inner heads of the Triceps muscle; accompanied by the musculo-spiral nerve it winds around the back part of the shaft of the humerus in the spiral groove, between the outer head of the Triceps and the bone, to the outer side of the humerus, where it reaches the external intermuscular septum and divides into two terminal branches. One of these pierces the external intermuscular septum, and descends, in company with the musculo-spiral nerve, to the space between the Brachialis anticus and Supinator longus, where it anastomoses with the recurrent branch of the radial artery; while the other, much the larger of the two, descends along the back of the external intermuscular septum to the back of the elbow-joint, where it anastomoses with the posterior interosseous recurrent, and across the back of the humerus with the posterior ulnar recurrent, the anastomotica magna, and inferior profunda (Fig. 418). The superior profunda supplies the Triceps muscle and gives off a nutrient artery which enters the bone at the upper end of the musculo-spiral groove. Near its commencement it sends off a branch which passes upward between the external and long heads of the Triceps muscle to anastomose with the posterior circumflex

1 Chellus's Surgery, vol. ii. p. 254. See also White's engravings, referred to by Mr. South, of the anastomosing branches after ligature of the brachial, in White's Cases in Surgery. Porta also gives a case (with drawings) of the circulation after ligature of both brachial and radial (Alterazioni Patologiche delle Arterie).—En. of 15th English edition.
artery, and, while in the groove, a small branch which accompanies a branch of the musculo-spiral nerve through the substance of the Triceps muscle and ends in the Anconeus below the outer condyle of the humerus.

The Nutrient Artery (a. nutricia humeri) of the shaft of the humerus arises from the brachial, about the middle of the arm. Passing downward it enters the nutrient canal of that bone near the insertion of the Coraco-brachialis muscle.

The Inferior Profunda (a. collateralis ulnaris superior), of small size, arises from the brachial, a little below the middle of the arm; piercing the internal intermuscular septum, it descends on the surface of the inner head of the Triceps muscle to the space between the inner condyle and olecranon, accompanied by the ulnar nerve, and terminates by anastomosing with the posterior ulnar recurrent and anastomotica magna. It sometimes supplies a branch to the front of the internal condyle, which anastomoses with the anterior ulnar recurrent.

The Anastomotica Magna (a. collateralis ulnaris inferior) arises from the brachial about two inches above the elbow-joint. It passes transversely inward upon the Brachialis anticus, and, piercing the internal intermuscular septum, winds round the back of the humerus between the Triceps and the bone, forming an arch above the olecranon fossa by its junction with the posterior articular branch of the superior profunda. As this vessel lies on the Brachialis anticus, branches ascend to join the inferior profunda, and others descend in front of the inner condyle to anastomose with the anterior ulnar recurrent. Behind the internal condyle an offset is given off which anastomoses with the inferior profunda and posterior ulnar recurrent arteries and supplies the Triceps.

The Muscular (rami musculares) are three or four large branches, which are distributed to the muscles in the course of the artery. They supply the Coraco-brachialis, Biceps, and Brachialis anticus muscles.
The Anastomosis around the Elbow-joint (Fig. 418).—The vessels engaged in this anastomosis may be conveniently divided into those situated in front and behind the internal and external condyles. The branches anastomosing in front of the internal condyle are the anastomotica magna, the anterior ulnar recurrent, and the anterior terminal branch of the inferior profunda. Those behind the internal condyle are the anastomotica magna, the posterior ulnar recurrent, and the posterior terminal branch of the inferior profunda. The branches anastomosing in front of the external condyle are the radial recurrent and the anterior terminal branch of the superior profunda. Those behind the external condyle (perhaps more properly described as being situated between the external condyle and the olecranon) are the anastomotica magna, the interosseous recurrent, and the posterior terminal branch of the superior profunda. There is also a large arch of anastomosis above the olecranon, formed by the interosseous recurrent, joining with the anastomotica magna and posterior ulnar recurrent.

From this description it will be observed that the anastomotica magna is the vessel most engaged, the only part of the anastomosis in which it is not employed being that in front of the external condyle.

The Radial Artery (A. Radialis) (Figs. 416, 417).

The radial artery appears, from its direction, to be the continuation of the brachial, but in size it is smaller than the ulnar. It commences at the bifurcation of the brachial, just below the bend of the elbow, and passes along the radial side of the forearm to the wrist; it then winds backward, round the outer side of the carpus, beneath the extensor tendons of the thumb, to the upper end of the space between the metacarpal bones of the thumb and index finger, and finally passes forward, between the two heads of the First dorsal interosseous muscle, into the palm of the hand, where it crosses the metacarpal bones to the ulnar border of the hand, to form the deep palmar arch. At its termination it inosculates with the deep branch of the ulnar artery. The relations of this vessel may thus be conveniently divided into three parts—viz., in the forearm, at the back of the wrist, and in the hand.

Relations.—In the forearm this vessel extends from opposite the neck of the radius to the forepart of the styloid process, being placed to the inner side of the shaft of the bone above and in front of it below. It is overlapped in the upper part of its course by the fleshy belly of the Supinator longus muscle; throughout the rest of its course it is superficial, being covered by the integument, the superficial and deep fasciae. In its course downward it lies upon the tendon of the Biceps, the Supinator brevis, the Pronator radii teres, the radial origin of the Flexor sublimis digitorum, the Flexor longus pollicis, the Pronator quadratus, and the lower extremity of the radius. In the upper third of its course it lies between the Supinator longus and the Pronator radii teres; in the lower two-thirds, between the tendons of the Supinator longus and the Flexor carpi radialis. The radial nerve lies close to the outer side of the artery in the middle third of its course, and some filaments of the musculo-cutaneous nerve, after piercing the deep fascia, run along the lower part of the artery as it winds round the wrist. The vessel is accompanied by vena comites throughout its whole course.

Plan of the Relations of the Radial Artery in the Forearm.

In front.

Supinator longus.

Inner side.
Pronator radii teres.
Flexor carpi radialis.

Radial Artery in Forearm.

Outer side.
Supinator longus.
Radial nerve (middle third).
At the wrist, as it winds round the outer side of the carpus from the styloid process to the first interosseous space, it lies upon the external lateral ligament, and then upon the scaphoid bone and trapezium, being covered by the extensor tendons of the thumb, subcutaneous veins, some filaments of the radial nerve, and the integument. It is accompanied by two veins and a filament of the musculo-cutaneous nerve.

In the hand it passes from the upper end of the first interosseous space, between the heads of the Adductor indicis or First dorsal interosseous muscle, transversely across the palm, to the base of the metacarpal bone of the little finger, where it inosculates with the communicating branch from the ulnar artery, forming the deep palmar arch.

The Deep Palmar Arch (arcus volaris profundus) (Fig. 417).—It lies upon the carpal extremities of the metacarpal bones and the Interossei muscles, being covered by the Adductor obliquus pollicis, the flexor tendons of the fingers, the Lumbricales, the Opponens, and Flexor brevis minimi digiti. Alongside of it is the deep branch of the ulnar nerve, but running in the opposite direction; that is to say, from within outward. The branches of the deep palmar arch are the palmar interosseous, perforating and palmar recurrent vessels (page 662).

Peculiarities.—The origin of the radial artery, according to Quain, is, in nearly one case in eight, higher than usual; more frequently arising from the axillary or upper part of the brachial than from the lower part of this vessel. The variations in the position of this vessel in the arm and at the bend of the elbow have been already mentioned. In the forearm it deviates less frequently from its position than the ulnar. It has been found lying over the fascia instead of beneath it. It has also been observed on the surface of the Supinator longus, instead of under its inner border; and in turning round the wrist it has been seen lying over, instead of beneath, the extensor tendons of the thumb.

Surface Marking.—The position of the radial artery in the forearm is represented by a line drawn from the outer border of the tendon of the Biceps in the centre of the hollow in front of the elbow-joint with a straight course to the inner side of the forepart of the styloid process of the radius.

Surgical Anatomy.—The radial artery is much exposed to injury in its lower third, and is frequently wounded by the hand being driven through a pane of glass, by the slipping of a knife or chisel held in the other hand, and similar accidents. The injury is often followed by a traumatic aneurism, for which the operation of extirpating or laying open the sac after securing the vessel above and below is required.

The operation of tying the radial artery is required in cases of wounds either of its trunk or of some of its branches, or for aneurism; and it will be observed that the vessel may be exposed in any part of its course through the forearm without the division of any muscular fibres. The operation in the middle or inferior third of the forearm is easily performed, but in the upper third, near the elbow, it is attended with some difficulty, from the greater depth of the vessel and from its being overlapped by the Supinator longus muscle.

To tie the artery in the upper third an incision three inches in length should be made through the integument, in a line drawn from the centre of the bend of the elbow to the front of the styloid process of the radius, avoiding the branches of the median vein; the fascia of the arm being divided and the Supinator longus drawn a little outward, the artery will be exposed. The vena comites should be carefully separated from the vessel, and the ligature passed from the radial to the ulnar side.

In the middle third of the forearm the artery may be exposed by making an incision of similar length on the inner margin of the Supinator longus. In this situation the radial nerve lies in close relation with the outer side of the artery, and should, as well as the veins, be carefully avoided.

In the lower third the artery is easily secured by dividing the integument and fascia in the interval between the tendons of the Supinator longus and Flexor carpi radialis muscles.
THE RADIAL ARTERY

Branches (Figs. 416, 417, and 418).—The branches of the radial artery may be divided into three groups, corresponding with the three regions in which the vessel is situated.

In the Forearm

The Radial Recurrent (a. recurrens radialis) (Fig. 417) is given off immediately below the elbow. It ascends between the branches of the musculo-spiral nerve lying on the Supinator brevis, and then between the Supinator longus and Brachialis anticus, supplying these muscles and the elbow-joint, and anastomosing with the terminal branches of the superior profunda.

The Muscular Branches (rami musculares) are distributed to the muscles on the radial side of the forearm.

The Anterior Radial Carpal (ramus carpeus volaris) (Fig. 417) is a small vessel which arises from the radial artery near the lower border of the Pronator quadratus, and, running inward in front of the radius, anastomoses with the anterior carpal branch of the ulnar artery. In this way an arterial anastomosis, the anterior carpal arch (rete carpi volare), is formed in front of the wrist; it is joined by branches from the anterior interosseous above, and by recurrent branches from the deep palmar arch below, and gives off branches which descend to supply the articulations of the wrist and carpus.

The Superficialis Volæ (ramus volaris superficialis) (Fig. 417) arises from the radial artery, just where this vessel is about to wind round the wrist. Running forward, it passes between, occasionally over, the muscles of the thumb, which it supplies, and sometimes anastomoses with the palmar portion of the ulnar artery, completing the superficial palmar arch. This vessel varies considerably in size; usually it is very small, and terminates in the muscles of the thumb; sometimes it is as large as the continuation of the radial.

The Posterior Radial Carpal (ramus carpeus dorsalis) (Fig. 418) is a small vessel which arises from the radial artery beneath the extensor tendons of the thumb; crossing the carpus transversely to the inner border of the hand, it anastomoses with the posterior carpal branch of the ulnar, forming the posterior carpal arch (rete carpi dorsale), which is joined by the termination of the anterior interosseous artery. From this arch are given off descending branches, the dorsal interosseous arteries (aa. metacarpeae dorsales) for the second, third, and fourth interosseous spaces, which run forward on the Second, Third, and Fourth dorsal interossei muscles, and divide into dorsal digital branches (aa. digitales dorsales), which supply the adjacent sides of the index, middle, ring, and little fingers respectively, communicating with the digital arteries of the superficial palmar arch. The dorsal interosseous arteries anastomose with the perforating branches from the deep palmar arch.

The Dorsales Pollicis (Fig. 418) are two vessels which run along the sides of the dorsal aspect of the thumb. They arise separately, or occasionally by a common trunk, near the base of the first metacarpal bone.

The Dorsalis Indicis (Fig. 418), also a small branch, runs along the radial side of the back of the index finger, sending a few branches to the Abductor indicis.
The Princeps Pollicis (a. princeps pollicis) (Fig. 417) arises from the radial just as it turns inward to the deep part of the hand; it descends between the Abductor indicis and Adductor obliquus pollicis, then between the Adductor transversus pollicis and Adductor obliquus pollicis, along the ulnar side of the metacarpal bone of the thumb, to the base of the first phalanx, where it divides into two branches, which run along the sides of the palmar aspect of the thumb, and form an arch on the palmar surface of the last phalanx, from which branches are distributed to the integument and pulp of the thumb.

The Radialis Indicis (a. volaris indicis radialis) (Fig. 417) arises close to the preceding, descends between the Abductor indicis and Adductor transversus pollicis, and runs along the radial side of the index finger to its extremity, where it anastomoses with the collateral digital artery from the superficial palmar arch. At the lower border of the Adductor transversus pollicis this vessel anastomoses with the princeps pollicis, and gives a communicating branch to the superficial palmar arch.

The Perforating Arteries (rami perforantes) (Fig. 417), three in number, pass backward from the deep palmar arch between the heads of the last three Dorsal interossei muscles, to inosculate with the dorsal interosseous arteries.

The Palmar Interosseous (aa. metacarpeae volares) (Fig. 417), three or four in number, arise from the convexity of the deep palmar arch; they run forward upon the Interossei muscles, and anastomose at the clefts of the fingers with the digital branches of the superficial arch.

The Palmar Recurrent Branches arise from the concavity of the deep palmar arch. They pass upward in front of the wrist, supplying the carpal articulations and anastomosing with the anterior carpal arch.

The Ulnar Artery (A. Ulnaris) (Figs. 416, 417).

The ulnar artery, the larger of the two terminal branches of the brachial, commences a little below the bend of the elbow, and crosses obliquely the
inner side of the forearm to the commencement of its lower half; it then runs along its ulnar border to the wrist, crosses the annular ligament on the radial side of the pisiform bone, and immediately beyond this bone divides into two branches which enter into the formation of the superficial and deep palmar arches.

Relations. In the Forearm.—In its upper half it is deeply seated, being covered by all the superficial Flexor muscles, excepting the Flexor carpi ulnaris; the median nerve is in relation with the inner side of the artery for about an inch and then crosses the vessel, being separated from it by the deep head of the Pronator radii teres; it lies upon the Brachialis anticus and Flexor profundus digitorum muscles. In the lower half of the forearm it lies upon the Flexor profundus, being covered by the integument, the superficial and deep fasciae, and is placed between the Flexor carpi ulnaris and Flexor sublimis digitorum muscles. It is accompanied by two vene comites; the ulnar nerve lies on its inner side for the lower two-thirds of its extent, and a small branch from the nerve descends on the lower part of the vessel to the palm of the hand.

Flexor profundus digitorum.

At the wrist (Fig. 416) the ulnar artery is covered by the integument and fascia, and lies upon the anterior annular ligament. On its inner side is the pisiform bone. The ulnar nerve lies at the inner side, and somewhat behind the artery; here the nerve and artery are crossed by a band of fibres, which extends from the pisiform bone to the anterior annular ligament.

Peculiarities.—The ulnar artery has been found to vary in its origin nearly in the proportion of one in thirteen cases, in one case arising lower than usual, about two or three inches below the elbow, and in all other cases much higher, the brachial being a more frequent source or origin than the axillary.

Variations in the position of this vessel are more frequent than in the radial. When its origin is normal the course of the vessel is rarely changed. When it arises high up it is almost invariably superficial to the Flexor muscles in the forearm, lying commonly beneath the fascia, more rarely between the fascia and integument. In a few cases its position was subcutaneous in the upper part of the forearm, subaponeurotic in the lower part.

Surface Marking.—On account of the curved direction of the ulnar artery the line on the surface of the body which indicates its course is somewhat complicated. First, draw a line from the front of the internal condyle of the humerus to the radial side of the pisiform bone; the lower two-thirds of this line represents the course of the middle and lower third of the ulnar artery. Secondly, draw a line from the centre of the antecubital space to the junction of the upper and middle third of the first line; this represents the course of the upper third of the artery.

Surgical Anatomy.—The application of a ligature to this vessel is required in cases of wound of the artery or of its branches, or in consequence of aneurism. In the upper half of the forearm the artery is deeply seated beneath the superficial flexor muscles, and the application of a ligature in this situation is attended with some difficulty. An incision is to be made in the course of a line drawn from the front of the internal condyle of the humerus to the outer side
of the pisiform bone, so that the centre of the incision is three fingers' breadth below the internal condyle. The skin and superficial fascia having been divided and the deep fascia exposed, the white line which separates the Flexor carpi ulnaris from the other flexor muscles is to be sought for, and the fascia incised in this line. The Flexor carpi ulnaris is now to be carefully separated from the other muscles, when the ulnar nerve will be exposed, and must be drawn aside. Some little distance below the nerve the artery will be found accompanied by its venae comites, and it may be ligatured by passing the needle from within outward. In the middle and lower third of the forearm this vessel may be easily secured by making an incision on the radial side of the tendon of the Flexor carpi ulnaris: the deep fascia being divided, and the Flexor carpi ulnaris and its companion muscle, the Flexor sublimis, being separated from each other, the vessel will be exposed, accompanied by its venae comites, the ulnar nerve lying on its inner side. The veins being separated from the artery, the ligature should be passed from the ulnar to the radial side, taking care to avoid the ulnar nerve.

Branches (Figs. 416, 417, and 418).—The branches of the ulnar artery may be arranged in the following groups:

- **Forearm**:
  - Anterior Ulnar Recurrent.
  - Posterior Ulnar Recurrent.
  - Interosseous:
    - Anterior Interosseous.
    - Posterior Interosseous.
  - Muscular.

- **Wrist**:
  - Anterior Carpal.
  - Posterior Carpal.

- **Hand**:
  - Deep Palmar or Communicating.
  - Superficial Palmar Arch.

The **Anterior Ulnar Recurrent** (*a. recurrentes ulnaris anterior*) (Fig. 417) arises immediately below the elbow-joint, passes upward and inward between the Brachialis anticus and Pronator radii teres, supplies twigs to those muscles, and, in front, of the inner condyle anastomoses with the anastomotica magna and inferior profunda.

The **Posterior Ulnar Recurrent** (*a. recurrentes ulnaris posterior*) (Figs. 417 and 418) is much larger, and arises somewhat lower than the preceding. It passes backward and inward, beneath the Flexor sublimis, and ascends behind the inner condyle of the humerus. In the interval between this process and the olecranon it lies beneath the Flexor carpi ulnaris, and ascending between the heads of that muscle, in relation with the ulnar nerve; it supplies the neighboring muscles and joint, and anastomoses with the inferior profunda, anastomotica magna, and interosseous recurrent arteries.

The **Interosseous Artery** (*a. interossea communis*) (Fig. 417) is a short trunk about half an inch in length, and of considerable size, which arises immediately, below the tuberosity of the radius, and, passing backward to the upper border of the interosseous membrane, divides into two branches, the anterior and posterior interosseous.

The **Anterior Interosseous** (*a. interossea volaris*) (Fig. 417) passes down the forearm on the anterior surface of the interosseous membrane, to which it is connected by a thin aponeurotic arch. It is accompanied by the interosseous branch of the median nerve, and overlapped by the contiguous margins of the Flexor profundus digitorum and Flexor longus pollicis muscles, giving off in this situation muscular branches and the nutrient arteries of the radius and ulna. At the upper border of the Pronator quadratus a branch, anterior communicating artery, descends beneath the muscle to anastomose in front of the carpus with the anterior carpal arch. The continuation of the artery passes behind the Pronator quadratus, and, piercing the interosseous membrane, reaches the back of the forearm, and anastomoses with the posterior interosseous artery (Fig. 418). It then descends to the back of the wrist to join the posterior carpal arch. The anterior interosseous gives
off a long, slender branch, the median artery or artery comes nervi mediana (a. mediana), which accompanies the median nerve and gives offsets to its substance. This artery is sometimes much enlarged, and accompanies the nerve into the palm of the hand.

The Posterior Interosseous Artery (a. interossea dorsalis) (Figs. 417 and 418) passes backward through the interval between the oblique ligament and the upper border of the interosseous membrane. It appears between the contiguous borders of the Supinator brevis and the Extensor ossis metacarpi pollicis, and runs down the back part of the forearm, between the superficial and deep layer of muscles, to both of which it distributes branches. At the lower part of the forearm it anastomoses with the termination of the anterior interosseous artery. Then, continuing its course over the head of the ulna, it joins the posterior carpal branch of the ulnar artery. This artery gives off, near its origin, the interosseous recurrent branch.

The interosseous recurrent artery (a. interossea recurrens) (Fig. 418) is a large vessel which ascends to the interval between the external condyle and olecranon, on or through the fibres of the Supinator brevis, but beneath the Anconeus, anastomosing with a branch from the superior profunda, and with the posterior ulnar recurrent and anastomotica magna.

The Muscular Branches (rami musculares) are distributed to the muscles along the ulnar side of the forearm.

The Anterior Carpal (ramus carpeus volaris) (Fig. 417) is a small vessel which crosses the front of the carpus beneath the tendons of the Flexor profundus, and inosculates with a corresponding branch of the radial artery.

The Posterior Carpal (ramus carpeus dorsalis) (Fig. 418) arises immediately above the pisiform bone, and winds backward beneath the tendon of the Flexor carpi ulnaris; it passes across the dorsal surface of the carpus beneath the extensor
tendons, anastomosing with a corresponding branch of the radial artery, and forming the posterior carpal arch (rete carpi dorsale) (Fig. 418). Immediately after its origin it gives off a small branch which runs along the ulnar side of the metacarpal bone of the little finger, forming one of the metacarpal arteries, and supplies the ulnar side of the dorsal surface of the little finger.

The Deep or Communicating Branch to the Deep Palmar Arch (ramus volaris profundus) (Fig. 417) passes deeply inward between the Abductor minimi digiti and Flexor brevis minimi digitii, near their origins; it anastomoses with the termination of the radial artery, completing the deep palmar arch.

The continuation of the trunk of the ulnar artery in the hand forms the greater part of the superficial palmar arch.

The Superficial Palmar Arch (arcus volaris superficialis) (Fig. 416) is formed by the ulnar artery in the hand, and is completed on the outer side by this vessel anastomosing with a branch from the radialis indicis, though sometimes the arch is completed by the ulnar anastomosing with the superficialis volae or the princeps pollicis of the radial artery. The arch passes across the palm, describing a curve, with its convexity forward, to the space between the ball of the thumb and the index finger, where the above-mentioned anastomosis takes place.

Relations.—The superficial palmar arch is covered by the skin, the Palmaris brevis, and the palmar fascia. It lies upon the annular ligament, the Flexor brevis of the little finger, the tendons of the superficial flexor of the fingers, and the divisions of the median and ulnar nerves.

Plan of the Relations of the Superficial Palmar Arch.

In front.
Skin.
Palmaris brevis.
Palmar fascia.

Behind.
Annular ligament.
Flexor brevis of little finger.
Superficial flexor tendons.
Divisions of median and ulnar nerves.

Branches.—The branches of the Superficial Palmar Arch are the Digital.

The Digital Branches (aa. digitales volares communes) (Fig. 416), four in number, are given off from the convexity of the superficial palmar arch. They supply the ulnar side of the little finger and the adjoining sides of the little, ring, middle, and index fingers, the radial side of the index finger and thumb being supplied from the radial artery. The digital arteries at first lie superficial to the flexor tendons, but as they pass forward with the digital nerves to the clefts between the fingers they lie between them, and are there joined by the interosseous branches from the deep palmar arch. The digital arteries on the sides of the fingers lie beneath the digital nerves; and about the middle of the last phalanx the two branches for each finger form an arch, from the convexity of which branches pass to supply the pulp of the finger.
Surface Marking.—The superficial palmar arch is represented by a curved line, starting from the outer side of the pisiform bone and carried downward as far as the middle third of the palm, and then curved outward on a level with the upper end of the cleft between the thumb and index finger. The deep palmar arch is situated about half an inch nearer to the carpus.

Surgical Anatomy.—Wounds of the palmar arches are of special interest, and are always difficult to deal with. When the superficial arch is wounded it is generally possible, by enlarging the wound if necessary, to secure the vessel and tie it; or in cases where it is found impossible to encircle the vessel with a ligature, a pair of hemostatic forceps may be applied and left on for twenty-four or forty-eight hours. Wounds of the deep arch are not so easily dealt with. It may be possible to secure the vessel by ligature or by forcipressure forceps, which may be left on; or, failing in this, the wound may be carefully plugged with gauze and an outside dressing carefully bandaged on. The plug should be allowed to remain untouched for three or four days. In wounds of the deep palmar arch a ligature may be applied to the bleeding points from the dorsum of the hand by resection of the upper part of the third metacarpal bone. It is use less in these cases to ligate one of the arteries of the forearm alone, and indeed simultaneous ligation of both radial and ulnar arteries above the wrist is often unsuccessful, on account of the anastomosis carried on by the carpal arches. Therefore, if unable to ligate the divided ends of the arch, upon the failure of pressure to arrest hemorrhage, it is expedient to apply a ligature to the brachial artery.

ARteries OF the TRUNK.

THE DESCENDING AORTA (Figs. 419, 420).

The descending aorta is divided into two portions, the thoracic and abdominal, in correspondence with the two great cavities of the trunk in which it is situated.

The Thoracic Aorta (Aorta Thoracalis) (Fig. 419).

The thoracic aorta commences at the lower border of the fourth thoracic vertebra, on the left side, and terminates at the aortic opening in the Diaphragm, in front of the lower border of the last thoracic vertebra. At its commencement it is situated on the left side of the spine; it approaches the median line as it descends, and at its termination lies directly in front of the spinal column. The direction of this vessel being influenced by the spine, upon which it rests, it describes a curve which is concave forward in the thoracic region. As the branches given off from it are small, the diminution in the size of the vessel is inconsiderable. It is contained in the back part of the posterior mediastinum.

Relations.—It is in relation, in front, from above downward, with the root of the left lung, the pericardium, the oesophagus, and the Diaphragm: behind, with the vertebral column and the vena azygos minor; on the right side, with the vena azygos major and thoracic duct; on the left side, with the left pleura and lung. The oesophagus, with its accompanying nerves, lies on the right side of the aorta above; but at the lower part of the thorax it gets in front of the aorta, and close to the Diaphragm is situated to its left side.

Superior and inferior azygos minor veins.
The aorta is occasionally found to be obliterated at a particular spot—viz., at the junction of the arch with the thoracic aorta just below the ductus arteriosus. Whether this is the result of disease or of congenital malformation is immaterial to our present purpose; it affords an interesting opportunity of observing the resources of the collateral circulation. The course of the anastomosing vessels, by which the blood is brought from the upper to the lower part of the artery, will be found well described in an account of two cases in the Pathological Transactions, vols. viii. and x. In the former (p. 162) Mr. Sydney Jones thus sums up the detailed description of the anastomosing vessels: "The principal communications by which the circulation was carried on, were—Firstly, the internal mammary, anastomosing with the intercostal arteries, with the phrenic of the abdominal aorta by means of the musculo-phrenic and comes nervi phrenici, and largely with the deep epigastric. Secondly, the superior intercostal, anastomosing anteriorly by means of a large branch with the first aortic intercostal, and posteriorly with the posterior branch of the same artery. Thirdly, the inferior thyroid, by means of a branch about the size of an ordinary radial, formed a communication with the first aortic intercostal. Fourthly, the transversalis colli, by means of very large communications with the posterior branches of the intercostals. Fifthly, the branches (of the subclavian and axillary) going to the side of the chest were large, and anastomosed freely with the lateral branches of the intercostals." In the second case also (vol. x. p. 97) Mr. Wood describes the anastomoses in a somewhat similar manner, adding the remark that "the blood which was brought into the aorta through the anastomoses of the intercostal arteries appeared to be expended principally in supplying the abdomen and pelvis, while the supply to the lower extremities had passed through the internal mammary and epigastrics."

**Surgical Anatomy.**—The student should now consider the effects likely to be produced by aneurism of the thoracic aorta, a disease of common occurrence. When we consider the great depth of the vessel from the surface and the number of important structures which surround it on every side, it may easily be conceived what a variety of obscure symptoms may arise from disease of this part of the arterial system, and how they may be liable to be mistaken for those of other affections. Aneurism of the thoracic aorta most usually extends backward along the left side of the spine, producing absorption of the bodies of the vertebrae, with curvature of the spine; whilst the irritation or pressure on the cord will give rise to pain, either in the chest, back, or loins, with radiating pain in the left upper intercostal spaces, from pressure on the intercostal nerves; at the same time the tumor may project backward on each side of the spine, beneath the integument, as a pulsating swelling, simulating abscess connected with diseased bone, or it may displace the oesophagus and compress the lung on one or the other side. If the tumor extend forward, it may press upon and displace the heart, giving rise to palpitation and other symptoms of disease of that organ; or it may displace, or even compress, the oesophagus, causing pain and difficulty of swallowing, as in stricture of that tube; and ultimately even open into it by ulceration, producing fatal hemorrhage. If the disease extends to the right side, it may press upon the thoracic duct; or it may burst into the pleural cavity or into the trachea or lung; and, lastly, it may open into the posterior mediastinum.

**Branches.**—Branches of the thoracic aorta supply the thoracic viscera. They are known as **rami viscerales**. The rami viscerales are the **bronchial**, **oesophageal, pericardial**, and **mediastinal arteries**. Other branches of the thoracic aorta supply the walls of the chest. They are known as **rami parietales** or **intercostal arteries**.

The **Bronchial Arteries** (aa. bronchiales) are the nutrient vessels of the lungs, and vary in number, size, and origin. That of the right side arises from the first aortic intercostal, or by a common trunk with the left bronchial from the front of the thoracic aorta. Those of the left side, usually two in number, arise from the thoracic aorta, one a little lower than the other. Each vessel is directed to the back part of the corresponding bronchus along which it runs, dividing and subdividing along the bronchial tube, supplying them, the cellular tissue of the lungs, the bronchial glands, and the oesophagus.

The **Oesophageal Arteries** (aa. oesophageae), usually four or five in number, arise from the front of the aorta, and pass obliquely downward to the oesophagus, forming a chain of anastomoses along that tube, anastomosing with the oesophageal branches of the inferior thyroid arteries above, and with ascending branches from the phrenic and gastric arteries below.

The **Pericardiac** (rami pericardiaci) are a few small vessels, irregular in their origin, distributed to the pericardium.

The **Posterior Mediastinal Arteries** (rami mediastinales) are numerous small vessels which supply the glands and loose areolar tissue in the mediastinum.
The lower mediastinal branches are known as the superior phrenic arteries (aa. phrenicae superiores), and are distributed to the posterior portion of the Diaphragm.

The Intercostal Arteries (aa. intercostales) (Fig. 419) arise from the back of the aorta. The aortic intercostals are usually nine in number on each side, the two superior intercostal spaces being supplied by the superior intercostal, a branch of the subclavian. The second space usually receives a considerable branch from the first aortic intercostal, which joins with the branch from the superior intercostal of the subclavian. The branch which runs along the lower border of the last rib is named the subcostal artery. The right intercostals are longer than the left, on account of the position of the aorta on the left side of the spine: they pass outward, across the bodies of the vertebrae, to the intercostal spaces, being covered by the pleura, the esophagus, thoracic duct, sympathetic nerve, and the vena azygos major; the left, passing outward, are crossed by the sympathetic; the upper two are also crossed by the superior intercostal vein, the lower by the azygos minor veins. In each intercostal space the artery passes outward, the External intercostal muscle being behind, the pleura and a thin fascia being in front. It then passes between the two layers of Intercostal muscles, and, having ascended obliquely to the lower border of the rib above it, is continued forward in the groove on its lower border and anastomoses with the anterior intercostal branches of the internal mammary. The first aortic intercostal anastomoses with the superior intercostal branch of the subclavian, and the last three intercostals pass between the abdominal muscles, inosculating with the epigastric in front and with the phrenic and lumbar arteries. Each intercostal artery is accompanied by a vein and nerve, the former being above, and the latter below, except in the upper intercostal spaces, where the nerve is at first above the artery. The arteries are protected from pressure during the action of the Intercostal muscles by fibrous arches thrown across, and attached by each extremity to the bone. The lower intercostal arteries are continued anteriorly from the intercostal spaces into the abdominal wall, except the subcostal, which lies throughout its whole course in the abdominal wall, since it is placed below the last rib. They pass behind the costal cartilages between the Internal oblique and Transversalis muscle to the sheath of the Rectus, where they anastomose with the internal mammary and the deep epigastric arteries. Behind, the subcostal artery anastomoses with the first lumbar artery.

Branches.—Each intercostal artery gives off numerous muscular branches (rami musculares).

Lateral cutaneous.
Posterior or dorsal branch.

Muscular.
Collateral intercostal.
Lateral Cutaneous Branches (rami cutanei laterales) come off from each intercostal and take a similar course to that of the lateral cutaneous branch of the intercostal nerve. These arteries are distributed to the walls of the chest and to the mammary gland (rami mammarii laterales).

Small branches pass to the mammary gland through the fourth, fifth, and sixth interspaces (rami mammarii medialis), and to the skin to the inner side of the nipple (rami cutanei anteriores).

The portion of the artery considered here as the prolongation of the main trunk is called by Spalteholz and others the anterior branch (ramus anterior).

The Posterior or Dorsal Branch (ramus posterior) of each intercostal artery passes backward to the inner side of the anterior costo-transverse ligament, and divides into an external branch (ramus cutaneus lateralis), and an internal branch (ramus cutaneus medialis), which are distributed to the muscles and integument of the back. Muscular branches (rami musculares) are given off by the dorsal branch soon after its origin. A spinal branch (ramus spinalis) comes off from the dorsal branch of the intercostal. It traverses the vertebral arches and enters the spinal canal through the intervertebral foramen, is distributed to the spinal cord and its membranes, and to the bodies of the vertebrae in the same manner as the lateral spinal branches from the vertebra. It gives off three branches, the neural, which accompanies the spinal nerve-roots, and is distributed to the membranes of the spinal cord. The post-central branch divides into ascending and descending branches, which, anastomosing with similar branches above and below, form a series of vertical arches in the back of the bodies of the vertebrae. The prelaminar branch is distributed to "the posterior wall of the spinal canal." 1

The Collateral Intercostal Branch comes off from the intercostal artery near the angle of the rib, and descends to the upper border of the rib below, along which it courses to anastomose with the anterior intercostal branch of the internal mammary or its branch, the musculo-phrenic.

The two lower intercostals on each side have not constant collateral branches. Even when present they are of small size and end in the wall of the abdomen. Each collateral intercostal branch gives off muscular branches.

Surgical Anatomy.—The position of the intercostal vessels should be borne in mind in performing the operation of paracentesis thoracis. The puncture should never be made nearer the middle line posteriorly than the angle of the rib, as the artery crosses the space internal to this point. In the lateral portion of the chest, where the puncture is usually made, the artery lies at the upper part of the intercostal space, and therefore the puncture should be made just above the upper border of the rib forming the lower boundary of the space.

The Abdominal Aorta (Aorta Abdominalis) (Fig. 420).

The abdominal aorta commences at the aortic opening of the Diaphragm, in front of the lower border of the body of the last thoracic vertebra, and, descending a little to the left side of the vertebral column, terminates on the body of the fourth lumbar vertebra, commonly a little to the left of the middle line, 2 where it divides into the two common iliac arteries. It diminishes rapidly in size, in consequence of the many large branches which it gives off. As it lies upon the bodies of the vertebrae, the curve which it describes is convex forward, the greatest convexity corresponding to the third lumbar vertebra, which is a little above and to the left side of the umbilicus.

1 Cunningham's Text-book of Anatomy.
2 Lord Lister, having accurately examined 30 bodies in order to ascertain the exact point of termination of this vessel, found it "either absolutely, or almost absolutely, mesial in 15, while in 13 it deviated more or less to the left, and in 2 was slightly to the right" (System of Surgery, edited by T. Holmes, 2d ed., vol. v, p. 632). —Ed. of 19th English edition.
Relations.—It is covered, in front, by the lesser omentum and stomach, behind which are the branches of the celiac axis and the solar plexus; below these, by the splenic vein, the pancreas, the left renal vein, the transverse portion of the duodenum, the mesentery, and aortic plexus. Behind, it is separated from the lumbar vertebrae and intervening disks by the anterior common ligament and left lumbar veins. On the right side it is in relation with the postcava (the right crus of the Diaphragm being interposed above), the vena azygos major, thoracic duct, and right semilunar ganglion; on the left side, with the sympathetic nerve and left semilunar ganglion.

Surface Marking.—In order to map out the abdominal aorta on the surface of the abdomen, a line must be drawn from the middle line of the body, on a level with the distal extremity of the seventh costal cartilage, downward and slightly to the left, so that it just skirts the umbilicus, to a zone drawn round the body opposite the highest point of the crest of the ilium. This point is generally half an inch below and to the left of the umbilicus, but as the position of this structure varies with the obesity of the individual, it is not a reliable landmark as to the situation of the bifurcation of the aorta.

Surgical Anatomy.—Aneurisms of the abdominal aorta near the celiac axis communicate in nearly equal proportion with the anterior and posterior parts of the artery.

When an aneurismatic sac is connected with the back part of the abdominal aorta, it usually produces absorption of the bodies of the vertebrae, and forms a pulsating tumor that presents itself in the left hypochondriac or epigastric regions, and is accompanied by symptoms of disturbance in the alimentary canal. Pain is invariably present, and is usually of two kinds—a fixed and constant pain in the back, caused by the tumor pressing on or displacing the branches of the solar plexus and splanchnic nerves; and a sharp lancinating pain, radiating along those branches of the lumbar nerves which are pressed on by the tumor; hence the pain in the loins, the testes, the hypogastrium, and in the lower limb (usually of the left side). This form of aneurism usually bursts into the peritoneal cavity or behind the peritoneum in the left hypochondriac region; or it may form a large aneurismatic sac, extending down as low as Poupart’s ligament; hemorrhage in these cases being generally very extensive, but slowly produced, and not rapidly fatal.

When an aneurismatic sac is connected with the front of the aorta near the celiac axis it forms a pulsating tumor in the left hypochondriac or epigastric regions, usually attended with symptoms of disturbance of the alimentary canal, as sickness, dyspepsia, or constipation, and is accompanied by pain, which is constant, but nearly always fixed in the loins, epigastrium, or some part of the abdomen; the radiating pain being rare, as the lumbar nerves are seldom implicated. This form of aneurism may burst into the peritoneal cavity or behind the peritoneum, between the layers of the mesentery, or, more rarely, into the duodenum; it seldom extends backward so as to affect the spine.

The abdominal aorta has been tied 15 times, and although none of the patients permanently recovered, still, as Prof. Keen’s lived 48 days, the possibility of the re-establishment of the circulation is proved. In the lower animals this artery has been often successfully tied. The vessel may be reached in several ways. In the original operation, performed by Sir A. Cooper, in 1817, an incision was made in the linea alba, the peritoneum opened in front, the finger carried down amongst the intestines toward the spine, the peritoneum again opened behind by scratching through the mesentery, and the vessel thus reached. Or either of the operations described below for securing the common iliac artery may, by extending the dissection a sufficient distance upward, be made use of to expose the aorta. The chief difficulty in the dead subject consists in isolating the artery in consequence of its great depth; but in the living subject the embarrassment resulting from the proximity of the aneurismal tumor, and the great probability of disease in the vessel itself, add to the dangers and difficulties of this formidable operation so greatly that it is very doubtful whether it ought ever to be performed.

The collateral circulation would be carried on by the anastomosis between the internal mam-
mary and the deep epigastric; by the free communication between the superior and inferior mesenteries if the ligature were placed above the latter vessel; or by the anastomosis between the inferior mesenteric and the internal pudic when (as is more common) the point of ligature is below the origin of the inferior mesenteric; and possibly by the anastomoses of the lumbar arteries with the branches of the internal iliac.

During an amputation at the hip the circulation through the abdominal aorta may be commanded by an assistant, who throws the entire weight of his body upon his rigidly extended forearm, the fist of which lies directly upon the patient's aorta (MacBurney's method). The abdominal tourniquet is no longer used, as modern methods enable the surgeon to do a practically bloodless hip-joint amputation (Wyeth's method, Senn's method, McBurney's method).

**Branches** (Fig. 420).—The branches of the abdominal aorta are—the

- Phrenic
- Coeliac Axis
- Gastric
- Hepatic
- Splenic
- Superior Mesenteric
- Suprarenal
- Renal
- Spermatic in male.**
- Ovarian in female.
- Lumbar.
- Sacra Media.

**Branches.**—The branches of the abdominal aorta may be divided into two sets: 1. Those supplying the visceræ (rami vicales). 2. Those distributed to the walls of the abdomen (rami parietales).

**Visceral Branches.**

- Coeliac Axis
- Gastric
- Hepatic
- Splenic
- Superior Mesenteric
- Inferior Mesenteric
- Suprarenal
- Renal
- Spermatic or Ovarian.

**Parietal Branches.**

- Inferior Phrenic.
- Lumbar.
- Sacra Media.

To expose the coeliac axis raise the liver, draw down the stomach, and then tear through the layers of the lesser omentum.

**The Coeliac Axis or Artery** *(a. coeliaca)* (Figs. 420, 421, and 422).—The coeliac axis is a short thick trunk, about half an inch in length, which arises from the aorta, close to the margin of the opening in the Diaphragm, behind the posterior parietal peritoneum, above the pancreas, and below the twelfth thoracic vertebra, and, passing nearly horizontally forward (in the erect posture), divides into three large branches, the *gastric*, *hepatic*, and *splenic*, occasionally giving off one of the phrenic arteries.

**Relations.**—It is covered by the lesser omentum. On the *right side* it is in relation with the right semilunar ganglion and the lobus Spigelii; on the *left side*, with the left semilunar ganglion and cardiac end of the stomach. *Below*, it rests upon the upper border of the pancreas.

The *Gastric* or *Coronary Artery* *(a. gastrica sinistra)* (Figs. 421 and 422), the smallest of the three branches of the coeliac axis, passes upward and to the left side, behind the peritoneum of the lesser peritoneal cavity, raising this portion of the peritoneum into a fold, known as the *left or secondary pancreatico-gastric fold*. It continues this course until it nearly reaches the lesser curvature of the stomach just below the cardia. It then turns to the front and curves forward to the cardiac orifice of the stomach, distributing branches to the oesophagus which Anastomose with the aortic oesophageal arteries; others supply the cardiac end of the stomach, inosculating with branches of the splenic artery; it then passes from left to right, along and upon the lesser curvature of the stomach and beneath the peritoneum to the pylorus, lying in its course between the layers of the lesser omentum, and sometimes dividing into two vessels, which run along each side
of the lesser curvature. One vascular arch gives branches to the anterior wall of the stomach and the other to the posterior wall, and both give them to the lesser omentum or the single artery gives branches to both surfaces of the organ and to the lesser omentum: at its termination it anastomoses with the pyloric branch or the two pyloric branches of the hepatic. It gives off **gastric branches** to both the anterior and posterior surfaces of the stomach, branches to the lesser omentum, a **small hepatic branch**, to the left lobe of the liver and **esophageal branches** (*rami oesophagei*) which anastomose with esophageal branches from the thoracic aorta and the inferior phrenic.

![Diagram of the blood vascular system](image)

**Fig. 421.**—The cœlic axis and its branches, the liver having been raised and the lesser omentum removed.

The **Hepatic Artery** (*a. hepatica*) (Figs. 421 and 422) in the adult is intermediate in size between the gastric and splenic; in the foetus it is the largest of the three branches of the cœlic axis. It is first directed forward and to the right, in the right pancreatico-gastric fold, to the upper margin of the pyloric end of the stomach, forming the lower boundary of the foramen of Winslow. It then passes upward between the layers of the lesser omentum, and in front of the foramen of Winslow, to the transverse fissure of the liver, where it divides into two branches, right and left, which supply the corresponding lobes of that organ, accompanying the ramifications of the vena portæ and hepatic duct. The hepatic artery, in its course along the right border of the lesser omentum, is in relation with the ductus communis choledochus and portal veins, the duct lying to the right of the artery and the vena portæ behind.
Its branches (Figs. 421 and 422) are—the
Pyloric.
Gastro-duodenalis  { Gastro-epiploica Dextra.
                { Pancreatico-duodenalis Superior
Cystic.

The pyloric or superior pyloric branch (a. gastrica dextra) arises from the hepatic, above the pylorus, descends between the layers of the lesser omentum to the pyloric end of the stomach, and passes from right to left along its lesser curvature, supplying it with branches and inosculating with the gastric branches of the coronary artery. The vessel often divides into two vascular arches to anastomose with two vascular arches from the gastric.

The gastro-duodenalis (Fig. 422) is a short but large branch, which descends near the pylorus, behind the first portion of the duodenum, and divides at the lower border of this viscus into two branches, the gastro-epiploica dextra and the pancreatico-duodenalis superior. Previous to its division, it gives off two or three small inferior pyloric branches, to the pyloric end of the stomach and pancreas.

The gastro-epiploica dextra runs from right to left along but distinctly below the greater curvature of the stomach, between the layers of the great omentum, anastomosing about the middle of the lower border of the stomach with the gastro-epiploica sinistra from the splenic artery. This vessel gives off numerous branches,
some of which ascend to supply both surfaces of the stomach, whilst others descend to supply the great omentum (rami epiploici).

The pancreatico-duodenalis superior descends between the contiguous margins of the duodenum and pancreas. It supplies the head of the pancreas by means of the rami pancreatica, and the duodenum by means of the rami duodenalis, and anastomoses with the inferior pancreatico-duodenal branch of the superior mesenteric artery and with the pancreatic branches of the splenic.

The cystic artery (a. cystica) (Fig. 421), usually a branch of the right hepatic, passes downward and forward along the cystic duct to the gall-bladder, and divides into two branches, one of which ramifies on its free surface beneath the peritoneum, the other between the gall-bladder and the substance of the liver.

The Splenic Artery (a. lienalis) (Figs. 421 and 422), in the adult, is the largest of the three branches of the celiac axis, and is remarkable for the extreme tortuosity of its course. It passes horizontally to the left side, behind the peritoneum and along the upper border of the pancreas, accompanied by the splenic vein, which lies below it, and on arriving near the spleen divides into branches, some of which enter the hilum of that organ to be distributed to its structure, whilst others are distributed to the pancreas and great end of the stomach. Its branches are—the

The pancreatic branches (rami pancreatici) are numerous small branches derived from the splenic as it runs behind the upper border of the pancreas, supplying its middle and left parts. One of these, larger than the rest, is given off from the splenic near the left extremity of the pancreas; it runs from left to right near the posterior surface of the gland, following the course of the pancreatic duct, and is called the pancreatica magna. The others are called the pancreaticae parvae. These vessels anastomose with the pancreatic branches of the pancreatico-duodenal arteries, derived from the hepatic on the one hand and superior mesenteric on the other.

The gastric branches or vasa brevia (aa. gastricae breves) consists of from five to seven small branches, which arise either from the termination of the splenic artery or from its terminal branches, and, passing from left to right, between the layers of the gastro-splenic omentum, are distributed to the great curvature of the stomach, anastomosing with branches of the gastric and gastro-epiploica sinistra arteries.

The gastro-epiploica sinistra, the largest branch of the splenic, runs from left to right along but distinctly below the great curvature of the stomach, between the layers of the great omentum, and anastomoses with the gastro-epiploica dextra. In its course it distributes several branches to the stomach, which ascend upon both surfaces; others descend to supply the omentum.

The rami lienales leave the splenic artery in the hilum and pass into the spleen.

Surgical Anatomy.—The operation of pylorectomy can be made an almost bloodless procedure by tying the gastric, the pyloric, and the right and left gastro-epiploic arteries. "The gastric is doubly tied about one inch below the cardiac orifice at a point where it joins the lesser curvature and is divided between the ligatures. The superior pyloric is doubly tied and divided. The fingers are passed beneath the pylorus, raising the gastro-colic omentum from the transverse mesocolon, and in this way safe ligation behind the pylorus of the right gastro-epiploic artery, or in most cases its parent vessel, the gastro-duodenal, is secured. The left gastro-epiploic is now tied at an appropriate point, and the necessary amount of gastro-colic omentum doubly tied and cut."1

The Superior Mesenteric Artery (*a. mesenterica superior*) (Figs. 420 and 423).—The superior mesenteric artery supplies the whole length of the small intestine, except the first part of the duodenum; it also supplies the cæcum and the ascending and transverse colon; it is a vessel of large size, arising from the forepart of the aorta about a quarter of an inch below the cæliac axis; being covered at its origin by the splenic vein and pancreas. It passes forward, between the pancreas and the transverse portion of the duodenum, crosses in front of this portion of the intestine, and descends between the layers of the mesentery to the right iliac fossa, where, considerably diminished in size, it anastomoses with one of its own branches—viz., the ileo-colic. In its course it forms an arch, the convexity of which is directed forward and downward to the left side, the concavity backward and upward to the right. It is accompanied by the superior mesenteric vein, and is surrounded by the superior mesenteric plexus of nerves.

In order to expose the superior mesenteric artery raise the great omentum and transverse colon, draw down the small intestines, and cut through the peritoneum where the transverse mesocolon and mesentery join; the artery will then be exposed just as it issues from beneath the lower border of the pancreas.

**Branches.**—Its branches are—the

- **Inferior Pancreatice-duodenal.**
- **Vasa Intestini Tenuis.**
- **Ileo-colic.**
- **Right Colic.**
- **Middle Colic.**

The **Inferior Pancreatice-duodenal** (*a. pancreatice-duodenalis inferior*) is given off from the superior mesenteric, or from its first intestinal branch behind the pancreas. It courses to the right between the head of the pancreas and duodenum, and then ascends to anastomose with the superior pancreatica-duodenal artery. It distributes branches to the head of the pancreas and to the transverse and descending portions of the duodenum.

The **Vasa Intestini Tenuis** (*aa. intestinales*) arise from the convex side of the superior mesenteric artery. They are usually from twelve to fifteen in number, and are distributed to the jejunum (*aa. jejunales*) and ileum (*aa. ileae*). They run parallel with one another between the layers of the mesentery, each vessel dividing into two branches, which unite with similar branches on each side, forming a series of arches the convexities of which are directed toward the intestine. From this first set of arches branches arise, which again unite with similar branches from either side, and thus a second series of arches is formed; and from these latter, a third and a fourth, or even a fifth, series of arches is constituted, diminishing in size the nearer they approach the intestine. From the terminal arches numerous small straight vessels arise which encircle the intestine, upon which they are distributed, ramifying between its coats. Throughout their course small branches are given off to the glands and other structures between the layers of the mesentery. (See the description of the vascular loops in the section upon the Intestines. The form and arrangement of the loops have been studied by Monks, of Boston.)

The **Ileo-colic Artery** (*a. ileocolica*) is the lowest branch given off from the concavity of the superior mesenteric artery. It descends between the layers of the mesentery to the right iliac fossa, where it divides into two branches. Of these, the inferior division inosculates with the termination of the superior mesenteric artery, forming with it an arch, from the convexity of which branches proceed to supply the termination of the ileum, the cæcum, the vermiform appendix, and the ileo-cecal valve. The superior division inosculates with the colica dextra and supplies the commencement of the colon.

The **Right Colic Artery** (*a. colica dextra*) arises from about the middle of the concavity of the superior mesenteric artery, and, passing behind the peritoneum
to the middle of the ascending colon, divides into two branches—a descending branch, which inosculates with the ileo-colic, and an ascending branch, which anastomoses with the colica media. These branches form arches, from the convexity of which vessels are distributed to the ascending colon. The branches of this vessel are covered with peritoneum only on their anterior aspect.

The Middle Colic Artery (a. colica media) arises from the upper part of the concavity of the superior mesenteric, and, passing forward between the layers of the transverse mesocolon, divides into two branches, the one on the right side inosculating with the colica dextra; that on the left side, with the colica sinistra, a branch of the inferior mesenteric. From the arches formed by their inosculation branches are distributed to the transverse colon. The branches of this vessel lie between the two layers of the transverse mesocolon.

Blood-supply of the Right Iliac Fossa.—The descending branch of the right colic artery by anastomosing with the ascending branch of the ileo-colic artery forms a vascular loop. The union of the descending branch of the ileo-colic artery with the terminal vessel of the superior mesenteric artery forms another vascular loop. These two loops give off secondary loops, and from the secondary loops come the vessels which supply the appendix, the cecum, and the lower end of the ileum. The branch which goes to the appendix is called the appendicular artery (a. appendicularis). If there is a distinct meso-appendix the artery passes along its unattached edge. If there is a rudimentary meso-appendix or no meso-appendix the artery

FIG. 423.—The superior mesenteric artery and its branches.
THE ABDOMINAL AORTA

usually lies upon the appendix from base to tip beneath the peritoneal covering. In females the appendix may receive an additional vessel from the ovarian, which vessel lies in the appendiculio-ovarian ligament.

The Inferior Mesenteric Artery (a. mesenterica inferior) (Figs. 420 and 424).—
The inferior mesenteric artery supplies the descending colon, the sigmoid flexure of the colon and the greater part of the rectum. It is smaller than the superior mesenteric, and arises from the left side of the aorta, between one and two inches above the division of that vessel into the common iliacs. It passes downward to the left iliac fossa, and then descends between the layers of the mesorectum,

into the pelvis, under the name of the superior hemorrhoidal artery. It lies at first in close relation with the left side of the aorta, and then passes as the superior hemorrhoidal in front of the left common iliac artery.

In order to expose the inferior mesenteric artery draw the small intestines and mesentery over to the right side of the abdomen, raise the transverse colon toward the thorax, and divide the peritoneum covering the front of the aorta.

Branches.—Its branches are—the

Left Colic. Superior Hæmorrhoidal. Sigmoid.
The Left Colic Artery (a. colica sinistra) passes behind the peritoneum, in front of the left kidney, to reach the descending colon, and divides into two branches—an ascending branch, which inosculates with the colica media; and a descending branch, which anastomoses with the sigmoid artery. From the arches formed by these inosculations branches are distributed to the descending colon.

The Sigmoid Arteries (aa. sigmoideae).—As a rule there are two of these vessels, but may be three. They run obliquely downward across the Psoas muscle to the sigmoid flexure of the colon, and divide into branches which supply that part of the intestine, anastomosing above with the left colic, and below with the superior hemorrhoidal artery.

The Superior Hemorrhoidal Artery (a. haemorrhoidalis superior) (Figs. 424 and 427), the continuation of the inferior mesenteric, descends into the pelvis between the layers of the mesorectum, crossing, in its course, the ureter and left common iliac vessels. Opposite the middle of the sacrum it divides into two branches, which descend one on each side of the rectum, and about five inches from the anus break up into several small branches, which pierce the muscular coat of the bowel and run downward, as straight vessels, placed at regular intervals from each other in the wall of the gut between its muscular and mucous coat, to the level of the internal sphincter; here they form a series of loops around the lower end of the rectum, and communicate with the middle hemorrhoidal arteries which are branches of the internal iliac and with the inferior hemorrhoidal branches of the internal pudic.

The Suprarenal Artery (a. suprarenalis media) (Fig. 420).—A suprarenal or capsular artery arises, one on each side of the aorta, opposite the superior mesenteric artery. It is a small vessel which passes obliquely upward and outward, over the crura of the Diaphragm, to the under surface of the suprarenal capsule, to which it is distributed, anastomosing with capsular branches from the phrenic and renal arteries. In the adult these arteries are of small size; in the fetus they are as large as the renal arteries.

The Renal Arteries (aa. renales) (Fig. 420).—The renal arteries are two large trunks which arise from the sides of the aorta immediately below the superior mesenteric artery. Each is directed outward across the crus of the Diaphragm, so as to form nearly a right angle with the aorta. The right is longer than the left, on account of the position of the aorta; it passes behind the postcava. The left is somewhat higher than the right. Before reaching the hilum of the kidney, each artery usually divides into four branches. Two of these vessels enter the anterior portion and two the posterior portion of the kidney. There may be but one renal artery; there may be two, three, four, or five branches. The greater number of the branches generally lie between the renal vein and ureter, the vein being in front of the arteries, the ureter behind. The anterior branches supply three-fourths of the kidney, the posterior supply one-fourth. Each vessel gives off a small branch to the suprarenal capsule (a. suprarenalis inferior) and branches to the ureter, ureteral branches, and to the surrounding cellular tissue and muscles, perirenal branches. Hyrtl, in 1870, pointed out that the renal artery gives off a branch which divides and supplies the dorsal or posterior portion of the kidney and its pelvis, and a branch which divides and supplies the ventral or anterior portion of the kidney and its pelvis. The two circulations are distinct and do not anastomose even at the periphery. Between these two sets of vessels is a bloodless zone, the exsanguinated renal zone of Hyrtl, which does not correspond to the median line, but is one-half inch dorsal to the lateral longitudinal renal border. The ventral or anterior segment is much the larger. In very rare instances the bloodless zone corresponds to the median line (Kümmel). An incision of the middle third of the kidney exactly at the junction of the two segments does not divide.
vessels. As the incision approaches either pole there is danger of cutting a branch (Schede). Frequently there is a second renal artery, which is given off from the abdominal aorta either above or below the renal artery proper, the former being the more common position. Instead of entering the kidney at the hilum, an accessory renal artery usually pierces the upper or the lower part of the gland.

The Spermatic Arteries (aa. spermaticae internae) (Fig. 420).—The internal spermatic arteries are distributed to the testes. They are two slender vessels of considerable length, which arise from the front of the aorta a little below the renal arteries. Each artery passes obliquely outward and downward behind the peritoneum, resting on the Psoas muscle, the right spermatic lying in front of the postcava, the left behind the sigmoid flexure of the colon. It then crosses obliquely over the ureter (to which it sends a few branches) and the lower part of the external iliac artery to reach the internal abdominal ring, through which it passes, and accompanies the other constituents of the spermatic cord along the inguinal canal to the scrotum, where it becomes tortuous and is prolonged as the testicular artery (a. testicularis), which accompanies the vas deferens, anastomosing with the artery of the vas deferens and is distributed to the epididymis, the back part of the tunica albuginea, and the substance of the testes. The spermatic artery in the inguinal canal gives off cremasteric branches to supply the Cremaster muscle. In the canal and scrotum the artery lies behind the pampiniform plexus and in front of the vas deferens.

The Ovarian Arteries (aa. ovaricae).—The ovarian arteries (Fig. 428) are the corresponding arteries in the female to the spermatic in the male. They supply the ovaries, are shorter than the spermatic, and do not pass out of the abdominal cavity. The origin and course of the first part of the artery are the same as the spermatic in the male, but on arriving at the margin of the pelvis the ovarian artery passes inward, between the two layers of the broad ligament of the uterus,
to be distributed to the ovary, **ovarian branches**. Branches go to the Fallopian tube, **tubal branches**, the ureter, **ureteral branches**, and the broad ligament, **ligamentous branches**. A branch passes on to the side of the uterus and anastomoses with the uterine arteries, **uterine branch**. Other offsets are continued along the round ligament through the inguinal canal, to the integument of the labium and groin.

At an early period of foetal life, when the testes or ovaries lie by the side of the spine below the kidneys, the spermatic or ovarian arteries are short; but as these organs descend from the abdomen into the scrotum or pelvis, the arteries become gradually lengthened.

**The Inferior Phrenic Arteries (aa. phrenicae inferiores)** (Fig. 420).—The inferior phrenic arteries are two small vessels which present much variety in their origin. They may **arise** separately from the front of the aorta, immediately above the coeliac axis, or by a common trunk, which may spring either from the aorta or from the coeliac axis. Sometimes one is derived from the aorta, and the other from one of the renal arteries. In only one out of thirty-six cases examined did these arteries arise as two separate vessels from the aorta. They diverge from one another across the crura of the Diaphragm, and then pass obliquely upward and outward upon the under surface of the Diaphragm. The **left phrenic** passes behind the esophagus and runs forward on the left side of the esophageal opening. The **right phrenic** passes behind the postcava, and ascends along the right side of the aperture for transmitting that vein. Near the back part of the central tendon each vessel divides into two branches. The **internal branch** runs forward to the front of the thorax, supplying the Diaphragm and anastomosing with its fellow of the opposite side, and with the **musculo-phrenic** and **comes nervi phrenici** branches of the internal mammary. The **external branch** passes toward the side of the thorax and inosulates with the **intercostal arteries**. The internal branch of the right phrenic gives off a few vessels to the postcava, and the left one some branches to the esophagus. Each vessel also sends **capsular branches (rami suprarenales superior)** to the suprarenal capsule of its own side. The spleen on the left side and the liver on the right also receive a few branches from these vessels.

**The Lumbar Arteries (aa. lumbales)**.—The lumbar arteries are analogous to the intercostals. They are usually four in number on each side, and **arise** from the back part of the aorta, nearly at right angles with that vessel. They pass outward and backward, around the sides of the bodies of the lumbar vertebrae, behind the sympathetic nerve and the Psoas magnus muscle, those on the right side being covered by the postcava, and the two upper ones on each side by the crura of the Diaphragm. In the interval between the transverse processes of the vertebra each artery gives off a **dorsal branch**.

After the formation of the dorsal branch the artery passes outward, having a variable relation to the Quadratus lumborum muscle. Most frequently the first lumbar passes in front of the muscle and the others behind it; sometimes the order is reversed and the lowest lumbar passes in front of the muscle. At the outer border of the Quadratus they are continued between the abdominal muscles, anastomose with branches of the epigastric and internal mammary in front, the intercostals above, and branches of the ilio-lumbar and circumflex iliac below. The lumbar arteries are also distributed to the skin of the sides of the abdomen.

The **Dorsal Branch (ramus dorsalis)** gives off, immediately after its origin, a **spinal branch**, which enters the spinal canal. The dorsal branch then continues its course backward between the transverse processes, and is distributed to the muscles and integument of the back, anastomosing with similar branches of the adjacent lumbar arteries and with the posterior branches of the intercostal arteries.
THE COMMON IliAC ARTERIES

The Spinal Branch (ramus spinalis) enters the vertebral canal through the intervertebral foramen, to be distributed to the spinal cord and its membranes and to the bodies of the vertebrae in the same manner as the lateral spinal branches from the vertebral (see page 640).

The Middle Sacral Artery (a. sacralis media) (Fig. 427).—The middle sacral artery is a small vessel, which arises from the back part of the aorta just at its bifurcation. It descends upon the last lumbar vertebra, and along the middle line of the front of the sacrum, to the upper part of the coccyx, where it anastomoses with the lateral sacral arteries, and terminates in a minute branch, which runs down to the situation of the body described as Luschka's gland. It gives off on each side opposite the body of the fifth lumbar vertebra a branch known as the a. lumbalis ima. From the middle sacral artery branches arise which run through the mesorectum to supply the posterior surface of the rectum. Other branches are given off on each side, which anastomose with the lateral sacral arteries, and send off small offsets which enter the anterior sacral foramina.

The artery is the representative of the caudal prolongation of the aorta of animals, and its lateral branches correspond to the intercostal and lumbar arteries in the thoracic and lumbar regions.

THE COMMON IliAC ARTERIES (AA. IliacaE Communes) (Figs. 420, 427).

The abdominal aorta divides into the two common iliac arteries. The bifurcation usually takes place on the left side of the body of the fourth lumbar vertebra. The common iliac arteries are about two inches in length; diverging from the termination of the aorta, they pass downward and outward to the margin of the pelvis, each divides opposite the intervertebral substance, between the last lumbar vertebra and the sacrum, into two branches, the internal and external iliac arteries, the latter supplying the lower extremity; the former, the viscera and parietae of the pelvis.

The right common iliac is somewhat longer than the left, and passes more obliquely across the body of the last lumbar vertebra. In front of it are the peritoneum, the small intestines, branches of the sympathetic nerve, and, at its point of division, the ureter. Behind, it is separated from the fourth and fifth lumbar vertebrae, with the intervening intervertebral disk, by the two common iliac veins. On its outer side, it is in relation with the postcava and the right common iliac vein, above, and the Psoas magnus muscle below.

The left common iliac is in relation, in front, with the peritoneum, branches of the sympathetic nerve, and the superior hemorrhoidal artery; and is crossed at its point of bifurcation by the ureter. It rests on the bodies of the fourth and fifth lumbar vertebrae, with the intervening intervertebral disk. The left common iliac vein lies partly on the inner side, and partly beneath the artery; on its outer side, the artery is in relation with the Psoas magnus muscle.

Branches.—The common iliac arteries give off small branches to the peritoneum, Psoas magnus, ureters, and the surrounding cellular tissue, and occasionally give origin to the iliolumbar or renal arteries.

Peculiarities.—The point of origin varies according to the bifurcation of the aorta. In three-fourths of a large number of cases the aorta bifurcated either upon the fourth lumbar vertebra or upon the intervertebral disk between it and the fifth, the bifurcation being, in one case out of nine below, and in one out of eleven above, this point. In ten out of every thirteen cases the vessel bifurcated within half an inch above or below the level of the crest of the ilium, more frequently below than above.

The point of division is subject to great variety. In two-thirds of a large number of cases it was between the last lumbar vertebra and the upper border of the sacrum, being above that point in one case out of eight and below it in one case out of six. The left common iliac artery divides lower down more frequently than the right.

The relative length, also, of the two common iliac arteries varies. The right common iliac was the longer in sixty-three cases, the left in fifty-two, whilst they were both equal in fifty-three. The length of the arteries varied in five-sevenths of the cases examined from an inch and a half to three inches; in about half of the remaining cases the artery was longer and in the other half shorter, the minimum length being less than half an inch, the maximum four and a half inches. In two instances the right common iliac has been found wanting, the external and internal iliacs arising directly from the aorta.

Surface Marking.—Draw a zone around the body opposite the highest part of the crest of the ilium; in this line take a point half an inch to the left of the middle line. From this draw two lines to points midway between the anterior superior spines of the ilium and the symphysis pubis. These two diverging lines will represent the course of the common and external iliac arteries. Draw a second zone round the body corresponding to the level of the anterior superior spines of the ilium: the portion of the diverging lines between the two zones will represent the course of the common iliac artery; the portion below the lower zone, that of the external iliac artery.

Surgical Anatomy.—The application of a ligature to the common iliac artery may be required on account of aneurism or hemorrhage implicating the external or internal iliacs. Now that the surgeon no longer dreads opening the peritoneal cavity, there can be no question that the easiest and best method of tying the artery is by a transperitoneal route. The abdomen is opened by an incision in either the semilunar line or the linea alba; the intestines are drawn to one side and the peritoneum covering the artery divided. The sheath is then opened, and the needle passed from within outward. On the right side great care must be exercised in passing the needle, since both the common iliac veins lie behind the artery. After the vessel has been tied the incision in the peritoneum over the artery should be sutured. Formerly there were two different methods by which the common iliac artery was tied without opening the peritoneal cavity: 1, an anterior or iliac incision, by which the vessel is approached more directly from the front; and 2, a posterior abdominal or lumbar incision, by which the vessel is reached from behind. If the surgeon select the iliac region, a curved incision, from five to eight inches in length, according to the amount of fat, is made, commencing just outside the middle of Poupart's ligament and a finger's breadth above it, and carried outward toward the anterior superior iliac spine, then upward toward the ribs, and finally curving inward toward the umbilicus. The abdominal muscles and transversalis fascia are divided, and the peritoneum raised upward and inward until the Psoas is reached. The artery will be found on the inner side of this muscle, and is to be cleared with a director, especial care being taken on the right side, as here the common iliac veins lie behind the artery. The aneurism needle is to be passed from within outward. But if the aneurismal tumor should extend high up in the abdomen, along the external iliac, it is better to select the posterior or lumbar route, making an incision partly in the abdomen, partly in the loin. The incision is commenced at the anterior extremity of the last rib, proceeding directly downward to the ilium; it is then curved forward along the crest of the ilium and a little above it to the anterior superior spine of that bone. The abdominal muscles having been cautiously divided in succession, the transversalis fascia must be carefully cut through, and the peritoneum, together with the ureter, separated from the artery and pushed aside; the sacro-iliac articulation must then be felt for, and upon it the vessel will be felt pulsating, and may be fully exposed in close connection with the accompanying vein. On the right side both common iliac veins, as well as the postcava, are in close connection with the artery, and must be carefully avoided. On the left side the vein usually lies on the inner side and behind the artery; but it occasionally happens that the two common iliac veins are joined on
the left instead of the right side, which would add much to the difficulty of an operation in such a case. The common iliac artery may be so short that danger may be apprehended from secondary hemorrhage if a ligature is applied to it. It would be preferable, in such a case, to tie both the external and internal iliacs near their origin.

**Collateral Circulation.**—The principal agents in carrying on the collateral circulation after the application of a ligature to the common iliac are—the anastomoses of the hemorrhoidal branches of the internal iliac with the superior hemorrhoidal from the inferior mesenteric; the anastomoses of the uterine and ovarian arteries and of the vesical arteries of opposite sides; of the lateral sacral with the middle sacral artery; of the epigastric with the internal mammary, inferior intercostal, and lumbar arteries; of the circumflex iliac with the lumbar arteries; of the ilio-lumbar with the last lumbar artery; of the obturator artery, by means of its pubic branch, with the vessel of the opposite side and with the deep epigastric.

**Compression of the Common Iliac Arteries.**—The common iliac arteries may be compressed by Davy’s lever. The instrument consists of a gum-elastic tube about two feet long, in which fits a round wooden “lever” considerably longer than the tube. A small quantity of olive oil having been injected into the rectum, the gum-elastic tube, softened in hot water, is passed into the bowel sufficiently far to permit its pressing upon the common iliac artery as it lies in the groove between the last lumbar vertebra and the Psoas muscle. The wooden lever is then inserted into the tube, and the projecting end carried toward the opposite thigh and raised, when it acts as a lever of the first order, the anus being the fulcrum. In cases where the mesorectum is abnormally short it may be impossible, without unjustifiable force, to compress the artery on the right side. In amputation of the hip-joint the common iliac can be compressed most certainly and safely by opening the abdomen and compressing the vessel by means of the fingers against the Psoas muscle (McBurney’s method).

**The Internal Iliac Artery** (Figs. 420, 427).

The internal iliac or hypogastric artery (a. hypogastrica) supplies the walls and viscera of the pelvis, the generative organs, and inner side of the thigh. It is a short thick vessel, smaller in the adult than the external iliac, and about an inch and a half in length. It arises at the point of bifurcation of the common iliac, and, passing downward to the upper margin of the great sacro-sciatic foramen, divides into two large trunks, an anterior and posterior; from its anterior division a partially obliterated cord, a part of the fetal hypogastric artery, extends forward to the bladder.

**Relations.**—*In front*, with the ureter, which is between the artery and the peritoneum. *Behind*, with the internal iliac vein, the lumbo-sacral cord, and Pyriformis muscle. By its *outer side*, near its origin, with the Psoas magnus muscle.

*In the foetus* the hypogastric artery is twice as large as the external iliac, and appears to be the continuation of the common iliac. Instead of dipping into the pelvis, it passes forward to the bladder, and ascends along the sides of that viscus to its summit, to which it gives branches; it then passes upward along the back part of the anterior wall of the abdomen to the umbilicus, converging toward its fellow of the opposite side. Having passed through the umbilical
opening, the two arteries twine round the umbilical vein in the umbilical cord, and ultimately ramify in the placenta. The portion of the vessel within the abdomen is called the hypogastric artery; the portion external to that cavity, the umbilical artery.

At birth, when the placental circulation ceases, the upper portion of the hypogastric artery, extending from the summit of the bladder to the umbilicus, contracts, and ultimately dwindles to a solid fibrous cord; but the lower portion, extending from its origin (in what is now the internal iliac artery) for about an inch and a half to the wall of the bladder, and thence to the summit of that organ, is not totally impervious, though it becomes considerably reduced in size, and serves to convey blood to the bladder under the name of the superior vesical artery.

Peculiarities as Regards Length.—In two-thirds of a large number of cases the length of the internal iliac varied between an inch and an inch and a half; in the remaining third it was more frequently longer than shorter, the maximum length being three inches, the minimum half an inch.

The lengths of the common and internal iliac arteries bear an inverse proportion to each other, the internal iliac artery being long when the common iliac is short, and vice versa.

As Regards its Place of Division.—The place of division of the internal iliac varies between the upper margin of the sacrum and the upper border of the sacro-sciatic foramen.

The arteries of the two sides in a series of cases often differed in length, but neither seemed constantly to exceed the other.
Surgical Anatomy.—The application of a ligature to the internal iliac artery may be required in cases of aneurism or hemorrhage affecting one of its branches. The vessel may be secured by making an incision through the abdominal parietes in the iliac region in a direction and to an extent similar to that for securing the common iliac; the transversalis fascia having been cautiously divided, and the peritoneum pushed inward from the iliac fossa toward the pelvis, the finger may feel the pulsation of the external iliac at the bottom of the wound, and by tracing this vessel upward the internal iliac is arrived at, opposite the sacro-iliac articulation. It should be remembered that the vein lies behind and on the right side, a little external to the artery, and in close contact with it; the ureter and peritoneum, which lie in front, must also be avoided. The degree of facility in applying a ligature to this vessel will mainly depend upon the length of the vessel. It has been seen that in the great majority of the cases examined the artery was short, varying from an inch to an inch and a half; in these cases the artery is deeply seated in the pelvis; when, on the contrary, the vessel is longer, it is found partly above that cavity. If the artery is very short, as occasionally happens, it would be preferable to apply a ligature to the common iliac or to both the external and internal iliacs at their origin.

A better method of tying the internal iliac artery is by an abdominal section in the median line and reaching the vessel through the peritoneal cavity. This plan has been advocated by Denis, of New York, on the following grounds: (1) It in no way increases the danger of the operation; (2) it prevents a series of accidents which have occurred during ligature of the artery by the older methods; (3) it enables the surgeon to ascertain the exact extent of disease in the main arterial trunk, and select his spot for the application of the ligature; and (4) it occupies much less time.

Collateral Circulation.—In Professor Owen’s dissection of a case in which the internal iliac artery had been tied by Stevens ten years before death for aneurism of the sciatic artery, the internal iliac was found impervious for about an inch above the point where the ligature had been applied, but the obliteration did not extend to the origin of the external iliac, as the ilio-lumbar artery arose just above this point. Below the point of obliteration the artery resumed its natural diameter, and continued so for half an inch, the obturator, lateral sacral, and gluteal arising in succession from the latter portion. The obturator artery was entirely obliterated. The lateral sacral artery was as large as a crow’s quill, and had a very free anastomosis with the artery of the opposite side and with the middle sacral artery. The sciatic artery was entirely obliterated as far as its point of connection with the aneurismal tumor, but on the distal side of the sac it was continued down along the back of the thigh nearly as large in size as the femoral, being pervious about an inch below the sac by receiving an anastomosing vessel from the profunda. The circulation was carried on by the anastomoses of the uterine and ovarian arteries; of the opposite vesical arteries; of the hemorrhoidal branches of the internal iliac with those from the inferior mesenteric; of the obturator artery, by means of its pubic branch, with the vessel of the opposite side and with the epigastric and internal circumflex; of the circumflex and perforating branches of the profunda femoris with the sciatic; of the gluteal with the posterior branches of the sacral arteries; of the ilio-lumbar with the last lumbar; of the lateral sacral with the middle sacral; and of the circumflex iliac with the ilio-lumbar and gluteal.

Branches (Fig. 427).—The branches of the internal iliac are:

**From the Anterior Trunk.**
- Superior Vesical.
- Middle Vesical.
- Inferior Vesical.
- Middle Haemorrhoidal.
- Obturator.
- Internal Pudic.
- Sciatic.

**From the Posterior Trunk.**
- Ilio-lumbar.
- Lateral Sacral.
- Gluteal.

**In female**
- Uterine.
- Vaginal.

The **Superior Vesical** (*a. vesicalis superior*) (Fig. 427), is that part of the foetal hypogastric artery, which remains pervious after birth. It extends to the side of the bladder, distributing numerous branches to the apex and body of the organ. From one of these a slender vessel is derived which accompanies the vas deferens in its course to the testis, where it anastomoses with the spermatic artery. This is the **artery of the vas deferens**. Other branches supply the ureter.

---

1 Medico-Chirurgical Transactions, vol. xvi.
The **Middle Vesical** (*a. vesicalis medialis*) (Fig. 427), usually a branch of the superior, is distributed to the base of the bladder and under surface of the vesiculae seminales.

The **Inferior Vesical** (*a. vesicalis inferior*) (Fig. 427) arises from the anterior division of the internal iliac, frequently in common with the middle hemorrhoidal, and is distributed to the base of the bladder, the prostate gland, and vesiculae seminales. The branches distributed to the prostate communicate with the corresponding vessel of the opposite side.

The **Middle Haemorrhoidal Artery** (*a. haemorrhoidalis media*) (Fig. 427) usually arises together with the preceding vessel. It supplies the anus and parts outside the rectum, anastomosing with the other hemorrhoidal arteries.

The **Uterine Artery** (*a. uterina*) (Fig. 428) passes inward from the anterior trunk of the internal iliac to the neck of the uterus. Ascending in a tortuous course on the side of this viscus, between the layers of the broad ligament, it distributes branches to its substance and to the round ligament and the Fallopian tube (*ramus tubarius*), anastomosing, near its termination, with the ovarian artery. It gives a branch to the ovary (*ramus ovarii*), which anastomoses with a branch from the ovarian branches to the cervix uteri (*cervico-uteri*), and a branch which descends on the vagina (*cervico-vaginal*), and, joining with branches from the vaginal arteries, form a median longitudinal vessel both in front and behind; these descend on the anterior and posterior surfaces of the vagina, and are named the **azygos arteries of the vagina**.

The **Vaginal Artery** (*a. vaginalis*) is analogous to the inferior vesical in the male; it descends upon the vagina, supplying its mucous membrane, and sending branches to the neck of the bladder and contiguous part of the rectum. There may be several vaginal arteries. The vaginal artery assists in forming the **azygos arteries** of the vagina, which are anterior and posterior vessels, running longitudinally, and due to anastomoses of the branches of the vaginal from each side and the cervico-vaginal artery.
Luschka, Hyrtl, Waldeyer, Robinson, and others, instead of describing the ovarian and uterine arteries as two distinct vessels, regard them as constituting the chief parts of one vessel, the *arteria uterina ovarica*. What has been called "the circle of Robinson" is composed of a spiral segment (the arteria uterina ovarica), with a portion of the abdominal aorta, common iliacs, and internal iliacs. Robinson¹ has made a careful study of this vascular circle; he shows that it is of great importance in certain surgical procedures, and that its remarkable "capacity for extension" saves it from damage when the uterus is enormously distended by pregnancy, or when it is "drawn through the pudendum with traction forceps for palpation, inspection, or repair."

The author just quoted says further that the utero-ovarian artery has three origins, because it develops from the Wolffian body: The *ovarian segment arises* from the abdominal aorta. The *uterine segment arises* from the anterior branch of the internal iliac artery. The *artery of the round ligament arises* from the deep epigastric. The arteria uterina ovarica artery secures nutrition to the uterus by bringing blood from three sources. It is spiral throughout its entire course, in certain parts is convoluted or looped, and it is accompanied by the pampiniform plexus of veins.

The three origins of this vessel are freely united by anastomoses, and rami laterales are given off, which unite the bilateral vessels in the median line. Robinson describes three bifurcations of the utero-ovarian artery. The *distal bifurcation*, which is "about midway between the uterus and the pelvic wall," and forms an acute angle with the main vessel. This bifurcation indicates the point of division of the external from the internal genitals. The cervico-vaginal artery supplies the external genitals. The *proximal bifurcation* marks the situation of the ovary. The artery bifurcates at an acute angle into two branches to supply the ovary and Fallopian tube. The *middle bifurcation* consists of (1) the division of the uterine segment at the angle formed by the uterus and oviduct ("forming the ramus oviductus and ramus ovarii") and (2) "the bifurcation of the ramus oviductus forming the ramus oviductus and the ramus ligamenti teretis, or the segment of the round ligament."²

**Surgical Anatomy.**—As pointed out by Robinson, the source of bleeding after vaginal hysterectomy is usually the torn and unclamped cervico-vaginal artery.

As previously pointed out, the spiral and convoluted shape of the utero-ovarian artery allows the uterus, ovary, and tube to be drawn into the vagina without injury to the vessels. Robinson points out that in vaginal hysterectomy the genital circle is not divided and only the rami laterales which go to the uterus are cut, the ovaries retaining a normal blood-supply and continuing to functionate.

The *Obturator Artery* (*a. obturatoria*) (Fig. 427) usually arises from the anterior trunk of the internal iliac; frequently from the posterior. It passes forward, below the brim of the pelvis, to the upper part of the obturator foramen, accompanied by the obturator nerve and vein, and, escaping from the pelvic cavity through a short canal formed by a groove on the under surface of the ascending ramus of the os pubis and the arched border of the obturator membrane, it divides into an internal and external branch. In the pelvic cavity this vessel lies upon the pelvic fascia, beneath the peritoneum, and a little below the obturator nerve.

**Branches.**—*Within the pelvis*, the obturator artery gives off an *iliac branch* (*ramus iliacus*) to the iliac fossa, which supplies the bone and the Iliacus muscle, and anastomoses with the ilio-lumbar artery; a *vesical branch* (*ramus vesicalis*), which runs backward to supply the bladder; and a *pubic branch* (*ramus pubicus*), which is given off from the vessel just before it leaves the pelvic cavity. This branch ascends upon the back of the os pubis, communicating with offsets from

¹ Robinson. The Utero-ovarian Artery.
² Ibid.
the deep epigastric artery and with the corresponding vessel of the opposite side. It is placed on the inner side of the femoral ring. External to the pelvis, the obturator artery divides into an internal and an external branch, which are deeply situated beneath the Obturator externus muscle.

The Internal Branch (ramus anterior) curves downward along the inner margin of the obturator foramen, lying beneath the Obturator externus muscle; it distributes branches to the Obturator externus, Pectineus, Adductors, and Gracilis, and anastomoses with the external branch and with the internal circumflex artery.

The External Branch (ramus posterior) curves round the outer margin of the obturator foramen, also lying beneath the Obturator externus muscle, to the space between the Gemellus inferior and Quadratus femoris, where it divides into two branches: one, smaller, courses inward around the lower margin of the foramen and anastomoses with the internal branch and with the internal circumflex; the other inclines outward in the groove below the acetabulum (a. acetabulis), and supplies the muscles attached to the tuberosity of the ischium and anastomoses with the sciatic artery. It sends a branch to the hip-joint through the cotyloid notch, which ramifies on the round ligament as far as the head of the femur.

Peculiarities (Fig. 429).—In two out of every three cases the obturator arises from the internal iliac; in one case in three and a half from the epigastric; and in about one in seventy-two cases by two roots from both vessels. It arises in about the same proportion from the external iliac artery. The origin of the obturator from the epigastric is not commonly found on both sides of the same body.

When the obturator artery arises at the front of the pelvis from the epigastric, it descends almost vertically to the upper part of the obturator foramen. The artery in this course usually lies in contact with the external iliac vein and on the outer side of the femoral ring (Fig. 429, A); in such cases it would not be endangered in the operation for femoral hernia. Occasionally, however, it curves inward along the free margin of Gimbernat’s ligament (Fig. 429, B), and under such circumstances would almost completely encircle the neck of a hernial sac (supposing a hernia to exist in such a case), and would be in great danger of being wounded if an operation was performed.

The Internal Pudic Artery (a. pudenda interna) (Figs. 427, 430, and 431) is the smaller of the two terminal branches of the anterior trunk of the internal iliac, and supplies the external organs of generation. Though the course of the artery is the same in the two sexes, the vessel is much smaller in the female than in the male, and the distribution of its branches somewhat different. The description of its arrangement in the male will first be given, and subsequently the differences which it presents in the female will be mentioned.

The Internal Pudic Artery in the Male passes downward and outward to the lower border of the great sacro-sciatic foramen, and emerges from the pelvis between the Pyriformis and Coecygeus muscles; it then crosses the spine of the ischium and re-enters the pelvis through the lesser sacro-sciatic foramen. The artery now crosses the Obturator internus muscle along the outer wall of the ischio-rectal fossa, being situated about an inch and a half above the lower margin of the ischial tuberosity. It is here contained in a sheath of the obturator fascia, and
gradually approaches the margin of the rami of the ischium, along which it passes forward and upward, pierces the base of the superficial layer of the triangular ligament of the urethra, and runs forward along the inner margin of the rami of the os pubis, and divides into its two terminal branches, the **dorsal artery of the penis** and the **artery of the corpus cavernosum**.

**Relations.**—In the first part of its course, within the pelvis, it lies in front of the Pyriformis muscle and sacral plexus of nerves, and the sciatic artery, and on the outer side of the rectum (on the left side). As it crosses the spine of the ischium it is covered by the Gluteus maximus and overlapped by the great sacro-sciatic ligament. Here the obturator nerve lies to the inner side and the nerve to the Obturator internus to the outer side of the vessel. In the pelvis it lies on the outer side of the ischio-rectal fossa, upon the surface of the Obturator internus muscle, contained in a fibrous canal, the **canal of Alcock**, formed by the splitting of the obturator fascia. It is accompanied by the pudic veins and the pudic nerve.

**Peculiarities.**—The internal pudic is sometimes smaller than usual, or fails to give off one or two of its usual branches; in such cases the deficiency is supplied by branches derived from an additional vessel, the **accessory pudic**, which generally arises from the internal pudic artery before its exit from the great sacro-sciatic foramen. It passes forward along the lower part of the bladder and across the side of the prostate gland to the root of the penis, where it perforates the triangular ligament and gives off the branches usually derived from the pudic artery. The deficiency most frequently met with is that in which the internal pudic ends as the artery of the bulb, the artery of the corpus cavernosum and arteria dorsalis penis being derived from the accessory pudic. Or the pudic may terminate as the superficial perineal, the artery of the bulb being derived, with the other two branches, from the accessory vessel. Occasionally the accessory pudic artery is derived from one of the other branches of the internal iliac, most frequently the inferior vesical or the obturator.

**Surgical Anatomy.**—The relation of the accessory pudic to the prostate gland and urethra is of the greatest interest in a surgical point of view, as this vessel is in danger of being wounded in the operation of lateral lithotomy. The student should also study the position of the internal pudic artery and its branches, when running a normal course with regard to the same operation. The superficial and the transverse perineal arteries are, of necessity, divided in this operation, but the hemorrhage from these vessels is seldom excessive; should a ligature be required, it can readily be applied on account of their superficial position. The artery of the bulb may be divided if the incision be carried too far forward, and injury of this vessel may be attended with serious or even fatal consequences. The main trunk of the internal pudic artery may be wounded if the incision be carried too far outward; but, being bound down by the strong obturator fascia and under cover of the rami of the ischium, the accident is not very likely to occur unless the vessel runs an anomalous course.

**Branches.**—The branches of the internal pudic artery are—the

- **Muscular**.
- **Inferior Haemorrhoidal**.
- **Superficial Perineal**.

**Dorsal Artery of the Penis.**

The **Muscular Branches** consist of two sets—one given off in the pelvis, the other as the vessel crosses the ischial spine. The former are several small offsets which supply the Levator ani, the Obturator internus, the Pyriformis, and the Coccygeus muscles. The branches given off outside the pelvis are distributed to the adjacent part of the Gluteus maximus and External rotator muscles. They Anastomose with branches of the sciatic artery.

The **Inferior Haemorrhoidal Artery** (*a. haemorrhoidalis inferior*) arises from the internal pudic as it passes above the tuberosity of the ischium. Crossing the ischio-rectal fossa it is distributed by two or three terminal branches to the muscles and integument of the anal region. Instead of one inferior hemorrhoidal artery two or three small vessels may arise from the internal pudic.

The **Superficial Perineal Artery** (*a. perinei*) (Fig. 430) supplies the scrotum and the muscles and integument of the perineum. It arises from the internal pudic in front
of the preceding branches, and turns upward, crossing either over or under the Transversus perinei superficialis muscle, and runs forward, parallel to the pubic arch, in the interspace between the Accelerator urinæ and Erector penis muscles, both of which it supplies, and is finally distributed to the skin and dartos of the scrotum. In its passage through the perineum it lies beneath the superficial perineal fascia.

The Transverso Perineal Artery is a small branch which arises either from the internal pudic or from the Transversus perinei superficialis muscle. It runs transversely inward along the cutaneous surface of the Transversus perinei superficialis muscle, which it supplies, as well as the structures between the anus and bulb of the urethra, and anastomoses with the like vessel of the opposite side.

The **Artery of the Bulb** (a. bulbi urethrae) is a large but very short vessel which arises from the internal pudic between the two layers of the triangular ligament, and, passing nearly transversely inward, between the fibres of the Compressor urethrae muscle, it pierces the bulb of the urethra, which it supplies, and continues anteriorly in the corpus spongiosum to the glans and anastomoses with its fellow of the opposite side. It gives off a small branch which descends to supply Cowper's gland.

**Surgical Anatomy.**—This artery is of considerable importance in a surgical point of view, as it is in danger of being wounded in the median or the lateral operation of lithotomy—an accident usually attended in the adult with alarming hemorrhage. The vessel is sometimes very small, occasionally wanting, or even double. It sometimes arises from the internal pudic earlier than usual, and crosses the perineum to reach the back part of the bulb. In such a case the vessel could hardly fail to be wounded in the performance of the lateral operation of lithotomy. If, on the contrary, it should arise from an accessory pudic, it lies more forward than usual and is out of danger in the operation.

The **Artery of the Corpus Cavernosum** (a. profunda penis), one of the terminal branches of the internal pudic, arises from that vessel while it is situated between

---

Fig. 430.—The superficial muscles and vessels of the perineum.
the two layers of the triangular ligament; it pierces the superficial layer, and, entering the crus penis obliquely, it runs forward in the centre of the corpus cavernosum, to which its branches are distributed.

The **Dorsal Artery of the Penis** (a. dorsalis penis) ascends between the crus and pubic symphysis, and, piercing the triangular ligament, passes between the two layers of the suspensory ligament of the penis, and runs forward on the dorsum of the penis to the glans, where it divides into two branches which supply the glans and prepuce. On the dorsum of the penis it lies immediately beneath the integument, parallel with the dorsal vein and the corresponding artery of the opposite side. It supplies the integument and fibrous sheath of the corpus cavernosum, sending branches through the sheath to anastomose with the preceding vessel.

The **Internal Pudic Artery in the Female** is smaller than in the male. Its origin and course are similar, and there is considerable analogy in the distribution of its branches. The superficial perineal artery supplies the labia pudendi; the artery of the bulb supplies the bulbi vestibuli and the erectile tissue of the vagina; the artery of the corpus cavernosum (a. profunda clitoridis) supplies the cavernous body of the clitoris; and the arteria dorsalis clitoridis supplies the dorsum of that organ, and terminates in the glans and in the membranous fold corresponding to the prepuce of the male.

The **Sciatic Artery** (a. glutaea inferior) (Fig. 431), the larger of the two terminal branches of the anterior trunk of the internal iliac, is distributed to the muscles at the back of the pelvis. It passes down to the lower part of the great sacro-sciatic foramen behind the internal pudic artery, resting on the sacral plexus of nerves and Pyriformis muscle, and escapes from the pelvis through this foramen between the Pyriformis and Coccygeus. It then descends in the interval between the trochanter major and tuberosity of the ischium, accompanied by the sciatic nerves, and covered by the Gluteus maximus, and is continued down the back of the thigh supplying the skin, and anastomosing with branches of the perforating arteries.
Within the pelvis it distributes branches to the Pyriformis, Coccygeus, and Levator ani muscles; some hemorrhoidal branches, which supply the rectum, and occasionally take the place of the middle hemorrhoidal artery; and vesical branches to the base and neck of the bladder, vesiculæ seminales, and prostate gland. External to the pelvis it gives off the following branches:

- Coccygeal.
- Inferior Gluteal.
- Comes Nervi Ischiadici.

The Coccygeal Branch runs inward, pierces the great sacro-sciatic ligament, and supplies the Gluteus maximus, the integument, and other structures on the back of the coccyx.

The Inferior Gluteal Branches, three or four in number, supply the Gluteus maximus muscle, anastomosing with the gluteal artery in the substance of the muscle.

The Comes Nervi Ischiadici (a. comitans n. ischiadici) is a long, slender vessel which accompanies the great sciatic nerve for a short distance; it then penetrates it and runs in its substance to the lower part of the thigh.

The Muscular Branches supply the Gluteus maximus, anastomosing with the gluteal artery in the substance of the muscle; the external rotators, anastomosing with the internal pudic artery; and the muscles attached to the tuberosity of the ischium, anastomosing with the external branch of the obturator and the internal circumflex arteries.

The Anastomotic Artery is directed downward across the external rotators and assists in forming the so-called crucial anastomosis by anastomosing with the superior perforating and the internal and external circumflex arteries.

The Articular Branch, generally derived from the anastomotic, is distributed to the capsule of the hip-joint.

The Ilio-lumbar Artery (a. ilio lumbalis), given off from the posterior trunk of the internal iliac, turns upward and outward between the obturator nerve and lumbo-sacral cord, to the inner margin of the Psoas muscle, behind which it divides into a lumbar and an iliac branch.

The Lumbar Branch (ramus lumbalis) supplies the Psoas and Quadratus lumborum muscles, anastomosing with the last lumbar artery, and sends a small spinal branch (ramus spinalis) through the intervertebral foramen, between the last lumbar vertebra and the sacrum, into the spinal canal, to supply the cauda equina.

The Iliac Branch (ramus iliacus) descends to supply the Iliacus muscle; some offsets, running between the muscle and the bone, anastomose with the iliac branch of the obturator; one of these enters an oblique canal to supply the diploë, whilst others run along the crest of the ilium, distributing branches to the Gluteal and Abdominal muscles, and anastomose in their course with the gluteal, circumflex iliac, and external circumflex arteries.

The Lateral Sacral Artery (a. sacralis lateralis) (Fig. 427) runs downward. It may be single, but usually there are two on each side, the superior and inferior divisions.

The Superior Division, which is of large size, passes inward, and, after anastomosing with branches from the middle sacral, enters the first or second anterior sacral foramen, gives spinal branches (rami spinalis) to the contents of the sacral canal, and, escaping by the corresponding posterior sacral foramen, supplies the skin and muscles on the dorsum of the sacrum, anastomosing with the gluteal.

The Inferior Division passes obliquely across the front of the Pyriformis muscle and sacral nerves to the inner side of the anterior sacral foramina, descends on the front of the sacrum, and anastomoses over the coccyx with the middle sacral and opposite lateral sacral arteries. In its course it gives off spinal branches which
enter the anterior sacral foramina (*rami spinales*); these, after supplying the contents of the sacral canal, escape by the posterior sacral foramina, and are distributed to the muscles and skin on the dorsal surface of the sacrum, anastomosing with the gluteal.

The **Gluteal Artery** (*a. glutaeæ superior*) (Fig. 431) is the largest branch of the internal iliac, and appears to be the continuation of the posterior division of that vessel. It is a short thick trunk, which passes out of the pelvis above the upper border of the Pyriformis muscle, and immediately divides into a **superficial** and **deep branch**. Within the pelvis it gives off a few muscular branches to the Iliacus, Pyriformis, and Obturator internus, and, just previous to emerging from that cavity, a nutrient artery, which enters the ilium.

The **Superficial Branch** passes beneath the Gluteus maximus and divides into numerous branches, some of which supply that muscle, whilst others perforate its tendinous origin, and supply the integument covering the posterior surface of the sacrum, anastomosing with the posterior branches of the sacral arteries.

The **Deep Branch** runs between the Gluteus medius and minimus, and subdivides into two. Of these, the **superior division** (*ramus superior*), continuing the original course of the vessel, passes along the upper border of the Gluteus minimus to the anterior superior spine of the ilium, anastomosing with the circumflex iliac and ascending branches of the external circumflex artery. The **inferior division** (*ramus inferior*) crosses the Gluteus minimus obliquely to the trochanter major, distributing branches to the Glutei muscles, and inosculates with the external circumflex artery. Some branches piece the Gluteus minimus to supply the hip-joint.

**Surface Marking.**—The position of the three main branches of the internal iliac, the sciatic, internal pudic, and gluteal, which may occasionally be the object of surgical interference, is indicated on the surface in the following way: A line is to be drawn from the posterior superior iliac spine to the posterior superior angle of the great trochanter, with the limb slightly flexed and rotated inward; the point of emergence of the gluteal artery from the upper part of the sciatic notch will correspond with the junction of the upper with the middle third of this line. A second line is to be drawn from the same point to the outer part of the tuberosity of the ischium; the junction of the lower with the middle third marks the point of emergence of the sciatic and pudic arteries from the great sciatic notch.

**Surgical Anatomy.**—Any of these three vessels may require *ligation* for a wound or for aneurism, which is generally traumatic. The gluteal artery is ligated by turning the patient two-thirds over on his face and making an incision from the posterior superior spine of the ilium to the upper and posterior angle of the great trochanter. This must expose the Gluteus maximus muscle, and its fibres are to be separated through the whole thickness of the muscle and pulled apart with retractors. The contiguous margins of the gluteus medius and Pyriformis are now to be separated from each other, and the artery will be exposed emerging from the sciatic notch. In ligation of the sciatic artery, the incision should be made parallel with that for ligation of the gluteal, but one inch and a half lower down. After the fibres of the Gluteus maximus have been separated, the vessel is to be sought for at the lower border of the Pyriformis; the great sciatic nerve, which lies just above it, forming the chief guide to the artery. The internal pudic can be reached through the incision used to reach the sciatic.

**The External Iliac Artery (A. Iliaca Externa)** (Fig. 427).

The external iliac artery is larger in the adult than is the internal iliac. It passes obliquely downward and outward along the inner border of the Psoas muscle, from the bifurcation of the common iliac to Poupart's ligament, where it enters the thigh and becomes the femoral artery.

**Relations.**—*In front*, with the peritoneum, subperitoneal areolar tissue or *Abernethy's fascia*, the termination of the ileum on the right side, and the sigmoid flexure on the left, and a thin layer of fascia derived from the iliac fascia, which surrounds the artery and vein. At its origin it is occasionally crossed by the ureter. The spermatic vessels descend for some distance upon it near its termination, and it is
crossed in this situation by the genital branch of the genito-femoral nerve and the deep circumflex iliac vein; the vas deferens curves down along its inner side. Behind, it is in relation with the external iliac vein, which, at Poupart's ligament, lies at its inner side; on the left side the vein is altogether internal to the artery. Externally, it rests against the Psoas muscle, from which it is separated by the iliac fascia. The artery rests upon this muscle, near Poupart's ligament. Numerous lymphatic vessels and glands are found lying on the front and inner side of the vessel.

**Plan of the Relations of the External Iliac Artery.**

*In front.*

- Peritoneum, intestines, and fascia.
- Lymphatic vessels and glands.
- Spermatic vessels.
- Genito-femoral nerve (genital branch).
- Deep circumflex iliac vein.

*Outer side.*

- Psoas magnus.
- Iliac fascia.

*Inner side.*

- External iliac vein and vas deferens near Poupart's ligament.

*Behind.*

- External iliac vein.
- Psoas magnus.

**Surface Marking.**—The surface line indicating the course of the external iliac artery has been already given (see page 684).

**Surgical Anatomy.**—The application of a ligature to the external iliac may be required in cases of aneurism of the femoral artery or for a wound of the artery. This vessel may be secured in any part of its course, excepting near its upper end, which is to be avoided on account of the proximity of the great stream of blood in the internal iliac, and near its lower end, which should also be avoided, on account of the proximity of the deep epigastric and circumflex iliac vessels. The patient having been placed in the supine position, an incision should be made, commencing below at a point about three-quarters of an inch above Poupart's ligament, and a little external to its middle, and running upward and outward, parallel to Poupart's ligament, to a point one inch internal and one inch above the anterior superior spine of the ilium. When the artery is deeply seated more room will be required, and may be obtained by curving the incision from the point last named inward toward the umbilicus for a short distance. Another mode of ligating the vessel is the plan advocated by Sir Astley Cooper, by making an incision close to Poupart's ligament from about half an inch outside of the external abdominal ring to one inch internal to the anterior superior spine of the ilium. This incision, being made in the course of the fibres of the aponeurosis of the external oblique, is less likely to be followed by a ventral hernia, but there is danger of wounding the epigastric artery, and only the lower end of the vessel can be ligated. Abernethy, who first tied this artery, made his incision in the course of the vessel. The abdominal muscles and transversalis fascia having been cautiously divided, the peritoneum should be separated from the iliac fossa and raised toward the pelvis; and on introducing the finger to the bottom of the wound, the artery may be felt pulsating along the inner border of the Psoas muscle. The external iliac vein is generally found on the inner side of the artery, and must be cautiously separated from it by the finger-nail or handle of the knife, and the aneurism needle should be introduced on the inner side, between the artery and the vein.

Ligation of the external iliac artery has recently been performed by a transperitoneal method. An incision four inches in length is made in the semilunar line, commencing about an inch below the umbilicus and carried through the abdominal wall into the peritoneal cavity. The intestines are then pushed upward and held out of the way by a broad abdominal retractor, and an incision is made through the peritoneum at the margin of the pelvis in the course of the artery, and the vessel is secured in any part of its course which may seem desirable to the operator. The advantages of this operation appear to be that if it is found necessary, the common iliac artery can be ligated instead of the external iliac without extension or modification of the incision; and secondly, that the vessel can be ligated without in any way interfering with the coverings of the sac of an aneurism. Possibly a disadvantage may exist in the greater risk of hernia after this method.
Collateral Circulation.—The principal anastomoses in carrying on the collateral circulation, after the application of a ligature to the external iliac, are—the iliolumbar with the circumflex iliac; the glutal with the external circumflex; the obturator with the internal circumflex; the sciatic with the superior perforating and circumflex branches of the profunda artery; and the internal pudic with the external pudic. When the obturator arises from the epigastric it is supplied with blood by branches, either from the internal iliac, the lateral sacral, or the internal pudic. The epigastric receives its supply from the internal mammary and inferior intercostal arteries, and from the internal iliac by the anastomoses of its branches with the obturator.

In the dissection of a limb eighteen years after the successful ligature of the external iliac artery by Sir A. Cooper, the report of which is to be found in Guy’s Hospital Reports, vol. i. p. 50, the anastomosing branches are described in three sets: An anterior set.—1. A very large branch from the iliolumbar artery to the circumflex iliac; 2. another branch from the iliolumbar, joined by one from the obturator, and breaking up into numerous tortuous branches to anastomose with the external circumflex; 3. two other branches from the obturator, which passed over the brim of the pelvis, communicated with the epigastric, and then broke up into a plexus to anastomose with the internal circumflex. An internal set.—Branches given off from the obturator, after quitting the pelvic, which ramified among the adductor muscles on the inner side of the hip-joint, and joined most freely with branches of the internal circumflex. A posterior set.—1. three large branches from the glutal to the external circumflex; 2. several branches from the sciatic around the great sciatic notch to the internal and external circumflex, and the perforating branches of the profunda.

Branches.—Besides several small branches to the Psoas muscle and the neighboring lymphatic glands, the external iliac gives off two branches of considerable size—the deep epigastric and deep circumflex iliac arteries.

The Internal or Deep Epigastric Artery (a. epigastrica inferior) (Fig. 427) arises from the external iliac a few lines above Poupart’s ligament. It at first descends to reach this ligament, and then ascends obliquely along the inner margin of the internal abdominal ring, lying between the transversalis fascia and peritoneum, and, continuing its course upward, it pierces the transversalis fascia, and passing over the semilunar fold of Douglas, enters the sheath of the Rectus muscle. It then ascends on the posterior surface of the muscle, and finally divides into numerous branches which anastomose, above the umbilicus, with the superior epigastric branch of the internal mammary and with the inferior intercostal arteries (Fig. 413). The deep epigastric artery bears a very important relation to the internal abdominal ring as it passes obliquely upward and inward from its origin from the external iliac. In this part of its course it lies along the lower and inner margin of the ring and beneath the commencement of the spermatic cord. As it passes to the inner side of the internal abdominal ring it is crossed by the vas deferens in the male and the round ligament in the female.

Branches.—The branches of this vessel are the following: The cremasteric (a. spermatica externa in the male, a. ligamenti teretis uteri in the female), which accompanies the spermatic cord, and supplies the Cremaster muscle and other coverings of the cord, anastomosing with the spermatic artery in the male, and which accompanies the round ligament in the female; a pubic branch (ramus pubicus), which runs along Poupart’s ligament, and then descends behind the os pubis to the inner side of the femoral ring, and anastomoses with offsets from the obturator artery; muscular branches, some of which are distributed to the abdominal muscles and peritoneum, anastomosing with the lumbar and circumflex iliac arteries; cutaneous branches perforate the tendon of the External oblique, and supply the integument, anastomosing with branches of the superficial epigastric.

Peculiarities.—The origin of the deep epigastric may take place from any part of the external iliac between Poupart’s ligament and two inches and a half above it, or it may arise below this ligament, from the common femoral or from the deep femoral.

Union with Branches.—It frequently arises from the external iliac by a common trunk with the obturator. Sometimes the epigastric arises from the obturator, the latter vessel being furnished by the internal iliac, or the epigastric may be formed by two branches, one derived from the external iliac, the other from the internal iliac.
Surgical Anatomy.—The deep epigastric artery follows a line drawn from the middle of Poupart's ligament toward the umbilicus; but shortly after this line crosses the linea semilunaris the direction changes, and the course of the vessel is directly upward in the line of junction of the inner third with the outer two-thirds of the Rectus muscle. It has important surgical relations, in addition to the fact that it is one of the principal means, through its anastomosis with the internal mammary, in establishing the collateral circulation after ligature of either the common or external iliac arteries. It lies close to the internal abdominal ring, and is therefore internal to an oblique inguinal hernia, but external to a direct inguinal hernia, as the hernia emerges from the abdomen. It forms the outer boundary of Hesselbach's triangle. It is in close relationship with the spermatic cord, which lies in front of it in the inguinal canal, separated only by the transversalis fascia. The vas deferens hooks round its outer side.

The Deep Circumflex Iliac Artery (\(a. \text{circumflexa ilium profunda}\)) (Fig. 427) arises from the outer side of the external iliac nearly opposite the epigastric artery. It ascends obliquely outward behind Poupart's ligament, contained in a fibrous sheath formed by the junction of the transversalis and iliac fasciae, to the anterior superior spinous process of the ilium. It then runs along the inner surface of the crest of the ilium to about its middle, where it pierces the Transversalis, and runs backward between that muscle and the Internal oblique, to anastomose with the ilio-lumbar and gluteal arteries. Opposite the anterior superior spine of the ilium it gives off a large branch which ascends between the Internal oblique and Transversalis muscles, supplying them, and anastomosing with the lumbar and epigastric arteries. It also gives off cutaneous branches.

**ARTERIES OF THE LOWER EXTREMITY.**

The artery which supplies the greater part of the lower extremity is the direct continuation of the external iliac. It continues as a single trunk from Poupart's ligament to the lower border of the Popliteus muscle, and here divides into two branches, the anterior and posterior tibial, an arrangement exactly similar to what occurs in the upper limb. For convenience of description, the upper part of the main trunk is named femoral, the lower part, popliteal.

**THE FEMORAL ARTERY (\(a. \text{femoralis}\)) (Figs. 432 and 433).**

The femoral artery commences immediately behind Poupart's ligament, midway between the anterior superior spine of the ilium and the symphysis pubis, and, passing down the forepart and inner side of the thigh, terminates at the opening in the Adductor magnus, at the junction of the middle with the lower third of the thigh, where it becomes the popliteal artery. The vessel, at the upper part of the thigh, lies in front of the hip-joint, just on a line with the innermost part of the head of the femur; in the lower part of its course it is in close relation with the inner side of the shaft of the bone, and between these two parts the vessel is some distance from the bone. In the upper third of the thigh it is contained in a triangular space called Scarpa's triangle. In the middle third of the thigh it is contained in an aponeurotic canal called Hunter's canal.

**Scarpa's Triangle (\( \text{trigonum femorale} \)).**—Scarpa's triangle corresponds to the depression seen immediately below the fold of the groin. It is a triangular space, the apex of which is directed downward, and the sides formed externally by the Sartorius, internally by the inner margin of the Adductor longus, and above by Poupart's ligament. The floor of the space is formed from without inward by the Iliacus, Psoas, Pectineus (in some cases a small part of the Adductor brevis), and the Adductor longus muscles; and it is divided into two nearly equal parts by the femoral vessels, which extend from the middle of its base to its apex, the artery
giving off in this situation its superficial and profunda branches, the vein receiving the deep femoral and internal saphenous. On the outer side of the femoral artery is the femoral nerve dividing into its branches. In the outer corner of the space is the external cutaneous nerve. Within the sheath of the artery, and lying upon the outer side of the vessel, is the crural branch of the genito-femoral nerve. At the base of the triangle the vein is to the inner side of the artery; at the apex of the triangle it is passing behind the artery. Besides the vessels and nerves, this space contains some fat and lymphatics.

Hunter's Canal or the Adductor Canal (canalis adductorius [Hunteri].) — This is the aponeurotic space in the middle third of the thigh, extending from the apex of Scarpa's triangle to the femoral opening in the Adductor magnus muscle. It is bounded, externally, by the Vastus internus; internally by the Adductors longus and magnus muscles; and is covered in by a strong aponeurosis which extends transversely from the Vastus internus across the femoral
vessels to the Adductor longus and magnus; lying on which aponeurosis is the Sartorius muscle. It contains the femoral artery and vein enclosed in their own sheath of areolar tissue, the vein being behind and on the outer side of the artery, and the internal or long saphenous nerve lying at first on the outer side and then in front of the vessels.

For convenience of description, and also in reference to its surgical anatomy, the femoral artery is divided into a short trunk, about an inch and a half or two inches long, which is known as the common femoral artery, while the remainder of the vessel is termed the superficial femoral artery, to distinguish it from the deep femoral (profunda femoris), a large branch given off from the common femoral at its termination, and which, by its derivation, from the parent trunk, marks the commencement of the superficial femoral artery.

The Common Femoral Artery (Figs. 432 and 433).

The common femoral artery is very superficial, being covered by the skin and superficial fascia, superficial inguinal lymphatic glands, the iliac portion of the fascia lata, and the prolongation downward of the transversalis fascia, which forms the anterior part of the sheath of the vessels. It has in front of it filaments from the crural branch of the genitofemoral nerve, the superficial circumflex iliac vein, and occasionally the superficial epigastric vein. It rests on the inner margin of the Psoas muscle, which separates it from the capsular ligament of the hip-joint, and a little lower on the Pectineus muscle; and crossing behind it is the branch to the Pectineus from the femoral nerve. Separating the artery from the Pectineus muscles is the pubic portion of the fascia lata and the prolongation from the fascia covering the Iliacus muscle, which forms the posterior layer of the sheath of the vessels. The femoral nerve lies about half an inch to the outer side of the common femoral artery, being separated from the artery by a small part of the Psoas muscle. To the inner side of the artery is the femoral vein, between the margins of the Pectineus and Psoas muscles. The two vessels are
en closed in a strong fibrous sheath formed by the proper sheath of the vessels, strengthened by fascia (see page 511); the artery and vein are separated, however, from one another by a thin fibrous partition.

**Plan of the Relations of the Common Femoral Artery.**

*In front.*
- Skin and superficial fascia.
- Superficial inguinal glands.
- Iliac portion of fascia lata.
- Prolongation of transversalis fascia.
- Crural branch of genito-femoral nerve.
- Superficial circumflex iliac vein.
- Superficial epigastric vein.

*Inner side.*
- Femoral vein.

*Behind.*
- Prolongation of fascia covering the Iliacus muscle.
- Pubic portion of fascia lata.
- Nerve to Pectineus.
- Psoas muscle.
- Pectineus muscle.
- Capsule of hip-joint.

*Outer side.*
- Small part of Psoas muscle, separating the artery from the femoral nerve.

**The Superficial Femoral Artery** (Figs. 432 and 433).

The superficial femoral artery is only superficial where it lies in Scarpa's triangle. Here it is covered by the skin, superficial and deep fascia, and crossed by the internal cutaneous branch of the femoral nerve. In Hunter's canal it is more deeply seated, being covered by the integument, the superficial and deep fascia, the Sartorius and the aponeurotic covering of Hunter's canal. The internal saphenous nerve crosses the artery from without inward. Behind, the artery lies at its upper part on the femoral vein and the profunda artery and vein, which separate it from the Pectineus muscle, and lower down on the Adductor longus and Adductor magnus muscles. To the outer side is the long saphenous nerve and the nerve to the Vastus internus, the Vastus internus muscle, and, at its lower part, the femoral vein. To the inner side is the Adductor longus above and the Adductor magnus and Sartorius below.

**Plan of the Relations of the Superficial Femoral Artery.**

*In front.*
- Skin, superficial and deep fascie.
- Internal cutaneous nerve.
- Sartorius.
- Aponeurotic covering of Hunter's canal.
- Internal saphenous nerve.

- Profunda artery and vein.
- Pectineus muscle.
- Adductor longus.
- Adductor magnus.

*Outer side.*
- Long saphenous nerve.
- Nerve to vastus internus.
- Vastus internus.
- Femoral vein (below).
The femoral vein, at Poupart’s ligament, lies close to the inner side of the artery, separated from it by a thin fibrous partition; but lower down it is behind it, and then to its outer side.

The internal saphenous nerve is situated on the outer side of the artery, in the middle third of the thigh, beneath the aponeurotic covering of Hunter’s canal, but not usually within the sheath of the vessels. The internal cutaneous nerve passes obliquely across the upper part of the sheath of the femoral artery.

Peculiarities. Double Femoral Reunited.—Several cases are recorded in which the femoral artery divided into two trunks below the origin of the profunda, and became reunited near the opening of the Adductor magnus so as to form a single popliteal artery. One of them occurred in a patient operated upon for popliteal aneurism.

Change of Position.—A few cases have been recorded in which the femoral artery was situated at the back of the thigh, the vessel being continuous above with the internal iliac, escaping from the pelvis through the great sacro-sciatic foramen, and accompanying the great sciatic nerve to the popliteal space, where its division occurred in the usual manner. The external iliac in these cases was small, and terminated in the profunda.

Position of the Vein.—The femoral vein is occasionally placed along the inner side of the artery, throughout the entire extent of Scarpa’s triangle, or it may be slit so that a large vein is placed on each side of the artery for a greater or less extent.

Origin of the Profunda.—This vessel occasionally arises from the inner side, and, more rarely, from the back of the common trunk; but the more important peculiarity, in a surgical point of view, is that which relates to the height at which the vessel arises from the femoral. In three-fourths of a large number of cases it arose between one or two inches below Poupart’s ligament; in a few cases the distance was less than an inch; more rarely, opposite the ligament; and in one case, above Poupart’s ligament, from the external iliac. Occasionally, the distance between the origin of the vessel and Poupart’s ligament exceeds two inches, and in one case it was found to be as much as four inches.

Surface Marking.—The upper two-thirds of a line drawn from a point midway between the anterior superior spine of the ilium and the symphysis pubis to the adductor tubercle on the inner condyle of the femur, with the thigh abducted and rotated outward, will indicate the course of the femoral artery.

Surgical Anatomy.—Compression of the femoral artery, which is constantly requisite in amputations and other operations on the lower limbs, and also for the cure of popliteal aneurisms, is most effectually made immediately below Poupart’s ligament. In this situation the artery is very superficial, and is merely separated from the ascending ramus of the os pubis by the Psoas muscle; so that the surgeon, by means of his thumb or a compressor, may effectually control the circulation through it. This vessel may also be compressed in the middle third of the thigh by placing a compress over the artery, beneath the tourniquet, and directing the pressure from without inward, so as to compress the vessel against the inner side of the shaft of the femur.

The application of a ligature to the femoral artery may be required in the cases of wound or aneurism of the arteries of the leg, of the popliteal or femoral; and the vessel may be exposed and tied in any part of its course. The great depth of this vessel at its lower part, its close connection with important structures, and the density of its sheath render the operation in this situation one of much greater difficulty than the application of a ligature at its upper part, where it is more superficial.

Ligature of the common femoral artery is usually considered unsafe, on account of the connection of large branches with it—viz., the deep epigastric and the deep circumflex iliac arising just above Poupart’s ligament; on account of the number of small branches which arise from it in its short course; and on account of the uncertainty of the origin of the profunda femoris, which, if it arise high up, would be too close to the ligature for the formation of a firm coagulum. The profunda sometimes arises higher than the point above mentioned, and rarely between two or three inches (in one case four) below Poupart’s ligament. It would appear, then, that the most favorable situation for the application of a ligature to the femoral is on the superficial femoral at the apex of Scarpa’s triangle. In order to expose the artery in this situation, an incision between three and four inches long should be made in the course of the vessel, the patient lying in the recumbent position, with the limb slightly flexed and abducted, and rotated outward. A large vein is frequently met with, passing in the course of the artery to the internal saphenous vein; this must be avoided, and the fascia lata having been cautiously divided and the Sartorius exposed, that muscle must be drawn outward in order to expose fully the sheath of the vessels. The finger being introduced into the wound and the pulsation of the artery felt, the sheath should be opened on the outer side of the vessel to a sufficient extent to allow of the

---

1  Ligature of the femoral artery has been also recommended and performed for elephantiasis of the leg and acute inflammation of the knee-joint (Maunder, Clin. Soc. Trans., vol. ii. p. 37).—Ed. of 15th English edition.
introduction of the ligature, but no farther; otherwise the nutrition of the coats of the vessel may be interfered with, or muscular branches which arise from the vessel at irregular intervals may be divided. In this part of the operation the long saphenous nerve and the nerve to the Vastus internus, which is in close relation with the sheath, should be avoided. The aneurism needle must be carefully introduced and kept close to the artery, to avoid the femoral vein, which lies behind the vessel in this part of its course.

To expose the artery in Hunter's canal, an incision should be made between three and four inches in length, a finger's breadth internal to the line of the artery, in the middle of the thigh—i.e., midway between the groin and the knee. The integument is first divided. The fascia lata having been divided, and the outer border of the Sartorius muscle exposed, it should be drawn inward, when the strong fascia which is stretched across from the Adductors to the Vastus internus will be exposed, and must be freely divided; the sheath of the vessels is now seen, and must be opened, and the artery secured by passing the aneurism needle between the vein and artery in the direction from without inward. The femoral vein in this situation lies on the outer side of the artery and the long saphenous nerve on the anterior and outer side of the artery.

It has been seen that the femoral artery occasionally divides into two trunks below the origin of the profunda. If in the operation for tying the femoral two vessels are met with, the surgeon should alternately compress each, in order to ascertain which vessel is connected with the aneurismal tumor or with the bleeding from the wound, and that one only should be tied which controls the pulsation or hemorrhage. If, however, it is necessary to compress both vessels before the circulation in the tumor is controlled, both should be tied, as it would be probable that they became reunited, as in the instances referred to above.

In wounds of the femoral artery the question of the mode of treatment is of considerable importance. If the wound in the superficial structures is a large one, the injured vessel must be exposed and tied; but if the wound is a punctured one and the bleeding has ceased, the question will arise whether to cut down upon the artery or to trust to pressure. Mr. Cripps advises that if the wound is in the "upper part of the thigh—that is to say, in a position where the femoral artery is comparatively superficial—the surgeon may enlarge the opening with a good prospect of finding the wounded vessel without an extensive or prolonged operation. If the wound be in the lower half of the thigh, owing to the greater depth of the artery and the possibility of its being the popliteal that is wounded, the search is rendered a far more severe and hazardous operation, and it should not be undertaken until a thorough trial of pressure has proved ineffectual."

Great care and attention are necessary for the successful application of pressure. The limb should be carefully bandaged from the foot upward to the wound, which is not covered, and then onward to the groin. The wound is then dusted with iodoform or boracic powder and a conical pad applied over the wound. Rollers the thickness of the index finger are then placed along the course of the vessel above and below the wound, and the whole carefully bandaged to a back splint with a foot-piece.

Collateral Circulation.—When the common femoral is tied the main channels for carrying on the circulation are the anastomoses of the gluteal and circumflex iliac arteries above with the external circumflex below; of the obturator and sciatic above with the internal circumflex below; and of the comes nervi ischiadici with the arteries in the ham.

The principal agents in carrying on the collateral circulation after ligature of the superficial femoral artery are, according to Sir A. Cooper, as follows:

"The arteria profunda formed the new channel for the blood. The first artery sent off passed down close to the back of the thigh-bone, and entered the two superior articular branches of the popliteal artery.

"The second new large vessel, arising from the profunda at the same part with the former, passed down by the inner side of the Biceps muscle to a branch of the popliteal which was distributed to the Gastrocnemius muscle; whilst a third artery, dividing into several branches, passed down with the sciatic nerve behind the knee-joint, and some of its branches united themselves with the inferior articular arteries of the popliteal, with some recurrent branches of those arteries, with arteries passing to the Gastrocnemii, and, lastly, with the origin of the anterior and posterior tibial arteries.

"It appears, then, that it is those branches of the profunda which accompany the sciatic nerve that are the principal supporters of the new circulation.""

In Porta's work (tab. xii., xiii.) is a good representation of the collateral circulation after the ligature of the femoral artery. The patient had survived the operation three years. The lower part of the artery is at least as large as the upper: about two inches of the vessel appear to have been obliterated. The external and internal circumflex arteries are seen anastomosing by a great number of branches with the lower branches of the femoral (muscular and anasto-

---

3 Alterazioni patologiche delle Arterie.
motica magna) and with the articular branches of the popliteal. The branches from the external circumflex are extremely large and numerous. One very distinct anastomosis can be traced between this artery on the outside and the anastomotica magna on the inside through the intervention of the superior external articular artery, with which they both anastomose; and blood reaches even the anterior tibial recurrent from the external circumflex by means of anastomosis with the same external articular artery. The perforating branches of the profunda are also seen bringing blood round the obliterated portion of the artery into long branches (muscular) which have been given off just below that portion. The termination of the profunda itself anastomoses most freely with the superior external articular. A long branch of anastomosis is also traced down from the internal iliac by means of the comites nervi ischiadici of the sciatic, which anastomoses on the popliteal nerves with branches from the popliteal and posterior tibial arteries. In this case the anastomosis had been too free, since the pulsation and growth of the aneurism recurred, and the patient died after ligature of the external iliac.

There is an interesting preparation in the Museum of the Royal College of Surgeons of a limb on which John Hunter had tied the femoral artery fifty years before the patient's death. The whole of the superficial femoral and popliteal artery seems to have been obliterated. The anastomosis by means of the comites nervi ischiadici, which is shown in Porta's plate, is distinctly seen: the external circumflex and the termination of the profunda artery seem to have been the chief channels of anastomoses; but the injection has not been a very successful one.

Branches (Figs. 432 and 433).—The branches of the femoral artery are—the

The **Superficial Epigastric (a. epigastrica superficialis)** arises from the femoral about half an inch below Poupart's ligament, and, passing through the saphenous opening in the fascia lata, ascends on the abdomen, in the superficial fascia covering the External oblique muscle, nearly as high as the umbilicus. It distributes branches to the superficial inguinal glands, the superficial fascia, and the integument, anastomosing with branches of the deep epigastric.

The **Superficial Circumflex Iliac (a. circumflexa ilium superficialis)**, the smallest of the cutaneous branches, arises close to the preceding, and, piercing the fascia lata, runs outward, parallel with Poupart's ligament, as far as the crest of the ilium, dividing into branches which supply the integument of the groin, the superficial fascia, and the superficial inguinal lymphatic glands, anastomosing with the deep circumflex iliac and with the gluteal and external circumflex arteries.

The **Superficial External Pudic** or the **Superior Superior External Pudic (a. pudenda externa superficialis)** arises from the inner side of the femoral artery, close to the preceding vessels, and, after passing through the saphenous opening, courses inward, across the spermatic cord or round ligament, to be distributed to the integument on the lower part of the abdomen, the penis and scrotum in the male, and the labium in the female, anastomosing with branches of the internal pudic.

The **Deep External Pudic** or the **Deep Superior External Pudic (a. pudenda externa profunda)**, more deeply seated than the preceding, passes inward across the Pectineus and Adductor longus muscles, covered by the fascia lata, which it pierces at the inner border of the thigh, its branches being distributed, in the male, to the integument of the scrotum and perineum; and in the female to the labium, anastomosing with branches of the superficial perineal artery.

The **Deep Femoral** or the **Profunda Femoris (a. profunda femoris)** (Figs. 432 and 433) nearly equals the size of the superficial femoral. It arises from the outer and back part of the femoral artery, from one to two inches below Poupart's
ligament. It at first lies on the outer side of the superficial femoral, and then passes behind it and the femoral vein to the inner side of the femur, and, passing downward beneath the Adductor longus, terminates at the lower third of the thigh in a small branch which pierces the Adductor magnus (and from this circumstance is sometimes called the **fourth perforating artery**), and is distributed to the flexor muscles on the back of the thigh, anastomosing with branches of the popliteal and inferior perforating arteries.

**Relations.**—*Behind*, it lies first upon the Iliacus, and then on the Pectineus, Adductor brevis, and Adductor magnus muscles. *In front*, it is separated from the superficial femoral artery, above by the femoral and profunda veins, and below by the Adductor longus. On its **outer side** the origin of the Vastus internus separates it from the femur.

**Plan of the Relations of the Profunda Artery.**

*In front.*
- Superficial femoral artery.
- Femoral and profunda veins.
- Adductor longus.

*Outer side.*
- Vastus internus.

*Profunda Femoris.*

*Behind.*
- Iliacus.
- Pectineus.
- Adductor brevis.
- Adductor magnus.

**Branches.**—The profunda gives off the following named branches:

- **Muscular.**
- **External circumflex.**
- **Internal circumflex.**
- **Four perforating.**

**Muscular Branches** are given off in Scarpa's triangle, and also from the vessel as it lies between the Adductor muscles.

The **External Circumflex Artery** (*a. circumflexa femoris lateralis*) supplies the muscles on the front of the thigh. It *arises* from the outer side of the profunda, passes horizontally outward, between the divisions of the femoral nerve and behind the Sartorius and Rectus muscles, and divides into three sets of branches—**ascending, transverse, and descending.**

The **ascending branch** (*ramus ascendens*) passes upward, beneath the Tensor fasciae femoris muscle, to the outer side of the hip, anastomosing with the terminal branches of the gluteal and deep circumflex iliac arteries. It sends out muscular branches. The **descending branch** (*ramus descendens*) passes downward, behind the Rectus, upon the Vasti muscles, to which its branches are distributed, one or two passing beneath the Vastus externus as far as the knee, anastomosing with the superior articular branches of the popliteal artery. These are accompanied by the branch of the femoral nerve to the Vastus externus. The **transverse branch**, the smallest, passes outward over the Crureus, pierces the Vastus externus, and winds round the femur to its back part, just below the great trochanter, anastomosing at the back of the thigh with the internal circumflex, sciatic, and superior perforating arteries.

The **Internal Circumflex Artery** (*a. circumflexa femoris medialis*), smaller than the external, *arises* from the inner and back part of the profunda, and winds round the inner side of the femur, between the Pectineus and Psoas muscles. On
reaching the upper border of the Adductor brevis it gives off two muscular branches, one of which passes inward to be distributed to the Adductor muscles, the Gracilis, and Obturator externus, anastomosing with the obturator artery; the other descends, and passes beneath the Adductor brevis, to supply it and the great Adductor; while the continuation of the vessel passes backward and divides into an ascending and a transverse branch (Fig. 348). The ascending branch (ramus profundus) passes obliquely upward upon the tendon of the Obturator externus and under cover of the Quadratus femoris toward the digital fossa, where it anastomoses with twigs from the gluteal and sciatic arteries. The transverse branch (ramus superficialis), larger than the ascending, appears between the Quadratus femoris and upper border of the Adductor magnus, anastomosing with the sciatic, external circumflex, and superior perforating arteries, the crucial anastomosis. Opposite the hip-joint the artery gives off an articular vessel (ramus acetabuli), which enters the joint beneath the transverse ligament; and, after supplying the adipose tissue, passes along the round ligament to the head of the bone.

The Perforating Arteries (Figs. 431, 432, and 433), usually three in number, are so called from their perforating the tendon of the Adductor magnus muscle to reach the back of the thigh. They pass backward close to the linea aspera of the femur, under cover of small tendinous arches in the Adductor magnus. The first is given off above the Adductor brevis, the second in front of that muscle, and the third immediately below it.

The first perforating artery (a. perforans prima) passes backward between the Pectineus and Adductor brevis (sometimes perforates the latter); it then pierces the Adductor magnus close to the linea aspera. It gives off branches which supply the Adductor brevis, the Adductor magnus, the Biceps, and Gluteus maximus muscles, and anastomoses with the sciatic, internal and external circumflex, and middle perforating arteries. The second perforating artery (a. perforans secunda), larger than the first, pierces the tendons of the Adductor brevis and Adductor magnus muscles, and divides into ascending and descending branches, which supply the flexor muscles of the thigh, anastomosing with the first and third perforating arteries. The second artery frequently arises in common with the first. The nutrient artery of the femur is usually given off from this branch. The third perforating artery (a. perforans tertia) is given off below the Adductor brevis; it pierces the Adductor magnus, and divides into branches which supply the flexor muscles of the thigh; anastomosing above with the higher perforating arteries, and below with the terminal branches of the profunda and the muscular branches of the popliteal. A fourth perforating artery is represented by the termination of the profunda femoris artery.

The nutritive artery of the femur (a. nutricia femoris), if single, comes from the second perforating artery; if double, from the first and third perforating arteries. If double, one vessel is called superior and the other inferior.

Muscular Branches (rami musculares) are given off from the superficial femoral throughout its entire course. They vary from two to seven in number, and supply chiefly the Sartorius and Vastus internus.

The Anastomotica Magna (a. genu suprema) (Figs. 432 and 433) arises from the femoral artery just before it passes through the tendinous opening in the Adductor magnus muscle, and immediately divides into a superficial and deep branch.

The Superficial Branch (ramus saphenus) pierces the aponeurotic covering of Hunter's canal, and accompanies the long saphenous nerve to the inner side of the thigh. It passes between the Sartorius and Gracilis muscles, and, piercing the fascia lata, is distributed to the integument of the upper and inner part of the leg, anastomosing with the inferior internal articular artery.

The Deep Branch (ramus musculoarticularis) descends in the substance of the Vastus internus, lying in front of the tendon of the Adductor magnus, to the inner side of the knee, where it anastomoses with the superior internal articular artery.
and the anterior recurrent branch of the anterior tibial. A branch from this vessel crosses outward above the articular surface of the femur, forming an anastomotic arch with the superior external articular artery, and supplies branches to the knee-joint.

THE POPLITEAL ARTERY (A. POPLITEA) (Figs. 431 and 432).

The popliteal artery commences at the termination of the femoral at the opening in the Adductor magnus, and, passing obliquely downward and outward behind the knee-joint to the lower border of the Popliteus muscle divides into the anterior and posterior tibial arteries. A portion of the artery lies in the popliteal space; but above and below, to a considerable extent, it is covered by the muscles which form the boundaries of the space, and is therefore beyond the confines of the hollow.

The Popliteal Space (Fig. 434).

Dissection.—A vertical incision about eight inches in length should be made along the back part of the knee-joint, connected above and below by a transverse incision from the inner to the outer side of the limb. The flaps of integument included between these incisions should be reflected in the direction shown in Fig. 345, page 525.

Boundaries.—The popliteal space, or the ham, is a lozenge-shaped space, widest at the back part of the knee-joint, and deepest above the articular end of the femur. It is bounded externally, above the joint, by the Biceps, and below by the joint by the Plantaris and external head of the Gastrocnemius. Internally, above the joint, by the Semimembranosus, Semiten- dinosus, Gracilis, and Sartorius; below the joint, by the inner head of the Gastrocnemius.

Above, it is limited by the apposition of the inner and outer hamstring muscles; below, by the junction of the two heads of the Gastrocnemius. The floor is formed by the lower part of the posterior surface of the shaft of the femur, the posterior ligament of the knee-joint, the upper end of the tibia, and the fascia covering the Popliteus muscle, and the space is covered in by the fascia lata.

Contents.—It contains the popliteal vessels and their branches, together with the termination of the external saphenous vein, the internal and external popliteal nerves and some of their branches, the lower extremity of the small sciatic nerve, the articular branch from the obturator nerve, a few small lymphatic glands, and a considerable quantity of loose adipose tissue.
Position of Contained Parts.—The internal popliteal nerve descends in the middle line of the space lying superficial and crossing the artery from without inward. The external popliteal nerve descends on the outer side of the upper part of the space, lying close to the tendon of the Biceps muscle. More deeply at the bottom of the space are the popliteal vessels, the vein lying superficial to the artery, to which it is closely united by dense areolar tissue; it is a thick-walled vessel, and lies at first to the outer side of the artery, and then crosses it to gain the inner side below; sometimes the vein is double, the artery lying between the two venae comitantes, which are usually connected by short transverse branches. More deeply and, at its upper part, close to the surface of the bone is the popliteal artery, and passing off from it at right angles are its articular branches. The articular branch from the obturator nerve descends upon the popliteal artery to supply the knee, and occasionally there is found deep in the space an articular filament from the great sciatic nerve.

The popliteal lymphatic glands, four or five in number, are found surrounding the artery; one usually lies superficial to the vessel; another is situated between it and the bone, and the rest are placed on either side of it.

The Popliteal Artery, in its course downward from the aperture in the Adductor magnus to the lower border of the Popliteus muscle, rests first on the inner surface of the femur, and is then separated by a little fat from the hollowed popliteal surface of the bone; in the middle of its course it rests on the posterior ligament of the knee-joint, and below on the fascia covering the Popliteus muscle. Superficially, it is covered above by the Semimembranosus; in the middle of its course, by a quantity of fat, which separates it from the deep fascia and integument; and below it is overlapped by the Gastrocnemius, Plantaris, and Soleus muscles, the popliteal vein, and the internal popliteal nerve. The popliteal vein, which is intimately attached to the artery, lies superficial and external to it above; it then crosses it and lies to its inner side. The internal popliteal nerve is still more superficial and external above, but below the joint it crosses the artery and lies on its inner side. Laterally, the artery is bounded by the muscles which are situated on either side of the popliteal space.

Peculiarities in Point of Division.—Occasionally the popliteal artery divides prematurely into its terminal branches; this unusual division occurs most frequently opposite the knee-joint. The anterior tibial under these circumstances may pass in front of the Popliteus muscle.

Unusual Branches.—The artery sometimes divides into the anterior tibial and peroneal, the posterior tibial being wanting or very small. Occasionally the popliteal is found to divide into three branches, the anterior and posterior tibial and peroneal.
THE POPLITEAL SPACE

Surface Marking.—The course of the upper part of the popliteal artery is indicated by a line drawn from the outer border of the Semimembranosus muscle at the junction of the middle and lower third of the thigh obliquely downward to the middle of the popliteal space, exactly behind the knee-joint. From this point it passes vertically downward to the level of a line drawn through the lower part of the tubercle of the tibia.

Surgical Anatomy.—The popliteal artery is not infrequently the seat of injury. It may be torn by direct violence, as by the passage of a cart-wheel over the knee or by hyper-extension of the knee, and in the dead body, at all events, the middle and internal coats may be ruptured by extreme flexion. It may also be lacerated by fracture of the lower part of the shaft of the femur or by antero-posterior dislocation of the knee-joint. It has been torn in breaking down adhesions in cases of fibrous ankylosis of the knee, and is in danger of being wounded, and in fact has been wounded, in performing Maceneew’s operation of osteotomy of the lower end of the femur for genu valgum. In addition, Spencer records a case in which the popliteal artery was wounded from in front by a stab just below the knee, the knife passing through the intersosseous space. The popliteal artery is more frequently the seat of aneurism than is any other artery in the body, with the exception of the thoracic aorta. This is due no doubt, in a great measure, to the amount of movement to which it is subjected, and to the fact that it is supported by loose and lax tissue only, and not by muscles, as is the case with most arteries.

Ligature of the popliteal artery is required in cases of wound of that vessel, but for aneurism of the posterior tibial it is preferable to tie the superficial femoral. The popliteal may be tied in the upper or lower part of its course; but in the middle of the ham the operation is attended with considerable difficulty, from the great depth of the artery and from the extreme degree of tension of the lateral boundaries of the space.

In order to expose the vessel in the upper part of its course, the patient should be placed in the supine position, with the knee flexed and the thigh rotated outward, so that it rests on its outer surface; an incision three inches in length, beginning at the junction of the middle and lower third of the thigh, is to be made parallel to and immediately behind the tendon of the Adductor magnus, and the skin, superficial and deep fascia divided. The tendon of the muscle is thus exposed, and is to be drawn forward and the hamstring tendons backward. A quantity of fatty tissue will now be opened up, in which the artery will be felt pulsating. This is to be separated with the point of a director until the artery is exposed. The vein and nerve will not be seen, as they lie to the outer side of the artery. The sheath is to be opened and the aneurism needle passed from before backward, keeping its point close to the artery for fear of injuring the vein. The only structure to avoid is the long saphenous vein in the superficial incision. The upper part of the popliteal artery may also be tied by an incision on the back of the limb, along the outer margin of the Semimembranosus, but the operation is a more difficult one, as the internal popliteal nerve and the popliteal vein are first exposed, and great care has to be exercised in separating them from the artery.

To expose the vessel in the lower part of its course, where the artery lies between the two heads of the Gastrocnemius, the patient should be placed in the prone position with the limb extended. An incision should then be made through the integument in the middle line, commencing opposite the bend of the knee-joint, care being taken to avoid the external saphenous vein and nerve. After dividing the deep fascia and separating some dense cellular membrane, the artery, vein, and nerve will be exposed, descending between the two heads of the Gastrocnemius. Some muscular branches of the popliteal should be avoided if possible, or, if divided, tied immediately. The leg being now flexed, in order the more effectually to separate the two heads of the Gastrocnemius, the nerve should be drawn inward and the vein outward, and the aneurism needle passed between the artery and vein from without inward.

Branches.—The branches of the popliteal artery are—

Muscular

Superior or Sural

Superior External Articular.

Azygos Articular.

Inferior Internal Articular.

Inferior External Articular.

The Superior Muscular Branches, two or three in number, arise from the upper part of the popliteal artery, and are distributed to the lower part of the Adductor magnus and flexor muscles of the thigh, anastomosing with the fourth perforating branch of the profunda.

The Inferior Muscular (aa. surales) are two large branches which are distributed to the two heads of the Gastrocnemius and to the Plantaris muscle. They arise from the popliteal artery opposite the knee-joint.
The Cutaneous Branches arise separately from the popliteal artery or from some of its branches; they descend between the two heads of the Gastrocnemius muscle, and, piercing the deep fascia, are distributed to the integument of the calf. One branch usually accompanies the short, or external, saphenous vein, the superficial sural artery.

The Superior Articular Arteries, two in number, arise one on each side of the popliteal, and wind round the femur immediately above its condyles to the front of the knee-joint. The internal branch (a. genu superior medialis) winds inward beneath the hamstring muscles, to which it supplies branches, above the inner head of the Gastrocnemius, and, passing beneath the tendon of the Adductor magnus, divides into two branches, one of which supplies the Vastus internus, inosculating with the anastomotica magna and inferior internal articular; the other ramifies close to the surface of the femur, supplying it and the knee-joint, and anastomosing with the superior external articular artery. This branch is frequently of small size, a condition which is associated with an increase in the size of the anastomotica magna. The external branch (a. genu superior lateralis) passes above the outer condyle, beneath the tendon of the Biceps, and divides into a superficial and deep branch: the superficial branch supplies the Vastus externus, and anastomoses with the descending branch of the external circumflex and the inferior external articular arteries; the deep branch supplies the lower part of the femur and knee-joint, and forms an anastomotic arch across the bone with the anastomotica magna and the inferior internal articular arteries.

The Azygos Articular (a. genu media) is a small branch arising from the popliteal artery opposite the bend of the knee-joint. It pierces the posterior ligament, and supplies the ligaments and synovial membrane in the interior of the articulation.

The Inferior Articular Arteries, two in number, arise from the popliteal beneath the Gastrocnemius, and wind round the head of the tibia below the joint. The internal branch (a. genu inferior medialis) first descends along the upper margin of the Popliteus muscle, to which it gives branches; it then passes below the inner tuberosity, beneath the interial lateral ligament, at the anterior border of which it ascends to the front and inner side of the joint, to supply the head of the tibia and the articulation of the knee, anastomosing with the inferior external articular and superior internal articular arteries. The external branch (a. genu inferior lateralis) passes outward above the head of the fibula, to the front of the knee-joint, passing in its course beneath the outer head of the Gastrocnemius, the external lateral ligament, and the tendon of the Biceps muscle, and divides into branches which anastomose with the inferior internal articular artery, the superior external articular artery, and the anterior recurrent branch of the anterior tibial.

Circumpatellar Anastomosis.—Around and above the patella, and on the contiguous ends of the femur and tibia, is a large network of vessels, forming a superficial and a deep plexus. The superficial plexus is situated between the fascia and skin round about the patella; the deep plexus, which forms a close network of vessels, lies on the surface of the lower end of the femur and upper end of the tibia around their articular surfaces, and sends numerous offsets into the interior of the joint. The arteries from which this plexus is formed are the two internal and two external articular branches of the popliteal, the anastomotica magna, the terminal branch of the profunda, the descending branch from the external circumflex and the anterior recurrent branch of the anterior tibial.

The Anterior Tibial Artery (A. Tibialis Anterior) (Fig. 435).

The anterior tibial artery commences at the bifurcation of the popliteal at the lower border of the Popliteus muscle, passes forward between the two
heads of the Tibialis posticus, and through the large oval aperture above the upper border of the interosseous membrane to the deep part of the front of the leg; it here lies close to the inner side of the neck of the fibula; it then descends on the anterior surface of the interosseous membrane, gradually approaching the tibia; and at the lower part of the leg lies on this bone, and then on the anterior ligament of the ankle to the bend of the ankle-joint, where it lies more superficially, and becomes the dorsalis pedis.

**Relations.**—In the upper two-thirds of its extent it rests upon the interosseous membrane, to which it is connected by delicate fibrous arches thrown across it; in the lower third, upon the front of the tibia and the anterior ligament of the ankle-joint. In the upper third of its course it lies between the Tibialis anticus and Extensor longus digitorum; in the middle third, between the Tibialis anticus and Extensor proprius hallucis. At the bend of the ankle it is crossed by the tendon of the Extensor proprius hallucis, and lies between it and the innermost tendon of the Extensor longus digitorum. It is covered, in the upper two-thirds of its course, by the muscles which lie on either side of it and by the deep fascia; in the lower third, by the integument, anterior annular ligament, and fascia.

The anterior tibial artery is accompanied by two veins, venae comites, which lie one on each side of the artery; the anterior tibial nerve, coursing round the outer side of the neck of the fibula, comes into relation with the outer side of the artery shortly after it has passed through the opening in the interosseous membrane; about the middle of the leg it is placed superficial to it; at the lower part of the artery the nerve is generally again on the outer side.

**Peculiarities in Size.**—This vessel may be very small, may be deficient to a greater or less extent, or may be entirely wanting, its place being supplied by perforating branches from the posterior tibial or by the anterior division of the peroneal artery.

**Course.**—The artery occasionally deviates in its course toward the fibular side of the leg, regaining its usual position beneath the annular ligament at the front of the ankle. In two instances the vessel has been found to approach the surface in the middle of the leg, being covered merely by the integument and fascia below that point.

**Surface Marking.**—Draw a line from the inner side of the head of the fibula to midway between the two malleoli. In this line take a point one inch and a quarter below the head of the fibula, and the portion of the line below this point will mark the course of the artery.

**Surgical Anatomy.**—The anterior tibial artery may be tied in the upper or lower part of the leg. In the upper part the operation is attended with great difficulty, on account of the depth of the vessel from the surface. An incision, about four inches in length, should be made
through the integument, midway between the spine of the tibia and the outer margin of the fibula, and the deep fascia exposed. The wound must now be carefully dried, its edges retracted, and the white line separating the Tibialis anticus from the Extensor longus digitorum sought for. When this has been clearly defined, the deep fascia is to be divided in this line, and the Tibialis anticus separated from adjacent muscles with the handle of the scalpel or a director until the interosseous membrane is reached. The foot is to be flexed in order to relax the muscles, and upon drawing them apart the artery will be found lying on the interosseous membrane with the nerve on its outer side or on the top of the artery. The nerve should be drawn outward, and the vena comites separated from the artery and the needle passed round it.

To tie the vessel in the lower third of the leg above the ankle-joint an incision about three inches in length should be made through the integument between the tendons of the Tibialis anticus and Extensor proprius hallucis muscles, the deep fascia being divided to the same extent. The tendon on either side should be held aside, when the vessel will be seen lying upon the tibia, with the nerve on the outer side and one of the vena comites on either side.

Branches.—The branches of the anterior tibial artery are—

Posterior Recurrent Tibial.
Superior Fibular.
Anterior Recurrent Tibial.
Muscular.
Internal Malleolar.
External Malleolar.

The Posterior Recurrent Tibial (a. recurrens tibialis posterior) is not a constant branch, and is given off from the anterior tibial before that vessel passes through the interosseous space. It ascends beneath the Popliteus muscle, which it supplies, and anastomoses with the lower articular branches of the popliteal artery, giving off an offset to the superior tibio-fibular joint.

The Superior Fibular is sometimes given off from the anterior tibial, sometimes from the posterior tibial. It passes outward, round the neck of the fibula, through the Soleus, which it supplies, and ends in the substance of the Peroneus longus muscle.
The Anterior Recurrent Tibial (a. recurrens tibialis anterior) arises from the anterior tibial as soon as that vessel has passed through the interosseous space; it ascends in the Tibialis anticus muscle, and ramifies on the front and sides of the knee-joint, Anastomosing with the articular branches of the popliteal, with the anastomotica magna, and the external articular branches of the popliteal, assisting in the formation of the circumarticularplexus.

The Muscular Branches are numerous; they are distributed to the muscles which lie on each side of the vessel, some cutaneous branches piercing the deep fascia to supply the integument, others passing through the interosseous membrane, and anastomosing with branches of the posterior tibial and peroneal arteries.

The Malleolar Arteries supply the ankle-joint. The internal branch (a. malleolaris anterior medialis) arises about two inches above the articulation, and passes beneath the tendons of the Extensor proprius hallucis and Tibialis anticus to the inner ankle, upon which it ramifies, anastomosing with branches of the posterior tibial and internal plantar arteries and with the internal calcanean from the posterior tibial. The external branch (a. malleolaris anterior lateralis) passes beneath the tendons of the Extensor longus digitorum and Peroneous tertius, and supplies the outer ankle, anastomosing with the anterior peroneal artery and with ascending branches from the tarsal branch of the dorsalis pedis.

The Dorsalis Pedis Artery (A. Dorsalis Pedis) (Figs. 435, 436).

The dorsalis pedis, the continuation of the anterior tibial, passes forward from the bend of the ankle along the tibial side of the foot to the back part of the first intermetatarsal space, where it divides into two branches, the dorsalis hallucis and communicating.

Relations.—This vessel, in its course forward, rests upon the astragalus, navicular, and middle cuneiform bones and the ligaments connecting them, being covered by the integument and fascia, anterior annular ligament, and crossed near its termination by the innermost tendon of the Extensor brevis digitorum. On its tibial side is the tendon of the Extensor proprius hallucis; on its fibular side, the innermost tendon of the Extensor longus digitorum, and the termination of the anterior tibial nerve. It is accompanied by two veins.

And their ligaments.

Peculiarities in Size.—The dorsal artery of the foot may be larger than usual, to compensate for a deficient plantar artery; or it may be deficient in its terminal branches to the toes, which are then derived from the internal plantar; or its place may be supplied altogether by a large anterior peroneal artery.
Position.—This artery frequently curves outward, lying external to the line between the middle of the ankle and the back part of the first interosseous space.

Surface Marking.—The dorsalis pedis artery is indicated on the surface of the dorsum of the foot by a line drawn from the centre of the space between the two malleoli to the back of the first intermetatarsal space.

Surgical Anatomy.—This artery may be tied, by making an incision through the integument between two and three inches in length, on the fibular side of the tendon of the Extensor proprius hallucis, in the interval between it and the inner border of the short Extensor muscle. The incision should not extend farther forward than the back part of the first intermetatarsal space; as the artery divides in that situation. The deep fascia being divided to the same extent, the artery will be exposed, the nerve lying upon its outer side.

Branches.—The branches of the dorsalis pedis are—the

Cutaneous. 
Tarsal. 
Metatarsal—Interosseous. 
Dorsalis Hallucis. 
Communicating.

Cutaneous Branches go to the skin of the dorsum and inner surface of the foot.

The Tarsal Artery (a. tarsae lateralis) arises from the dorsalis pedis, as that vessel crosses the navicular bone; it passes in an arched direction outward, lying upon the tarsal bones, and covered by the Extensor brevis digitorum; it supplies that muscle and the articulations of the tarsus, and anastomoses with branches from the metatarsal, external malleolar, peroneal, and external plantar arteries.
The Metatarsal (a. arcuata) arises a little anterior to the preceding; it passes outward to the outer part of the foot, over the bases of the metatarsal bones, beneath the tendons of the short Extensor, its direction being influenced by its point of origin; and it anastomoses with the tarsal and external plantar arteries. This vessel gives off three branches, the dorsal interosseous arteries (aa. metatarsae dorsales), which pass forward upon the three outer Dorsal interossei muscles, and, in the clefts between the toes, divide into two dorsal collateral branches for the adjoining toes (aa. digitales dorsales). At the back part of each interosseous space these vessels receive the posterior perforating branches from the plantar arch, and at the forepart of each interosseous space they are joined by the anterior perforating branches from the digital arteries. The outermost interosseous artery gives off a branch which supplies the outer side of the little toe.

The Dorsalis Hallucis or the First Dorsal Interosseous (a. dorsalis hallucis) is one of the terminal branches of the dorsalis pedis. It runs forward along the outer border of the first metatarsal bone, and at the cleft between the first and second toes divides into two branches, one of which passes inward, beneath the tendon of the Extensor proprius hallucis, and is distributed to the inner border of the great toe; the outer branch bifurcates, to supply the adjoining sides of the great and second toes.

The Communicating Artery (ramus plantaris profundus), the other terminal branch of the dorsalis pedis, dips down into the sole of the foot, between the two heads of the First dorsal interosseous muscle, and inosculates with the termination of the external plantar artery, to complete the plantar arch. It here gives off its plantar digital branch, which is named the arteria magna hallucis, or the princeps hallucis. This artery passes forward along the first interosseous space, and, after sending a branch along the inner side of the great toe, bifurcates for the supply of the adjacent sides of the great and second toes.

The Posterior Tibial Artery (A. Tibialis Posterior) (Fig. 434).

The posterior tibial is an artery of large size, which extends obliquely downward from the lower border of the Popliteus muscle, along the tibial side of the leg, to the fossa between the inner ankle and the heel, where it divides beneath the origin of the Abductor hallucis, on a level with a line drawn from the point of the internal malleolus to the centre of the convexity of the heel, into the internal and external plantar arteries. At its origin it lies opposite the interval between the tibia and fibula; as it descends, it approaches the inner side of the leg, lying behind the tibia, and, in the lower part of its course, is situated midway between the inner malleolus and the tuberosity of the os calcis.

Relations.—It lies successively upon the Tibialis posticus, the Flexor longus digitorum, the tibia, and the back part of the ankle-joint. It is covered by the deep transverse fascia, which separates it above from the Gastrocnemius and Soleus muscles; at its termination it is covered by the Abductor hallucis muscle. In the lower third, where it is more superficial, it is covered only by the integument and fascia, and runs parallel with the inner border of the tendon Achillis. It is accompanied by two veins and by the posterior tibial nerve, which lies at first to the inner side of the artery, but soon crosses it, and is, in the greater part of its course, on its outer side.

Plan of the Relations of the Posterior Tibial Artery.

In front.
Tibialis posticus.
Flexor longus digitorum.
Tibia.
Ankle-joint.
Behind the inner ankle the tendons and blood-vessels are arranged, under cover of the internal annular ligament, in the following order, from within outward: First, the tendons of the Tibialis posticus and Flexor longus digitorum, lying in the same groove, behind the inner malleolus, the former being the most internal. External to these is the posterior tibial artery, having a vein on either side: and, still more externally, the posterior tibial nerve. About half an inch nearer the heel is the tendon of the Flexor longus hallucis.

Peculiarities in Size.—The posterior tibial is not unfrequently smaller than usual, or absent, its place being supplied by a large peroneal artery which passes inward at the lower end of the tibia, and either joins the small tibial artery or continues alone to the sole of the foot.

Surface Marking.—The course of the posterior tibial artery is indicated by a line drawn from a point one inch below the centre of the popliteal space to midway between the tip of the internal malleolus and the centre of the convexity of the heel.

Surgical Anatomy.—The application of a ligature to the posterior tibial may be required in cases of wound of the sole of the foot attended with great hemorrhage, when the vessel should be tied at the inner ankle. In cases of wound of the posterior tibial it will be necessary to enlarge the opening so as to expose the vessel at the wounded point, excepting where the vessel is injured by a punctured wound from the front of the leg. In cases of aneurism from wound of the artery low down, the vessel should be tied in the middle of the leg. But in aneurism of the posterior tibial high up it would be better to tie the femoral artery.

To tie the posterior tibial artery at the ankle, a semilunar incision, convex backward, should be made through the integument, about two inches and a half in length, midway between the heel and the inner ankle or a little nearer the latter. The subcutaneous cellular tissue having been divided, a strong and dense fascia, the internal annular ligament, is exposed. This ligament is continuous above with the deep fascia of the leg, covers the vessels and nerves, and is intimately adherent to the sheaths of the tendons. This having been cautiously divided upon a director, the sheath of the vessels is exposed, and, being opened, the artery is seen with one of the venous comites on each side. The aneurism needle should be passed round the vessel from the heel toward the ankle, in order to avoid the posterior tibial nerve, care being at the same time taken not to include the venous comites.

The vessel may also be tied in the lower third of the leg by making an incision, about three inches in length, parallel with the inner margin of the tendon Achilles. The internal saphenous vein being carefully avoided, the two layers of fascia must be divided upon a director, when the artery is exposed along the outer margin of the Flexor longus digitorum, with one of its venous comites on either side and the nerve lying external to it.

To tie the posterior tibial in the middle of the leg is a very difficult operation, on account of the great depth of the vessel from the surface. The patient being placed in the recumbent position, the injured limb should rest on its outer side, the knee being partially bent and the foot extended, so as to relax the muscles of the calf. An incision about four inches in length should then be made through the integument a finger’s breadth behind the inner margin of the tibia, taking care to avoid the internal saphenous vein. The deep fascia having been divided, the margin of the Gastrocnemius is exposed, and must be drawn aside, and the tibial attachment of the Soleus divided, a director being previously passed beneath it. The artery may now be felt pulsating beneath the deep fascia about an inch from the margin of the tibia. The fascia having been divided, and the limb placed in such a position as to relax the muscles of the calf as much as possible, the veins should be separated from the artery, and the aneurism needle passed round the vessel from without inward, so as to avoid wounding the posterior tibial nerve.

Branches.—The branches of the posterior tibial artery are—the

- Peroneal.
- Nutrient.
- Muscular.
- Cutaneous.
- Communicating.
- Internal Calcanean.
- Malleolar cutaneous.
The Peroneal Artery (a. peronaea) (Fig. 434) lies, deeply seated, along the back part of the fibular side of the leg. It arises from the posterior tibial about an inch below the lower border of the Popliteus muscle, passes obliquely outward to the fibula, and then descends along the inner border of that bone, contained in a fibrous canal between the Tibialis posticus and the Flexor longus hallucis, or in the substance of the latter muscle to the lower third of the leg, where it gives off the anterior peroneal. It then passes across the articulation between the tibia and fibula to the outer side of the os calcis, where it gives off its terminal branches, the external calcanean.

Relations.—This vessel rests at first upon the Tibialis posticus, and then, for the greater part of its course, in a fibrous canal between the origins of the Flexor longus hallucis and Tibialis posticus, covered or surrounded by the fibres of the Flexor longus hallucis. It is covered, in the upper part of its course, by the Soleus and deep transverse fascia; below, by the Flexor longus hallucis.

**Plan of the Relations of the Peroneal Artery.**

**In front.**

**Inner side.**

Peroneal Artery.
Flexor longus hallucis.

**Behind.**

Soleus.
Deep transverse fascia.
Flexor longus hallucis.

**Peculiarities in Origin.**—The peroneal artery may arise three inches below the Popliteus, or from the posterior tibial high up, or even from the popliteal.

Its size is more frequently increased than diminished; and then it either reinforces the posterior tibial by its junction with it, or altogether takes the place of the posterior tibial in the lower part of the leg and foot, the latter vessel only existing as a short muscular branch. In those rare cases where the peroneal artery is smaller than usual a branch from the posterior tibial supplies its place, and a branch from the anterior tibial compensates for the diminished anterior peroneal artery. In one case the peroneal artery has been found entirely wanting.

The anterior peroneal is sometimes enlarged, and takes the place of the dorsal artery of the foot.

**Branches.**—The branches of the peroneal are—the

Muscular.
Nutrient.
Anterior Peroneal.

**Communicating.**

Posterior Peroneal.
External Calcanean.

**Muscular Branches.**—The peroneal artery in its course gives off branches to the Soleus, Tibialis posticus, Flexor longus hallucis, and Peronei muscles.

The Nutrient Artery (a. nutritia fibulae) supplies the fibula.

The Anterior Peroneal (ramus perforans) (Fig. 436) pierces the interosseous membrane, about two inches above the outer malleolus, to reach the forepart of the leg, and, passing down beneath the Peroneus tertius to the outer ankle, ramifies on the front and outer side of the tarsus, anastomosing with the external malleolar and tarsal arteries.

The Communicating (ramus communicans) is given off from the peroneal about an inch from its lower end, and, passing inward, join the communicating branch of the posterior tibial.
The **Posterior Peroneal** passes down behind the outer ankle to the back of the external malleolus, to terminate in branches which ramify on the outer surface and back of the os calcis.

**External Calcanean** (*ramus calcaneus lateralis*) are the terminal branches of the peroneal artery; they pass to the outer side of the heel, and communicate with the external malleolar, and, on the back of the heel, with the internal calcanean arteries.

**Cutaneous Branches** come from the posterior tibial and supply the skin of the inner side and back of the leg.

The **Nutrient Artery** of the tibia (*a. nutricia tibiae*) arises from the posterior tibial near its origin, and, after supplying a few muscular branches, enters the nutrient canal of that bone, which it traverses obliquely from above downward. This is the largest nutrient artery of bone in the body.

The **Muscular Branches** of the posterior tibial are distributed to the Soleus and deep muscles along the back of the leg.

The **Communicating Branch** (*ramus communicans*), to join a similar branch of the peroneal, runs transversely across the back of the tibia, about two inches above its lower end, passing beneath the Flexor longus hallucis.

The **Malleolar** or **Internal Malleolar** (*a. malleolaris posterior medialis*) lies upon the tibia, sends branches over the inner ankle, and anastomoses with the inner malleolar branch of the anterior tibial.

The **Internal Calcanean** (*rami calcanei mediales*) are several large arteries which arise from the posterior tibial just before its division: they are distributed to the fat and integument behind the tendo Achillis and about the heel, and to the muscles on the inner side of the sole, anastomosing with the peroneal and internal malleolar, and, on the back of the heel, with the external calcanean arteries.

The **Internal Plantar Artery** (*a. plantaris medialis*) (Figs. 437 and 438), much smaller than the external, passes forward along the inner side of the foot. It is
at first situated above⁠¹ the Abductor hallucis, and then between it and the Flexor brevis digitorum, both of which it supplies. At the base of the first metatarsal bone, where it has become much diminished in size, it passes along the inner border of the great toe, inosculating with its digital branch. Small superficial digital branches (ramus superficialis) accompany the digital branches of the medial plantar nerve and join the plantar digital arteries of the three inner spaces. In addition, this vessel gives off numerous cutaneous branches.

The External Plantar Artery (a. plantaris lateralis) (Figs. 437 and 438), much larger than the internal, passes obliquely outward and forward to the base of the fifth metatarsal bone. It then turns obliquely inward to the interval between the bases of the first and second metatarsal bones, where it anastomoses with the communicating branch from the dorsalis pedis artery, thus completing the plantar arch (arcus plantaris) (Fig. 438). As this artery passes outward, it is first placed between the os calcis and Abductor hallucis, and then between the Flexor brevis digitorum and Flexor accessorius, and as it passes forward to the base of the little toe it lies more superficially between the Flexor brevis digitorum and Abductor minimi digitii, covered by the deep fascia and integument. The remaining portion of the vessel is deeply situated: it extends from the base of the metatarsal bone of the little toe to the back part of the first interosseous space, and forms the plantar arch; it is convex forward, lies upon the Interossei muscles opposite the tarsal ends of the metatarsal bones, and is covered by the Adductor obliquus hallucis, the flexor tendons of the toes, and the Lumbricales.

Surface Marking.—The course of the internal plantar artery is represented by a line drawn from the midpoint of the tip of the internal malleolus and the centre of the convexity of the heel to the middle of the under surface of the great toe; the external plantar by a line from the same point to within a finger's breadth of the tuberosity of the fifth metatarsal bone. The plantar arch is indicated by a line drawn from this point—i.e., a finger's breadth internal to the tuberosity of the fifth metatarsal bone transversely across the foot to the back of the first interosseous space.

Surgical Anatomy.—Wounds of the plantar arch are always serious, on account of the depth of the vessel and the important structures which must be interfered with in an attempt to ligate it. They must be treated on similar lines to those of wounds of the palmar arches (see page 667). Delorme has shown that the plantar arch may be ligated from the dorsum of the foot in almost any part of its course by removing a portion of one of the three middle metatarsal bones.

Branches.—The plantar arch, besides distributing numerous branches to the muscles, integument, and fasciae in the sole, gives off the following branches:

Posterior Perforating. Digital.

The Posterior Perforating (rami perforantes posteriores) are three small branches which ascend through the back part of the three outer interosseous spaces, between the heads of the Dorsal interossei muscles, and anastomoses with the interosseous branches from the metatarsal artery.

The Digital Branches (aa. metatarsae plantares) are four in number, and supply the three outer toes and half the second toe. It will be remembered that the arteria princeps hallucis is the plantar digital branch of the communicating arms in the first interosseous space and supplies the adjacent sides of the great and little toes. The first digital branch of the plantar arch passes outward from the outer side of the plantar arch, and is distributed to the outer side of the little toe, passing in its course beneath the Abductor and short Flexor muscles. The second, third, and fourth run forward along the interosseous spaces, and on arriving at the clefts between the toes divides into collateral digital branches (aa: digitales plantares), which supply the adjacent sides of the three outer toes and

¹ This refers to the erect position of the body. In the ordinary position for dissection the artery is deeper than the muscle.
the outer side of the second. At the bifurcation of the toes each digital artery sends upward, through the forepart of the corresponding interosseous space, a small branch which inosculates with the interosseous branches of the metatarsal artery. These are the **anterior perforating branches** (*rami perforantes anteriores*).

From the arrangement already described of the distribution of the vessels to the toes it will be seen that both sides of the three outer toes and the outer side of the second toe are supplied by branches from the plantar arch; both sides of the great toe and the inner side of the second are supplied by the communicating branch of the dorsalis pedis.
THE VEINS.

The Veins are the vessels which serve to return the blood from the capillaries of the different parts of the body to the heart. They consist of two distinct sets of vessels, the pulmonary and systemic veins, and an appendage to the systemic, the portal system.

The Pulmonary Veins are concerned in the circulation in the lungs. Unlike other vessels of this kind, they contain arterial blood, which they return from the lungs to the left auricle of the heart. The pulmonary veins are four in number.

The Systemic Veins are concerned in the general circulation; they return the venous blood from the body generally to the right auricle of the heart. The systemic veins are the precava or superior vena cava, the postcava or inferior vena cava, and the coronary sinus.

The Portal Vein and its radicles constitute the portal system. The portal system is in reality an appendage to the systemic venous system. It is confined to the abdominal cavity, returning the venous blood from the viscera of digestion, and carrying it to the liver by a single trunk of large size, the portal vein or vena portae. This vessel ramifies in the substance of the liver and breaks up into a minute
network of capillaries. These capillaries then re-collect to form the hepatic veins, by which the blood is conveyed to the postcava.

The veins, like the arteries, are found in nearly every tissue of the body. They commence by minute plexuses which receive the blood from the capillaries. The branches which have their commencement in these plexuses unite together into trunks, and these, in their passage toward the heart, constantly increase in size as they receive tributaries or join other veins. The veins are larger and altogether more numerous than the arteries; hence the entire capacity of the venous system is much greater than that of the arterial, the pulmonary veins excepted, which only slightly exceed in capacity the pulmonary arteries. From the combined area of the smaller venous branches being greater than the main trunks, it results that the venous system represents a cone, the summit of which corresponds to the heart, its base to the circumference of the body. In form the veins are perfectly cylindrical, like the arteries, their walls being collapsed when empty, and the uniformity of their surface being interrupted at intervals by slight constrictions, which indicate the existence of valves in their interior (Fig. 439). They usually retain, however, about the same calibre as long as they receive no branches, but not so uniformly as do the arteries.

The veins communicate very freely with one another (Fig. 441), especially in certain regions of the body, and this communication exists between the larger trunks as well as between the smaller branches. Thus, in the cavity of the cranium and between the veins of the neck, where obstruction would be attended with imminent danger to the cerebral-venous system, we find that the sinuses and larger veins have large and very frequent anastomoses (Fig. 440). The same free communication exists between the veins throughout the whole extent of the spinal canal, and between the veins composing the various venous plexuses in the abdomen and pelvis, as the spermatic, uterine, vesical, and prostatic.

Veins have thinner walls than arteries, the difference in thickness being due to the small amount of elastic and muscular tissues which the veins contain. The superficial veins usually have thicker coats than the deep veins, and the veins of the lower limb are thicker than those of the upper.

**Histology of the Veins.**—As previously stated, capillaries enter into venules or precapillary veins. The venules empty into larger veins. Vein walls are much thinner than arterial walls. A vein has a much thinner media and much less elastic tissue than an artery, and a very strongly developed adventitia. The intima is a connective-tissue layer containing a small number of elastic fibres and lined with endothelium. The media contains some circular muscle fibres and some fine elastic fibres. In some veins the media is thoroughly well developed (veins of the lower extremities), in others it is practically absent (veins of the retina, of the pia, of bone, the precava). The adventitia is dense and strong, and is composed of connective-tissue elastic fibres and non-striated muscle fibres placed longitudinally. Fig. 442 shows a transverse section of part of the wall of a vein. The vein valves (Fig. 439) are composed of intima and contain elastic fibres. The large veins and the veins of medium size possess vasa vaso-
THE PULMONARY VEINS

723
titia and to some extent in the media. The walls of veins contain vasomotor nerves. "Small blood-vessels are often surrounded by lymph capillaries and sometimes by endothelium-lined spaces which are in communication with the lymphatic system. These are called perivascular lymph spaces."1

The systemic veins are subdivided into three sets: superficial, deep, and sinuses. The Superficial or Cutaneous Veins are found between the layers of the superficial fascia, immediately beneath the integument; they return the blood from these structures, and communicate with the deep veins by perforating the deep fascia.

![Transverse section of part of the wall of one of the posterior tibial veins](image)

The Deep Veins accompany the arteries, and are usually enclosed in the same sheath with those vessels. With the smaller arteries—as the radial, ulnar, brachial, tibial, and peroneal—they exist generally in pairs, one lying on each side of the vessel, and are called venæ comites. The larger arteries—as the axillary, subclavian, popliteal, and femoral—have usually only one accompanying vein. In certain organs of the body, however, the deep veins do not accompany the arteries; for instance, the veins in the skull and spinal canal, the hepatic veins in the liver, and the larger veins returning blood from the osseous tissue.

Sinuses are venous channels which, in their structure and mode of distribution, differ altogether from the veins. They are found only in the interior of the skull, and consist of channels formed by a separation of the two layers of the dura, their outer coat consisting of fibrous tissue, their inner of an endothelial layer continuous with the lining membrane of the veins.

THE PULMONARY VEINS (V. PULMONALES) (Fig. 443).

The pulmonary veins return the arterial blood from the lungs to the left auricle of the heart. They are four in number, two for each lung. The pulmonary veins differ from other veins in several respects: 1. They carry arterial instead of venous blood. 2. They are destitute of valves. 3. They are only slightly larger than the arteries they accompany. 4. They accompany those vessels singly. They commence in a capillary network upon the walls of the air-cells, where they are continuous with the capillary ramifications of the pulmonary artery, and, uniting together, form one vessel for each lobe. These vessels, uniting successively, form a single trunk for each lobe, three for the right and two for the left lung. The vein from the middle lobe of the right lung generally unites with that from the upper lobe, forming two trunks on each side, which open separately into the left auricle. Occasionally they remain separate; there are then three

---

1 Histology and Microscopic Anatomy. By Szymonowicz and MacCallum.
veins on the right side. Not unfrequently the two left pulmonary veins terminate by a common opening.

Within the lung, the branches of the pulmonary artery are in front, the veins behind, and the bronchi between the two.

At the root of the lung, the veins are in front, the artery in the middle, and the bronchus behind.

Within the pericardium, their anterior surface is invested by the serous layer of this membrane. The right pulmonary veins pass behind the right auricle and ascending aorta and precava; the left pass in front of the thoracic aorta with the left pulmonary artery.

THE SYSTEMIC VEINS.

The systemic veins may be arranged into three groups: 1. Those of the head and neck, upper extremity, and thorax, which terminate in the precava. 2. Those of the lower extremity, abdomen, and pelvis, which terminate in the postcava. 3. The cardiac veins, which open directly into the right auricle of the heart.

VEINS OF THE HEAD AND NECK.

The veins of the head and neck may be subdivided into three groups: 1. The veins of the exterior of the head and face. 2. The veins of the neck. 3. The veins of the diploë and interior of the cranium.
Veins of the Exterior of the Head and Face (Fig. 444).

The veins of the exterior of the head and face are—the

Frontal.                     Temporal.
Supraorbital.                Internal Maxillary.
Angular.                     Temporo-maxillary.
Facial.                      Posterior Auricular.
Occipital.

The **Frontal Vein** (*v. frontalis*) commences on the anterior part of the skull by a venous plexus which communicates with the anterior tributaries of the temporal vein. The veins converge to form a single trunk, which runs downward near the middle line of the forehead parallel with the vein of the opposite side, and unites with it at the root of the nose by a transverse branch called the **nasal arch** (*v. naso-frontalis*). Occasionally the frontal veins join to form a single trunk, which
bifurcates at the root of the nose into the two angular veins. At the root of
the nose the veins diverge and join the supraorbital vein, at the inner angle of
the orbit, to form the angular vein.

The Supraorbital Vein (v. supraorbitalis) commences on the forehead, com-
municating with the anterior temporal vein, and runs downward and inward,
superficial to the Occipito-frontalis muscle, receiving tributaries from the neigh-
boring structures, and from the frontal vein of the diploë, and joins the frontal
vein at the inner angle of the orbit to form the angular vein.

The Angular Vein (v. angularis), formed by the junction of the frontal and
supraorbital veins, runs obliquely downward and outward on the side of the root
of the nose, and receives the veins of the ala nasi on its inner side and the superior
corneal veins on its outer side; it moreover communicates with the ophthalmic
vein, thus establishing an important anastomosis between this vessel and the
cavernous sinus. Some small veins from the dorsum of the nose terminate in the
nasal arch.

The Anterior Facial Vein (v. facialis anterior) commences at the side of the
root of the nose, being a direct continuation of the angular vein, which is itself
formed by the union of the frontal vein and the supraorbital vein. It lies behind
and follows a less tortuous course than the facial artery. It passes obliquely
downward and outward, beneath the Zygomaticus major and minor muscles,
descends along the anterior border of the Masseter, crosses over the body of the
lower jaw, with the facial artery to beneath the angle, and unites with the anterior
division of the temporo-maxillary vein (v. facialis posterior) to form the common
facial vein.

The Common Facial Vein (v. facialis communis) is formed by the union of the
anterior facial and the anterior division of the temporo-maxillary vein, just beneath
the angle of the mandible. The vein is covered by the Platysma myoid muscle,
runs downward and backward beneath the Sterno-cleido-mastoid muscle, crosses
the external carotid artery, and empties into the internal jugular vein at the level
of the hyoid line. It receives a large branch at the anterior border of the Sterno-
cleido-mastoid muscle, which comes from the anterior jugular vein in the supra-
sternal fossa.

Tributaries of the Anterior and Common Facial Veins.—The anterior facial vein
receives, near the angle of the mouth, communicating tributaries of considerable
size, the deep facial or anterior internal maxillary vein, from the pterygoid
plexus. It is also joined by the inferior palpebral, the superior and inferior
labial veins, the buccal veins from the cheek, and the masseteric veins. The
common facial vein receives the submental; the inferior palatine, which returns
the blood from the plexus round the tonsil and soft palate; the submaxillary
vein, which commences in the submaxillary gland; and, generally, the ranine
vein.

Surgical Anatomy.—There are some points about the facial vein which render it of great
importance in surgery. It is not so flaccid as are most superficial veins, and, in consequence of
this, remains more patent when divided. It has, moreover, no valves. It communicates freely
with the intra-cranial circulation, not only at its commencement by its tributaries, the angular
and supraorbital veins, communicating with the ophthalmic vein, a tributary of the cavernous
sinus, but also by its deep branch, which communicates through the pterygoid plexus with the
cavernous sinus by branches which pass through the foramen ovale and foramen lacerum
medium. These facts have an important bearing upon the surgery of some diseases of the
face, for on account of its patency the facial vein favors septic absorption, and therefore any
phlegmonous inflammation of the face following a poisoned wound is liable to set up thrombosis
in the facial vein, and detached portions of the clot may give rise to purulent foci in other
parts of the body. And on account of its communications with the cerebral sinuses these
thrombi are apt to extend upward into them and so induce a fatal issue.
The Superficial Temporal Vein (vv. temporales superficiales) commences by a minute plexus on the side and vertex of the skull, which communicates with the frontal and supraorbital veins in front, the corresponding vein of the opposite side, and the posterior auricular and occipital veins behind. From this network anterior and posterior branches are formed which unite above the zygoma, forming the trunk of the vein. The trunk is joined in this situation by a large vein, the middle temporal (v. temporalis media), which receives blood from the substance of the Temporal muscle and pierces the fascia at the upper border of the zygoma. The junction of the superficial temporal and the middle temporal veins forms the common temporal vein (v. temporalis communis), which descends between the external auditory meatus and the condyle of the jaw, enters the substance of the parotid gland, and unites with the internal maxillary vein to form the temporo-massillay vein.

Tributaries.—The common temporal vein receives in its course some parotid veins, an articular branch from the articulation of the jaw, anterior auricular veins from the external ear, and a vein of large size, the transverse facial (v. transversa faciei), from the side of the face. The middle temporal vein, previous to its junction with the temporal vein, receives a branch, the orbital vein (v. orbitalis), which is formed by some external palpebral branches, and passes backward between the layers of the temporal fascia.

The Pterygoid Plexus (plexus pterygoideus) and the Internal Maxillary Vein.—The internal maxillary vein is a vessel of considerable size, receiving branches which correspond with those of the internal maxillary artery. Thus it receives the two mediulral or middle meningeal veins, the deep temporal, the pterygoid, masseteric, buccal, and alveolar veins, some palatine veins, the sphenopalatine and the inferior dental veins. The deep temporal veins (vv. temporales profundae) come to the pterygoid plexus from the temporal muscle. These branches form a large plexus, the pterygoid plexus, which is placed between the Temporal and External pterygoid and partly between the Pterygoid muscles. This plexus is a tributary of the internal maxillary vein, and communicates very freely with the facial vein and with the cavernous sinus by branches through the foramen Vesali, foramen ovale, and foramen lacerum medium, at the base of the skull. The trunk of the internal maxillary vein comes from the plexus, then passes backward behind the neck of the lower jaw, and unites with the temporal vein, forming the temporo-massillay vein.

The Temporo-massillay Vein (v. facialis posterior), formed by the union of the superficial temporal and internal maxillary veins, descends in the substance of the parotid gland on the outer surface of the external carotid artery, between the ramus of the jaw and the Sterno-mastoid muscle, and divides into two branches, an anterior, which passes inward to join the facial vein, and a posterior, which is joined by the posterior auricular vein and becomes the external jugular.

The Posterior Auricular Vein (v. auricularis posterior) commences upon the side of the head by a plexus which communicates with the tributaries of the temporal and occipital veins. The vein descends behind the external ear and joins the posterior division of the temporo-massillay vein, forming the external jugular. This vessel receives the stylo-mastoid vein and some tributaries from the back part of the external ear.

The Occipital Vein (v. occipitalis) commences at the back part of the vertex of the skull by a plexus in a similar manner to the other veins. From the plexus comes one or two veins, which follow the course of the occipital artery, passing deeply beneath the muscles of the back part of the neck, and terminating in the suboccipital triangle by becoming continuous with the posterior vertebral vein. Sometimes they are more superficial, and in this case they are tributaries of the
external jugular vein. As the outermost occipital vein passes across the mastoid portion of the temporal bone, it receives the mastoid vein, which thus establishes a communication with the lateral sinus.

**The Veins of the Neck (Fig. 444).**

The veins of the neck, which return the blood from the head and face, are—the

- **External Jugular.**
- **Posterior External Jugular.**
- **Vertebral.**
- **Anterior Jugular.**
- **Internal Jugular.**

The **External Jugular Vein** (*v. jugularis externa*) receives the greater part of the blood from the exterior of the cranium and deep parts of the face, being formed by the junction of the posterior division of the temporo-maxillary and the posterior auricular veins. It commences in the substance of the parotid gland, on a level with the angle of the lower jaw, and runs perpendicularly down the neck in the direction of a line drawn from the angle of the jaw to the middle of the clavicle. In its course it crosses the Sterno-mastoid muscle, and runs parallel with its posterior border as far as its attachment to the clavicle, where it perforates the deep fascia, and terminates in the subclavian vein, on the outer side of, or in front of, the Scalemus anticus muscle. In the neck it is separated from the Sterno-mastoid by the investing layer of the deep cervical fascia, and is covered by the Platysma, the superficial fascia, and the integument. This vein is crossed about its middle by the superficialis colli nerve, and throughout the upper half of its course is accompanied by the auricularis magnus nerve. The external jugular vein varies in size, bearing an inverse proportion to that of the other veins of the neck; it is occasionally double. It is provided with two pairs of valves, the lower pair being placed at its entrance into the subclavian vein, the upper pair in most cases about an inch and a half above the clavicle. The portion of vein between the two sets of valves is often dilated, and is termed the **sinus**. These valves do not prevent the regurgitation of the blood or the passage of injection from below upward.¹

**Tributaries.**—This vein receives the occipital occasionally, the posterior external jugular, and, near its termination, the suprascapular and transverse cervical veins. It communicates with the anterior jugular, and, in the substance of the parotid, receives a large branch of communication from the internal jugular.

The **Posterior External Jugular Vein** (*v. jugularis posterior*) commences in the occipital region, and returns the blood from the integument and superficial muscles in the upper and back part of the neck, lying between the Splenius and Trapezius muscles. It runs down the back part of the neck, and opens into the external jugular just below the middle of its course.

The **Anterior Jugular Vein** (*v. jugularis anterior*) commences near the hyoid bone from the convergence of the inferior coronary, the submental and the mental veins, and communicating branches. It passes down between the median line and the anterior border of the Sterno-mastoid, and at the lower part of the neck passes beneath that muscle to open into the termination of the external jugular or into the subclavian vein (Fig. 465). This vein varies considerably in size, bearing almost always an inverse proportion to the external jugular. Most frequently there are two anterior jugulars, a right and left, but occasionally only one. This vein receives some laryngeal veins, and occasionally a small thyroid vein. Just above the sternum the two anterior jugular veins communicate by a

---

¹ The student may refer to an interesting paper by Dr. Struthers, "On Jugular Venesection in Asphyxia, Anatomically and Experimentally Considered, including the Demonstration of Valves in the Veins of the Neck," in the Edinburgh Medical Journal for November, 1856.—Ed. of 15th English edition.
transverse trunk, which receives tributaries from the inferior thyroid veins. It also communicates with the internal jugular. There are no valves in this vein.

The **Internal Jugular Vein** (*v. jugularis interna*) collects the blood from the interior of the cranium, from the superficial parts of the face, and from the neck. It *commences* just external to the jugular foramen, at the base of the skull, being formed by the coalescence of the lateral and inferior petrosal sinuses (Fig. 458). At its origin it is somewhat dilated, and this dilatation is called the *sinus* or *gulf of the internal jugular vein* (*bulbus v. jugularis superior*). It runs down the side of the neck in a vertical direction, lying at first on the outer side of the internal carotid artery, and then on the outer side of the common carotid artery, and at the root of the neck unites with the subclavian vein to form the innominate vein. Just before its termination it is distinctly dilated (*bulbus v. jugularis inferior*). The internal jugular vein, at its *commencement*, lies upon the Rectus capitis lateralis, and behind the internal carotid artery and the nerves passing through the jugular foramen; lower down, the vein and artery lie upon the same plane, the glossopharyngeal and hypoglossal nerves passing forward between them; the vagus descends between and behind them in the same sheath, and the accessory passes obliquely outward, behind or in front of the vein. At the root of the neck the vein of the right side is placed at a little distance from the artery; on the left side it usually lies over the artery at its lower part. The right internal jugular vein crosses the first part of the subclavian artery. The internal jugular vein is of considerable size, but varies in different individuals, the left one being usually the smaller. It is provided with a pair of valves, which are placed at its point of termination or from one-half to three-quarters of an inch above it.

**Tributaries.**—This vein receives in its course the facial, lingual, pharyngeal, superior, and middle thyroid veins. A branch from the cochlea opens into the sinus of the internal jugular vein. A venous plexus from the lateral sinus (*plexus venosus caroticus internus*) surrounds the internal carotid artery in the carotid canal and empties into the internal jugular vein. At its point of junction with the common facial vein it becomes increased in size. (See Facial Veins, p. 726.)

The **Lingual Veins** (*vv. linguale*) (Fig. 445) *commence* on the dorsum, sides, and under surface of the tongue, and, passing backward, following the course of the lingual artery and its branches, terminate in the internal jugular. Sometimes the **ranine vein**, which is a branch of considerable size commencing below the tip of the

---

**Fig. 445.**—Veins of the tongue. (Testut, modified from Hirschfeld.)
tongue, joins the lingual. Generally, however, it passes backward, crosses the Hyo-glossus muscle in company with the hypoglossal nerve, and joins the internal jugular. The lingual vein receives the sublingual vein and the dorsalis lingue veins.

The Pharyngeal Veins (vv. pharyngeae) vary in number. They commence in a minute plexus, the pharyngeal plexus (plexus pharyngeus), at the back part and sides of the pharynx, and, after receiving meningeal tributaries, the dural or meningeal veins (vv. meningeae), the Vidian veins (vv. canalis pterygoidei [Vidiī]), and the sphenopalatine veins, terminate in the internal jugular. They occasionally open into the facial, lingual, or superior thyroid vein.

The Superior Thyroid Vein (v. thyreoida superioris) (Fig. 446) commences in the substance and on the surface of the thyroid gland by tributaries corresponding with the branches of the superior thyroid artery, and terminates in the upper part of the internal jugular vein. It receives the superior laryngeal and cricothyroid veins. Some anatomists teach that there are two superior thyroid veins on each side, the upper vein being the one just considered, the lower vein being the one usually pointed out as the middle thyroid.

The Middle Thyroid Vein (Fig. 448) collects the blood from the lower part of the lateral lobe of the thyroid gland, and, being joined by some veins from the larynx and trachea, terminates in the lower part of the internal jugular vein. Often in
place of the middle thyroid vein there are two veins, the superior and inferior accessory thyroid. These veins pass into the internal jugular.

Veins of the Thyroid Gland\(^1\) (Fig. 447).—On the surface of the thyroid glands the veins form a plexus between the capsule and the gland. A number of veins

---

\(^1\) See Kocher's description in Langenbeck's Arch. f. klin. Chir., vol. xxix., and James Berry's description in his treatise on Diseases of the Thyroid Gland.
penetrate the capsule and pass into adjacent trunks. The most important veins coming from the gland are the superior, middle, and inferior thyroids (or instead of the middle thyroid the superior and inferior accessory thyroid) and the thyreoidea ima.

The superior thyroid vein emerges from the summit of the superior horn of the gland, runs along by the superior thyroid artery, and terminates in the internal jugular vein. A large branch which passes along the inner margin of the upper horn and across the upper surface of the isthmus joins the superior thyroid veins of each side. The middle thyroid vein when present emerges from the side of the gland and empties into the internal jugular. This single vein may be replaced by two veins, the superior and inferior accessory thyroid veins. The superior vein emerges from the outer surface of the upper horn somewhat below the apex. The inferior vein comes from the posterior and inferior portion of the gland. Both empty into the internal jugular. The lower surface of the isthmus and the inner side of each inferior horn is drained by two veins. Each vein is called the thyreoidea ima (Kocher). The left vein empties into the left innominate vein. The right vein empties into either the right or left innominate vein. These veins may be very small, may be absent, or may join and form one vein which empties into the left innominate. An inferior thyroid is often also present. It comes from the outer portion of the inferior horn of the gland and empties into the innominate vein.

The facial and occipital veins have been described on pages 726 and 727.

Surgical Anatomy.—The internal jugular vein occasionally requires ligature in cases of septic thrombosis of the lateral sinus from suppuration in the middle ear. This is done in order to prevent septic emboli being carried into the general circulation. This operation has been performed in a number of cases, with satisfactory results. The cases are generally those of chronic disease of the middle ear, with discharge of pus which perhaps has existed for many years. The patient is seized with acute septic inflammation, spreading to the mastoid cells, and, consequent on this, septic thrombosis of the lateral sinus extending to the internal jugular vein. Such cases are always extremely grave, for there is danger that a portion of the septic clot will be detached and cause septic embolism in the thoracic visceræ. If thrombo-phlebitis of the sinus is suspected the mastoid should be opened and cleansed and the sinus should be at once exposed and explored. If the sinus is found to be thrombosed the surgeon should at once proceed to ligate the internal jugular vein, by an incision along the anterior border of the sternomastoid, the centre of which is on a level with the greater cornu of the hyoid bone. The vein should be ligated in two places and divided between. After the vessel has been secured and divided the lateral sinus is to be thoroughly cleared out, and, by removing the ligature from the upper end of the divided vein, all septic clots may be removed by syringing from the sinus through the vein. If hemorrhage occurs from the distal end of the sinus, it can be arrested by careful plugging with antiseptic gauze.

The thyroid veins are small vessels when the gland is of normal size, but become enormous when the gland is much enlarged.

In the operation of thyroidectomy the veins as well as the arteries are ligated before the gland, or rather before one lobe of it is extirpated.

The Vertebral Vein (v. vertebrai) (Fig. 449) commences by numerous small veins from the intraspinal venous plexuses (plexus venosi vertebrales); these pass outward and enter the foramen in the transverse process of the atlas, and descend, forming a dense plexus around the vertebral artery in the canal formed by the foramina in the transverse processes of the cervical vertebrae. The vessels of this plexus unite at the lower part of the neck into two main trunks, one of which emerges from the foramen in the transverse process of the sixth cervical vertebra, and the other through that of the seventh. Uniting, these two trunks form a single vessel which terminates at the root of the neck in the back part of the innominate vein near its origin, its mouth being guarded by a pair of valves. On the right side it crosses the first part of the subclavian artery.

Tributaries.—The vertebral vein receives in its course a vein from the inside of the skull through the posterior condylloid foramen. It anastomoses with the
THE VEINS OF THE DIPLOÈ

...occipital vein and receives muscular veins from the muscles in the prevertebral region; dorsi-spinal veins, from the back part of the cervical portion of the spine; meningo-rachidian veins, from the interior of the spinal canal; the anterior and posterior vertebral veins; and close to its termination it is joined by a small vein from the first intercostal space which accompanies the superior intercostal artery.

The Anterior Vertebral or Anterior Deep Cervical Vein commences in a plexus around the transverse processes of the upper cervical vertebrae, descends in company with the ascending cervical artery between the Scalenus anticus and Rectus capitis anticus major muscles, and opens into the vertebral vein just before its termination.

The Posterior Vertebral or Posterior Deep Cervical Vein (v. cervicalis profunda) (Fig. 449) accompanies the profunda cervicis artery, lying between the Complexus and Semispinalis colli. It commences in the suboccipital region by communicating branches from the occipital vein and tributaries from the deep muscles at the back of the neck. It receives tributaries from the plexuses around the spinous processes of the cervical vertebrae, and terminates in the lower end of the vertebral vein.

The Veins of the Diploë (Venae Diploicae) (Fig. 450).

The diploë of the cranial bones is channelled in the adult by a number of tortuous canals, the diploic canals or canals of Breschet (canales diploici [Brescheti]), which are lined by a more or less complete layer of compact tissue. The veins they contain are large and capacious, their walls being thin, and formed only of endothelium resting upon a layer of elastic tissue, and they present at irregular intervals pouch-like dilatations, or culs-de-sac, which serve as reservoirs for the blood. These are the veins of the diploë; they can only be displayed by removing the outer table of the skull.

In adult life, as long as the cranial bones are distinct and separable, these veins are confined to the particular bones; but in old age, when the sutures are...
united, they communicate with each other and increase in size. These vessels communicate, in the interior of the cranium, with the dural veins and with the sinuses of the dura, and on the exterior of the skull with the veins of the pericranium. They are divided into the frontal diploic vein (v. diploica frontalis), which opens into the supraorbital vein by an aperture in the supraorbital notch and into the superior longitudinal sinus; the anterior temporal diploic vein (v. diploica temporalis anterior), which is confined chiefly to the frontal bone, communicates with the sphenoparietal sinus and, after escaping by an aperture in the great wing of the sphenoid, opens into one of the deep temporal veins; the posterior temporal, or external parietal diploic vein (v. diploica temporalis posterior), is between the emissarium parietale and the emissarium mastoideum; and the occipital diploic vein (v. diploica occipitalis), the largest of the four, which is confined to the occipital bone, and opens into the emissarium occipitale.

Fig. 450.—Veins of the diploë as displayed by the removal of the outer table of the skull.

The Emissary Veins are considered on page 743.

The Dural or Meningeal Veins (vv. meningeae).—They are numerous in the dura, are without valves, anastomose freely with each other, do not increase in size as they reach the sinus which receives them, and bear no regular relation to the dural arteries. The medidural artery has two vena comites. The other dural arteries usually have two apiece, but may have but one. The medidural or middle meningeal veins (vv. mediduralis, vv. meningeae mediae) accompany the medidural artery, are united to the sphenoparietal sinus, pass through the foramen spinosum, and join the pterygoid plexus. The other dural veins empty into the longitudinal sinus and communicate with the plexus of the foramen ovale.

The Cerebral Veins (Venae Cerebri).

The cerebral veins are remarkable for the absence of valves and for the extreme thinness of their coats. The coats are thin because they contain no muscular tissue. The cerebral veins may be divided into two sets: the superficial veins, which are placed on the surface, and the deep veins, which occupy the interior of the organ. The veins of the brain do not accompany associated arteries.
The **Superficial** or **Cortical Cerebral Veins** (*venae cerebri externae*) ramify upon the surface of the brain, being lodged in the fissures between the convolutions, a few running across the convolutions. They receive branches from the substance of the brain and terminate in the sinuses. They are named, from the position they occupy, **super cerebra**l or **superior, medici** cerebral or **median**, and **sub cerebra**l or **in**ferior cerebra**l** veins.

The **Super cerebra**l or **Superior Cerebral Veins** (*vv. super cerebrales, vv. cerebri superiores*), eight to twelve in number on each side, return the blood from the convolutions on the superior surface of the hemisphere; they pass forward and inward toward the intercerebral fissure, where they receive the medicerebral veins; near their termination they become invested with a tubular sheath of the arachnoid, and open into the longitudinal sinus in the opposite direction to the course of the current of the blood.

The **Medi cerebra**l or **Median Cerebral Veins** (*v. medici cerebrales, v. cerebri media*) return the blood from the convolutions of the mesial surface of the corresponding hemisphere; they open into the supercerebral veins, or occasionally into the falcial sinus.

The **Sub cerebra**l or **Inferior Cerebral Veins** (*vv. sub cerebrales, vv. cerebri inferiores*) ramify on the lower part of the outer surface and on the under surface of the cerebral hemisphere. Some, collecting tributaries from the under surface of the frontal lobes of the brain, terminate in the cavernous sinus. One vein of large size, the **medi cerebra**l or **superficial sylvian vein**, commences on the under surface of the temporal lobe, and, running along a portion of the sylvian fissure, opens into the cavernous sinus. The **great anastomotic vein of Trolard or the superficial communicating vein** establishes a union between the sinuses of the vertex and those of the base of the brain. It comes from one of the supercerebral veins, passes downward into the sylvian fissure, and, by means of the medicerebral vein, effects a communication with the cavernous sinus. The **posterior anastomotic vein** connects the medicerebral vein with the lateral sinus. Other veins commence on the under surface of the base of the brain, and unite to form from three to five veins, which open into the superpetrosal and lateral sinuses from before backward.

The **Velar, Deep Cerebral, Central, or Ventricular Veins, Veins of Galen** (*vv. velares, venae Galeni, vv. cerebri internae*) (Fig. 647), are two in number. Each is formed by the union of two veins, the **vena corporis striati**, and the **choroid vein**, on either side. The velar veins run backward, parallel with one another, between the layers of the velum, and in the region of the epiphysis unite to form one vein, the **vena magna Galeni** (*v. cerebri magna*), which passes out of the brain at the great transverse fissure, between the posterior extremity, or splenium, of the callosum and the quadrigemina, to enter the tentorial sinus. The two velar veins receive tributaries from the callosal region, from a portion of the occipital lobe, and just before their union each vein receives the basilar vein. The vena magna Galeni receives the **vermian vein** from the superficial cerebellar veins.

The **Vena Corporis Striati** on each side **commences** in the groove between the corpus striatum and optic thalamus, receives numerous veins from both of these parts, and unites behind the fornix column with the choroid vein to form one of the velar veins.

The **Choroid Vein** (*v. choroidae*) originates in the extreme end of the mediusern of the lateral ventricle and runs along the whole length of the outer border of the parapleura, receiving veins from the hippocampus, the fornix, and callosum, and unites, at the anterior extremity of the parapleura, with the vein of the corpus striatum to form the velar vein of that side.

The **Basilar Vein** (*v. basalis*) **commences** at the preperforatum at the base of the brain by the union of a small precerebral vein, which courses backward between the frontal lobes of the cerebrum, with the deep sylvian vein, which
descends through the lower part of the sylvian fissure and receives veins from the insula. It passes backward over the crus, receiving the inferior striate vein from the corpus striatum, intercural veins from the interceral space, ventricular veins from the medullary of the lateral ventricles, and tributaries from the uncinate gyre, and enters the vein of Galen just before its junction with the vein of the opposite side.

The Superficial Cerebellar Veins (Fig. 645) occupy the surface of the cerebellum, and are disposed in two sets, supercerebellar or superior, and subcerebellar or inferior.

The Superficial or Superior Superficial Cerebellar Veins (vv. supercerebellares, vv. cerebelli superiores) pass partly forward and inward, across the superior vermis (prevermis), to terminate in lateral branches which pass partly to the tentorial sinus and partly outward to the lateral and superpetrosal sinuses.

The Subcerebellar or Inferior Superficial Cerebellar Veins (vv. subcerebellares, vv. cerebelli inferiores), of large size, terminate in the lateral, subpetrosal, and occipital sinuses.

The Deep Cerebellar Veins bring blood from the interior of the cerebellum to the superficial veins.

Veins of the Pons.—Veins come from the depth of the pons, the deep veins, and empty into a plexus of superficial veins. From this superficial venous plexus a superior vein passes to the basilar vein, and an inferior vein either into a cerebellar vein or into the superpetrosal sinus.

Veins of the Oblongata.—Veins pass from the depth of the oblongata and end in a plexus on the surface. From this plexus comes a ventro-median vein, which is a prolongation of a like vein of the spinal cord—a dorso-median vein corresponding to a like vein of the cord—and small branches which pass with the roots of the glosso-pharyngeal, vagus, accessory, and hypoglossal nerves, and empty into the occipital and the subpetrosal sinuses.

The perivascular lymph-spaces are especially found in connection with the vessels of the brain. These vessels are enclosed in a sheath, which acts as a lymphatic channel, through which the lymph is carried to the subarachnoid and subdural spaces, from which it is returned into the general circulation.

The Sinuses of the Dura (Sinus Durae Matris) (Figs. 451, 452, 453, 456, 457)

Ophthalmic Veins and Emissary Veins.

The sinuses of the dura are venous channels formed by a separation of the two layers of this membrane, the outer coat consisting of fibrous tissue, the inner coat of an endothelial layer continuous with the lining membrane of the veins. The thick walls of a sinus resist intracranial pressure. They are divided into two sets: (1) those situated at the upper and back part of the skull; (2) those at the base of the skull. The former are—the

Longitudinal or Superior Longitudinal Sinus. Tentorial or Straight Sinus.

Falcial or Inferior Longitudinal Sinus. Lateral Sinuses.

Occipital Sinus.

The Longitudinal or Superior Longitudinal Sinus (sinus longitudinalis, sinus sagittalis superior) (Figs. 451, 452, and 453) occupies the attached margin of the falx. Commencing at the foramen cæcum, through which, in the child, it constantly communicates by a small branch with the veins of the nasal fossa, it runs from before backward, grooving the inner surface of the frontal, the adjacent margins of the two parietal, and the superior division of the crucial ridge of the occipital bone, and terminates by opening into the torcular. The sinus is triangular on transverse section, is narrow in front, and gradually increases in size as it passes backward. On examining its inner surface it presents the internal openings of the supercerebral veins, which run, for the most part, from behind forward, and open

1 A. W. Hughes.
chiefly at the back part of the sinus, their orifices being concealed by fibrous folds; numerous fibrous bands, chordae Willisii (Fig. 453), are also seen extending transversely across the inferior angle of the sinus; and some small, white, projecting bodies, the glandulae Pacchioni (granulationes arachnoidales). This sinus communicates by numerous small apertures with spaces in the dura

known as lacunae laterales or parasinoidal spaces (Fig. 453). The arachnoid villi project into these spaces. This sinus receives the supercerebral veins, numerous veins from the diploë and dura, the outlets of the parasinoidal spaces, and, at the posterior extremity of the sagittal suture, veins from the pericranium, which pass through the parietal foramina. In children the longitudinal sinus receives a twig from the nose which passes through the foramen cæcum.

The Torcular or the Confluence of the Sinuses (Figs. 452 and 456) is the dilated extremity of the longitudinal sinus. It is of irregular form, and is lodged on one
side (generally the right) of the internal occipital protuberance. From it the lateral sinus of the side to which it is deflected is derived. It receives also the blood from the occipital sinus.

The Falcial or Inferior Longitudinal Sinus (sinus falcialis, sinus sagittalis inferior) (Fig. 452), more correctly described as the inferior longitudinal vein, is contained in the posterior part of the free margin of the falx. It is of a cylindrical form, increases in size as it passes backward, and terminates in the tentorial sinus. It receives several veins from the falx, and occasionally a few from the mesal surface of the hemispheres.

The Tentorial or Straight Sinus (sinus tentorii, sinus rectus) (Figs. 451 and 452) is situated at the line of junction of the falx with the tentorium. It is triangular in form, increases in size as it proceeds backward, and runs obliquely downward and backward from the termination of the falcial sinus to the lateral sinus of the opposite side to that into which the longitudinal sinus is prolonged. It communicates by a cross-branch with the torcular. Besides the falcial sinus, it receives the vena magna Galeni and the supereerebellar veins. A few transverse bands cross its interior. This sinus is usually considered to be formed by the union of the great vein of Galen and the falcial sinus.

The Lateral Sinus (sinus lateralis, sinus transversus) (Figs. 451, 452, 456, and 457) is of large size. There are two lateral sinuses situated in the attached margin of the tentorium throughout most of its extent. They commence at the internal occipital protuberance, one, generally the right, being the direct continuation of the
longitudinal sinus, the other of the tentorial sinus. Each passes outward and forward, describing a slight curve with its convexity upward, to the base of the petrous portion of the temporal bone, then, leaving the tentorium, curves downward and inward to reach the jugular foramen, where it terminates in the internal jugular vein. It rests, in its course, upon the inner surface of the occipital, the posterior inferior angle of the parietal, and the mastoid portion of the temporal bone, and on the occipital again, at the jugular process, just before its termination. The portion of the sinus resting on the mastoid process of the temporal and the jugular process of the occipital bone is not covered by the tentorium and is often called the sigmoid sinus because of its shape, which resembles the letter S. These sinuses are frequently of unequal size, that formed by the longitudinal sinus being the larger, and they increase in size as they proceed from behind forward. The horizontal portion is of a triangular form, the curved portion semicylindrical. Their inner surface is smooth, and not crossed by the fibrous bands found in the other sinuses. The lateral sinuses receive the blood from the superpetrosal sinuses at the base of the petrous portion of the temporal bone, and they unite with the subpetrosal sinus, just external to the jugular foramen, to form the internal jugular vein (Fig. 457). They communicate with the veins of the pericranium by means of the mastoid and posterior condyloid veins, and they receive some of the subcerebral and subcerebellar veins, some veins from the diploë, and often veins from the internal ear (\textit{v. auditivae internae}), which come out of the internal auditory meatus. The petro-squamous sinus, when present, runs backward along the junction of the petrous and squamous portions of the temporal bone, and opens into the lateral sinus.

**Surgical Anatomy.**—The lateral sinus may, as a result of middle-ear disease, be attacked by supplicative inflammation, which leads to blocking (\textit{septic thrombo-phlebitis}). In such a case the surgeon will be obliged to open the sinus to remove infected clot and tie the internal jugular vein to intercept thrombi. The line overlying the sinus is as follows: Draw a line horizontally outward from the occipital protuberance to a point one inch posterior to a vertical line drawn through the external auditory meatus and from this point drop a second line to the mastoid process.

The \textbf{Occipital Sinus} (\textit{sinus occipitalis}) (Fig. 452) is the smallest of the cranial sinuses. There is often but a single occipital sinus, but occasionally there are two. It is situated in the attached margin of the falx. It commences by several small veins around the margin of the foramen magnum, one of which joins the termination of the lateral sinus; it communicates with the posterior spinal veins and terminates in the torcular.

The sinuses at the base of the skull are—the

</table>

The \textbf{Cavernous Sinus} (\textit{sinus cavernosus}) (Figs. 456 and 457) is named from presenting a reticulated structure, due to being traversed by numerous interlacing filaments (Fig. 454). There are two cavernous sinuses, of irregular form, larger behind than in front, and placed one on each side of the sella turcica, extending from the sphenoidal fissure to the apex of the petrous portion of the temporal bone. Each receives anteriorly the ophthalmic vein through the sphenoidal fissure, and opens behind into the petrosal sinuses. On the inner wall of each sinus is found the internal carotid artery, accompanied by filaments of the carotid plexus and by the abducent nerve; and on its outer wall, the oculomotor, trochlear, and ophthalmic division of the trigeminal nerve (Fig. 454). These parts are separated
from the blood flowing along the sinus by the lining membrane, which is continuous with the inner coat of the veins. The cavernous sinuses receive some of the cerebral veins, and also the sphenoparietal sinuses. They communicate with the lateral sinuses by means of the super- and subpetrosal sinuses, and with the facial veins through the ophthalmic veins. They also communicate with each other by means of the circular sinus.

**Surgical Anatomy.**—An arterio-venous communication may be established between the cavernous sinus and the carotid artery, as it lies in it, giving rise to a pulsating tumor in the orbit. Such a communication may be the result of injury, such as a bullet wound, a stab, or a blow or fall sufficiently severe to cause a fracture of the base of the skull in this situation, or it may occur from the rupture of an aneurism or a diseased condition of the internal carotid artery. The disease begins with sudden noise and pain in the head, followed by exophthalmos, swelling and congestion of the lids and conjunctive. A pulsating tumor develops at the margin of the orbit, with thrill and the characteristic bruit; accompanying these symptoms there may be impairment of sight, paralysis of the iris and orbital muscles, and pain of varying intensity. In some cases the opposite orbit becomes affected by the passage of the arterial blood into the opposite sinus by means of the circular sinus. Or the arterial blood may find its way through the emissary veins into the pterygoid plexus, and thence into the veins of the face. Pulsating tumors of the orbit may also be due to traumatic aneurism of one of the orbital arteries, and symptoms resembling those of pulsating tumor may be produced by pressure on the ophthalmic vein, as it enters the sinus, by an aneurism of the internal carotid artery.

The Sphenoparietal Sinus or Sinus Alae Parvae (sinus sphenoparietalis).—Each of these sinuses is lodged in the dura on the under surface of the lesser wing of the sphenoid bone. It takes origin from one of the medullar veins, usually receives blood from the diploë of the skull, passes inward, and ends in the anterior part of the cavernous sinus.

The Ophthalmic Veins are two in number, superior and inferior.

The superior ophthalmic vein (v. ophthalmica superior) (Fig. 455) begins as the naso-frontal vein (v. nasofrontalis), at the inner angle of the orbit, which communicates with the angular vein. It joins the angular vein with the cavernous sinus; it pursues the same course as the ophthalmic artery, and receives tributaries corresponding to the branches derived from that vessel. Forming a short single trunk, it passes through the inner extremity of the sphenoidal fissure, and terminates in the cavernous sinus. It anastomoses with the inferior ophthalmic vein and receives lachrymal, anterior, and posterior ethmoidal and muscular branches, and veins of the eyelids and of the bulbus oculi.
The inferior ophthamlic vein (*v. ophthalmica inferior*) (Fig. 455) arises in the veins of the eyelids and lachrymal sac, receives the veins from the floor of the orbit, and from the portion of the nasal fossa supplied by the anterior and posterior ethmoidal arteries. It either passes out of the orbit through the spheno-maxillary fissure to join the pterygoid plexus of veins, or else, passing backward through the sphenoidal fissure, it enters the cavernous sinus, either by a separate opening, or, more frequently, in common with the superior ophthalmic vein. It receives muscular
The blood-vascular system

tributaries and veins of the bulbus oculi, and anastomoses with the superior ophthalmic vein.

The **Circular Sinus** (*sinus circularis*) (Figs. 454 and 456) is formed by two transverse vessels, the **anterior** and **posterior intercavernous sinuses** (*sinus intercavernous anterior* and *sinus intercavernous posterior*), which connect together the two cavernous sinuses; the one passing in front and the other behind the hypophysis, and thus forming with the cavernous sinuses a venous circle around that body. The anterior one is usually the larger of the two, and one or other is occasionally found to be absent.

The **Superpetrosal** or **Superior Petrosal Sinus** (*sinus superpetrosus, sinus petrosus superior*) (Figs. 452 and 456) is situated along the superior border of the petrous portion of the temporal bone, in the front part of the attached margin of the tentorium. It is small and narrow, and connects together the cavernous and lateral sinuses at each side. It receives some cerebellar and subcerebral veins, and usually veins from the tympanic cavity.

The **Subpetrosal** or **Inferior Petrosal Sinus** (*sinus subpetrosus, sinus petrosus inferior*) (Figs. 452 and 456) is situated in the groove formed by the junction of the posterior border of the petrous portion of the temporal with the basilar process of the occipital bone. It *commences* in front at the termination of the cavernous sinus, and behind joins the lateral sinus after it has passed through the jugular foramen; the junction of these two sinuses forming the commencement of the internal jugular vein. The subpetrosal sinus receives a vein from the internal ear and also veins from the medulla, pons, and under surface of the cerebellum.

The junction of the two sinuses takes place at the lower border of, or just external to, the jugular foramen. The exact relation of the parts to one another in the
foramen is as follows: The subpetrosal sinus is in front, with the dural branch of the ascending pharyngeal artery, and is directed obliquely downward and backward; the lateral sinus is situated at the back part of the foramen with a dural branch of the occipital artery, and between the two are the glossopharyngeal, vagus, and accessory nerves (Fig. 457). These three sets of structures are divided from each other by two processes of fibrous tissue. The junction of the sinuses takes place superficial to the nerves, so that these latter lie a little internal to the venous channels in the foramen (Fig. 457). These sinuses are semicylindrical in form.

The Transverse or Basilar Sinus (plexus basilaris) (Figs. 456 and 457) consists of several interlacing veins between the layers of the dura over the basilar process of the occipital bone, which serve to connect the two subpetrosal sinuses. With them the anterior spinal veins communicate.

Emissary Veins (emissaria).—The emissary veins are vessels which pass through apertures in the cranial wall and establish communications between the sinuses inside the skull and the diploic veins in the diploë, and the veins external to the skull. Some of these are always present, others only occasionally so. They vary much in size in different individuals. The principal emissary veins are the following: 1. A vein, almost always present, which passes through the mastoid foramen (emissarium mastoideum) and connects the lateral sinus with the posterior auricular or with an occipital vein. 2. A constant vein which passes through the parietal foramen (emissarium parietale) and connects the longitudinal sinus with the veins of the scalp. 3. A plexus of minute veins which pass through the anterior condyloid foramen (emissarium condyloideum) and connect the occipital sinus with the vertebral vein and deep veins of the neck. 4. An inconstant vein which passes through the posterior condyloid foramen and connects the lateral sinus with the deep veins of the neck. 5. One or two veins of considerable size which pass through the foramen ovale and connect the cavernous sinus with the pterygoid and pharyngeal plexuses. 6. Two or three small veins which pass through the foramen lacerum medium and connect the cavernous sinus with the pterygoid and pharyngeal plexuses. 7. There is sometimes a small vein connecting the same parts and passing through the inconstant foramen of Vesalius at the root of the pterygoid process of the sphenoid bone. 8. A plexus of veins passing through the carotid canal and connecting the cavernous sinus with the internal jugular vein. 9. A small vein (emissarium occipitale) usually connects the occipital vein with the lateral sinus or the torcular and the occipital diploic vein.

Surgical Anatomy.—These emissary veins are of great importance in surgery. In addition to them there are, however, other communications between the intra- and extra-cranial circulation, as, for instance, the communication of the angular and supra-orbital veins with the ophthalmic vein at the inner angle of the orbit, and the communication of the veins of the scalp with the diploic veins. Through these communications inflammatory processes commencing on the outside of the skull may travel inward, leading to osteo-phlebitis of the diploë and inflammation of the membranes of the brain. To this in former days was to be attributed one of the principal dangers of scalp wounds and other injuries of the scalp.

By means of these emissary veins blood may be abstracted almost directly from the intracranial circulation. For instance, leeches applied behind the ear abstract blood almost directly from the lateral sinus by means of the vein passing through the mastoid foramen. Again, epistaxis in children will frequently relieve severe headache, the blood which flows from the nose being derived from the longitudinal sinus by means of the vein which passes through the foramen cecum, which is another communication between the intracranial and extracranial circulation constantly found in children.
THE BLOOD-VASCULAR SYSTEM

VEINS OF THE UPPER EXTREMITY AND THORAX.

The veins of the Upper Extremity are divided into two sets, superficial and deep.

The Superficial Veins are placed immediately beneath the integument between the layers of superficial fascia.

The Deep Veins accompany the arteries, and constitute the venae comites of those vessels.

Both sets of vessels are provided with valves, which are more numerous in the deep than in the superficial veins.
The Superficial Veins of the Upper Extremity (Fig. 459).

The superficial veins of the upper extremity are—the

Superficial Veins of the Hand.

Posterior Ulnar.  
Common Ulnar.  
Radial.  
Median.  
Median Cephalic.  
Median Basilic.  
Basilic.  
Cephalic.

The **Superficial Veins of the Hand and Fingers** (Figs. 458 and 459) are principally situated on the dorsal surface. These dorsal veins begin in each finger as a venous plexus, in which are distinct veins running in a longitudinal direction, and called **dorsal digital veins** (vv. digitales dorsales propriae). The dorsal digital veins terminate over the first phalanges, in the **venous arches of the fingers** (areus venosi digitales). From these arches take origin the four **dorsal interosseous** or the **interdigital veins** (vv. metacarpeae dorsales). These veins form the **dorsal venous plexus of the hand** (rete venosum dorsale manus). This plexus lies in a line with the lower ends of the shafts of the metacarpal bones. It receives the dorsal interosseous veins, the radial digital vein of the index finger, and numerous superficial veins from the back of the hand. It gives origin to the superficial radial vein and the posterior ulnar vein. The superficial veins of the palmar surface are of less diameter than the dorsal veins. They arise from each of the phalanges by a plexus (vv. digitales volares propriae). Vessels at the edges of the fingers take most of the blood to the dorsal veins. There are also veins in the finger webs (vv. intercapitulares), which take blood from the palm to the dorsum. A superficial plexus, the **palmar plexus**, lies upon the palmar fascia, the fascia of the thenar eminence, and the fascia of the hypothenar eminence.

The **Anterior Ulnar Vein** (v. ulnaris anterior) (Fig. 459) commences on the anterior surface of the ulnar side of the hand and wrist, and ascends along the anterior surface of the ulnar side of the forearm to the bend of the elbow, where it joins with the posterior ulnar vein to form the common ulnar. Occasionally it opens separately into the median basilic vein. It communicates with branches of the median vein in front and with the posterior ulnar behind.

The **Posterior or Dorsal Ulnar Vein** (v. ulnaris posterior) (Fig. 458) commences on the posterior surface of the ulnar side of the wrist. It runs on the posterior surface of the ulnar side of the forearm, and just below the elbow unites with the anterior ulnar vein to form the common ulnar, or else joins the median basilic and helps to form the basilic. It communicates with the deep veins of the palm by a branch which emerges from beneath the Abductor minimi digitii muscle.

The **Common Ulnar Vein** (v. ulnaris communis) (Fig. 459) is a short trunk which is not constant. When it exists it is formed by the junction of the two preceding veins, and, passing upward and outward, joins the median basilic to form the basilic vein. When it does not exist the anterior and posterior ulnar veins open separately into the median basilic vein.

The **Radial Vein** (v. radialis) (Figs. 459 and 460) commences upon the dorsal surface of the wrist, communicating with the deep veins of the palm by a branch which passes through the first interosseous space. The radial vein soon forms a large vessel, which ascends along the radial side of the forearm and receives numerous veins from both its surfaces. At the bend of the elbow it unites with the median cephalic to form the cephalic vein. Spalteholz considers the ulnar vein as a portion of the basilic and the radial vein a portion of the cephalic.

The **Median Vein** (v. mediana cubiti) (Fig. 459) ascends on the front of the forearm, and communicates with the anterior ulnar and radial veins. At the bend
of the elbow it receives a branch of communication from the deep veins, the **deep median vein**, and divides into two branches, the **median cephalic** and **median basilic**, which diverge from each other as they ascend.

The **Median Cephalic** (v. mediana cephalica) (Fig. 459), usually the smaller of the two, passes outward in the groove between the Supinator longus and Biceps muscles, and joins with the radial to form the cephalic vein. The branches of the external cutaneous nerve pass beneath this vessel.

The **Median Basilic Vein** (v. mediana basilica) (Fig. 459) passes obliquely inward, in the groove between the Biceps and Pronator radii teres muscles, and joins the common ulnar to form the basilic. This vein passes in front of the brachial artery, from which it is separated by a fibrous expansion, the **bicipital fascia**, which is given off from the tendon of the Biceps to the fascia covering the Flexor muscles of the forearm. Filaments of the internal cutaneous nerve pass in front as well as behind this vessel.¹

**Venesection** is usually performed at the bend of the elbow, and as a matter of practice the largest vein in this situation is commonly selected. This is usually the median basilic, and there are anatomical advantages and disadvantages in selecting this vein. The advantages are, that in addition to its being the largest, and therefore yielding a greater supply of blood, it is the least movable and can be easily steadied on the bicipital fascia on which it rests. The disadvantages are, that it is in close relationship with the brachial artery, separated only by the bicipital fascia; and formerly, when venesection was frequently practised, arterio-venous aneurism was no uncommon result of this practice. Another disadvantage is, that the median basilic is crossed by some of the branches of the internal cutaneous nerve, and these may be divided in the operation, giving rise to “traumatic neuralgia of extreme intensity” (Tillaux).

The **Basilic Vein** (v. basilica) (Figs. 460 and 462) is of considerable size and is formed by the coalescence of the common ulnar vein with the median

¹ Cruveilhier says: “Numerous varieties are observed in the disposition of the veins of the elbow; sometimes the common median vein is wanting; but in those cases its two branches are furnished by the radial vein, and the cephalic is almost always in a rudimentary condition. In other cases only two veins are found at the bend of the elbow, the radial and ulnar, which are continuous, without any demarcation, with the cephalic and basilic.”—Ed. of 15th English edition.
It passes upward along the inner side of the Biceps muscle and pierces the deep fascia a little below the middle of the arm. The opening in the fascia is known as the semilunar hiatus (hiatus semilunaris). The vein ascends in the course of the brachial artery to the lower border of the tendons of the Latissimus dorsi and Teres major muscles, and is continued onward as the axillary vein.

The Cephalic Vein (v. cephalica) (Fig. 459) is formed by the union of the median cephalic and the radial veins. It courses along the outer border of the Biceps muscle, lying in the same groove with the upper external cutaneous branch of the musculo-spiral nerve, to the upper third of the arm; it then passes in the interval between the Pectoralis major and Deltoid muscles, lying in the same groove with the descending or humeral branch of the acromial-thoracic artery. It pierces the costo-coracoid membrane, and, crossing the axillary artery, terminates in the axillary vein just below the clavicle. This vein is occasionally connected with the external jugular or subclavian by a branch which passes from it upward in front of the clavicle.

The Deep Veins of the Upper Extremity (Fig. 460).

The deep veins of the upper extremity follow the course of the arteries, forming their venæ comites or companion veins. Usually there is one vein lying on each side of the corresponding artery, and they are connected at intervals by short transverse branches.

There are two digital veins accompanying each artery along the sides of the fingers: these, uniting at their base, pass along the interosseous spaces in the palm, and terminate in the two venæ comites which accompany the superficial palmar arch. Branches from these vessels on the radial side of the hand accompany the superficialis volae, and on the ulnar side terminate in the deep ulnar veins (Fig. 460). The deep ulnar veins, as they pass in front of the wrist, communicate with the interosseous and superficial veins, and at the elbow unite with the deep radial veins to form the venæ comites of the brachial artery. The venæ comites of the brachial communicate by numerous transverse branches, which cross over or under the artery.

The Interosseous Veins (Fig. 460) accompany the anterior and posterior interosseous arteries. The anterior interosseous veins commence in front of the wrist, where they communicate with the deep radial and ulnar veins; at the upper part of the forearm they receive the posterior interosseous veins, and terminate in the venæ comites of the ulnar artery.

The Deep Palmar Veins accompany the deep palmar arch, being formed by tributaries which accompany the ramifications of that vessel. At the wrist they receive a dorsal and a palmar tributary from the thumb. The deep palmar veins communicate with the deep ulnar veins at the inner side of the hand, and on the outer side terminate in the deep radial veins (Fig. 460), which are the venæ comites of the radial artery. Accompanying the radial artery the deep radial veins terminate in the venæ comites of the brachial artery.

The Brachial Veins (vv. brachiales) (Fig. 460) are placed one on each side of the brachial artery, receiving tributaries corresponding with the branches given off from that vessel; at the lower margin of the Subscapularis muscle they join the axillary vein.

These deep veins have numerous anastomoses, not only with each other, but also with the superficial veins. One of the brachial veins empties into the axillary, the other, usually the smaller, generally unites with the basilic.

The Axillary Vein (v. axillaris) (Fig. 461) is of large size, and may be regarded as the continuation upward of the basilic vein, or as formed by the fusion of a brachial vein with the basilic vein. If the first view is accepted a brachial vein is described as one of the tributaries of the axillary vein. The axillary vein com-
mences at the lower border of the tendons of the Teres major and Latissimus dorsi muscles, increases in size as it ascends, by receiving tributaries corresponding with the branches of the axillary artery, and terminates immediately beneath the clavicle at the outer border of the first rib, where it becomes the subclavian vein. This vessel is covered in front by the Pectoral muscles and costocoracoid membrane, and lies on the thoracic side of the axillary artery, which it partially overlaps. It receives the brachial veins, the venae comites of the axillary artery except the circumflex veins; and near its termination the cephalic vein. This vein is provided with a pair of valves opposite the lower border of the Subscapularis muscle; valves are also found at the termination of the cephalic and subscapular veins. The circumflex veins end in the subscapular or one of the brachial veins.

The **Long Thoracic Branch** (*v. thoracalis lateralis*) (Fig. 462) receives the **thoracoepigastric vein** (*v. thoracoepigastrica*), which comes all the way from the superficial epigastric or from the femoral vein.

The **Costo-axillary Veins** (*vv. costoaxillares*) (Fig. 462) come from the first six intercostal spaces and bring blood from the intercostal veins to the axillary.

---

**Surgical Anatomy.**—There are several points of surgical interest in connection with the axillary vein. Being more superficial, larger, and slightly overlapping the axillary artery, it is more liable to be wounded in the operation of extirpation of the axillary glands, especially as these glands, when diseased, are apt to become adherent to the vessel. When wounded there is always danger of air being drawn into its interior, and death resulting. This is due not only to the fact that it is near the thorax, and therefore liable to be influenced by the respiratory movements, but also because it is adherent by its anterior surface to the costo-coracoid membrane, and therefore if wounded is likely to remain patulous and favor the chance of air being sucked in. This adhesion of the vein to the fascia prevents its collapsing, and therefore favors the furious bleeding which takes place in these cases.
To avoid wounding the axillary vein in the extirpation of glands from the axilla no undue force should be used in isolating the glands. If the vein is found to be so embedded in the malignant deposit that the latter cannot be removed without taking away a part of the vein, this must be done, the vessel having been first ligated above and below.

The Subclavian Vein (*v. subclavia*) (Figs. 424 and 446), the continuation of the axillary, extends from the outer border of the first rib to the inner end of the clavicle, where it unites with the internal jugular to form the innominate vein. It is in relation, in front, with the clavicle and Subclavius muscle; behind and above, with the subclavian artery, from which it is separated internally by the Scalenus anticus muscle and phrenic nerve. Below, it rests in a depression on the first rib and upon the pleura. Above, it is covered by the cervical fascia and integument.

An expansion of the aponeurosis of the Subclavius muscle lies upon the vein (Fig. 462).

The subclavian vein occasionally rises in the neck to a level with the third part of the subclavian artery, and in two instances has been seen passing with this vessel behind the Scalenus anticus. This vessel is usually provided with valves about an inch from its termination in the innominate, just external to the entrance of the external jugular vein.

**Tributaries.**—It receives the external and anterior jugular veins and a small branch from the cephalic, outside the Scalenus, and on the inner side of that muscle the internal jugular vein. At the angle of junction with the internal...
jugular the left subclavian vein receives the thoracic duct (Fig. 463), while the right subclavian vein receives the right lymphatic duct.

The **Innominate** or **Brachio-cephalic Veins** (*vv. anonymae*) (Fig. 464) are two large trunks, placed one on each side of the root of the neck, and formed by the union of the internal jugular and subclavian veins of the corresponding side.

The **Right Innominate Vein** (*v. anonyma dextra*) is a short vessel, an inch in length, which commences at the inner end of the clavicle, and, passing almost vertically downward, joins with the left innominate vein just below the cartilage of the first rib, close to the right border of the sternum, to form the precava, or **superior vena cava**. It lies superficial and external to the innominate artery; on its right side is the phrenic nerve, and the pleura is here interposed between it and the apex of the lung. This vein, at the angle of junction of the internal jugular with the subclavian, receives the right vertebral vein, and, lower down, the right internal mammary, right inferior thyroid, and sometimes the right thyroidea ima and the right superior intercostal veins.

The **Left Innominate Vein** (*v. anonyma sinistra*), about two and a half inches in length, and larger than the right, passes from left to right across the upper and front part of the chest, at the same time inclining downward, and unites with

---

![Diagram of the thoracic duct and its termination in the subclavian vein.](image)

**Fig. 463.**—The bend of the thoracic duct at its termination in the subclavian vein. (Poirier and Charpy.)

the right innominate vein to form the precava. It is in relation, in *front*, with the first piece of the sternum, from which it is separated by the Sterno-hyoid and Sterno-thyroid muscles, the thymus gland or its remains, and some loose areolar tissue. *Behind*, it lies across the roots of the three large arteries arising from the arch of the aorta. This vessel is joined by the left vertebral, left internal mammary, left inferior thyroid, left thyroidea ima, and the left superior intercostal veins, and occasionally some thymic and pericardiac veins, and the right thyroidea ima. There are no valves in the innominate veins.

**Peculiarities.**—Sometimes the innominate veins open *separately* into the right auricle; in such cases the right vein takes the ordinary course of the precava; but the left vein—the left precava, or left superior vena cava, as it is termed—after communicating by a small branch with the right one, passes in front of the root of the left lung, and, turning to the back of the heart, receives the cardiac veins, and terminates in the back of the right auricle. This occasional condition in the adult is due to the persistence of the early foetal condition, and is the normal state of things in birds and some mammals.

The **Internal Mammary Vein** (*v. mammaria interna*) corresponds to the internal mammary artery, follows the course of that vessel, and receives branches corresponding with those derived from it. There are two internal mammary veins in the region of the Triangularis sterni muscle, but above this point the vein is single. The double vein is formed by the union of the venae comites of the superior epigastric
artery (vv. epigastricae superiores) and the vena comites of the musculo-phrenic artery (vv. musculophrenicae). It receives the twelve anterior intercostal veins from the upper six intercostal spaces of the corresponding side—six anterior perforating veins (rami perforantes)—veins from the surface of the sternum (rami sternalis) —muscular veins, and vessels from the mediastinum and pleura. The two veins of each side unite into a single trunk, at the upper margin of the triangularis sterni muscle, which terminates in the innominate vein.  

The Vertebral Vein (see p. 732).

The Inferior Thyroid Veins (vv. thyreoideae inferiores) (Fig. 464), two, frequently three or four, in number, arise in the venous plexus on the thyroid body (plexus thyreoideus impar), communicating with the middle and superior thyroid veins. (See Kocher’s views, pages 731 and 732.) Kocher states that two thyroid ima veins are present, and that inferior thyroid veins may also be present. The veins from the lower portion of the gland form a plexus in front of the trachea, behind the Sterno-thyroid muscles. From this plexus a left vein descends and joins the left innominate trunk, and a right vein passes obliquely downward and outward across the innominate artery to open into the right innominate vein, just at its junction with the precava. The thyreoidea ima vein (v. thyreoidea ima) passes downward in front of the trachea and terminates in the left innominate vein. These veins receive tributaries from the tracheal veins (vv. tracheales), from the oesophageal veins (vv. oesophageae), from the inferior laryngeal vein (v. laryngea inferior).
The Intercostal Veins (vv. intercostales) are divided into anterior and posterior intercostals.

The Anterior Intercostal Veins are tributaries of the internal mammary or the musculo-phrenic veins (p. 750).

The Posterior Intercostal Veins (Fig. 464) number eleven on each side, there being one vein in each intercostal space. Each vein lies in the groove at the lower margin of the rib above the corresponding intercostal artery. On the right side the first posterior intercostal vein crosses the neck of the first rib anteriorly and opens into the vertebral vein or the innominate vein. The first posterior intercostal of the left side follows a like course, and empties into the vertebral or innominate vein. The posterior intercostals of the right side, from the fifth to the eleventh, inclusive, open individually into the vena azygos major. The left upper azygos vein receives the fifth, sixth, seventh, and eighth posterior intercostals of the left side. The left lower azygos vein receives the ninth, tenth, and eleventh left posterior intercostals.

The Right Superior Intercostal Vein (v. intercostalis suprema dextra) is formed by the union of the second, third, and fourth right posterior intercostals. It passes downward and inward and opens into the vena azygos major.

The Left Superior Intercostal Vein (v. intercostalis suprema sinister) runs across the transverse aorta and opens into the left innominate vein. It usually receives the bronchial and left superior phrenic vein, and communicates below with the vena azygos minor superior. Each posterior intercostal vein obtains branches from the ribs and muscles and also a dorsal branch, which receives blood from the muscles of the back, from in front of the vertebral bodies, from back of the vertebral arches, and from the spinal canal by way of a vein which passes through the intervertebral foramen.

The Precava or Superior Vena Cava (v. cava superior) (Fig. 464) receives the blood which is conveyed to the heart from the whole of the upper half of the body. It is a short trunk, varying from two inches and a half to three inches in length, formed by the junction of the two innominate veins. It commences immediately below the cartilage of the first rib close to the sternum on the right side, and, descending vertically, enters the pericardium about an inch and a half above the heart, and terminates in the upper part of the right auricle opposite the upper border of the third right costal cartilage. In its course it describes a slight curve, the convexity of which is turned to the right side.

Relations.—In front, with the pericardium and process of cervical fascia which is continuous with it; this separates it from the thymus gland and from the sternum; behind, with the root of the right lung; on its right side, with the phrenic nerve and right pleura; on its left side, with the commencement of the innominate artery and ascending part of the aorta. The portion contained within the pericardium is covered by the serous layer of that membrane in its anterior three-fourths. It receives the vena azygos major just before it enters the pericardium, and several small veins from the pericardium and parts in the mediastinum. The precava has no valves.

The Azygos Veins connect together the precava and postcava, taking the place of those vessels in that part of the chest occupied by the heart.

The Larger or Right Azygos Vein or the Vena Azygos Major (v. azygos) (Fig. 464) commences opposite the first or second lumbar vertebra by a branch from the right lumbar veins, called the right ascending lumbar vein (v. lumbalis ascendens dextra); sometimes by a branch from the right renal vein or from the postcava. It enters the thorax through the aortic opening in the Diaphragm, and passes along the right side of the vertebral column to the fourth thoracic vertebra, where it arches forward over the root of the right lung, and terminates in the precava just before that vessel enters the pericardium. Whilst passing through the aortic opening
of the Diaphragm it lies with the thoracic duct on the right side of the aorta, and in the thorax it lies upon the intercostal arteries on the right side of the aorta and thoracic duct, and is partly covered by pleura.

**Tributaries.**—It receives the lower ten posterior intercostal veins of the right side, the upper two or three of these opening, first of all, into the right superior intercostal vein. It receives the azygos minor veins, several esophageal, mediastinal, and pericardial veins; near its termination, the right bronchial vein; and generally the right superior intercostal vein. A few imperfect valves are found in this vein; but its tributaries are provided with complete valves.

The intercostal veins on the left side, below the three upper intercostal spaces, usually form two trunks, named the **left lower and the left upper azygos veins.**

The **Left Lower or Smaller Azygos Vein** or the **Vena Azygos Minor** (v. hemiazygos) (Fig. 464) commences in the lumbar region by a branch from one of the lumbar veins, **ascending lumbar** (v. lumbalis ascendens), or from the left renal. It passes into the thorax through the left crus of the Diaphragm, and, ascending on the left side of the spine as high as the ninth thoracic vertebra, passes across the column, behind the aorta and thoracic duct, to terminate in the right azygos vein. It receives the four or five lower intercostal veins of the left side, and some esophageal and mediastinal veins.

The **Left Upper Azygos Vein** (v. hemiazygos accessoria) varies inversely with the size of the left superior intercostal. It receives veins from the intercostal spaces between the left superior intercostal vein and highest tributary of the left lower azygos. They are usually three or four in number, usually the fourth, fifth, sixth, and seventh left posterior intercostal veins. They join to form a trunk which ends in the right azygos vein or in the left lower azygos. It sometimes receives the left bronchial vein. When this vein is small or altogether wanting, the left superior intercostal vein will extend as low as the fifth or sixth intercostal space.

**Surgical Anatomy.**—In obstruction of the postcava the azygos veins are one of the principal means by which the venous circulation is carried on, connecting as they do the precava and postcava, and communicating with the common iliac veins by the ascending lumbar veins, and with many of the tributaries of the postcava.

The **Bronchial Veins** (vv. bronchiales) return the blood from the substance of the lungs, except from the smaller bronchial tubes and alveola. The blood from them is received by the pulmonary veins. The bronchial vein of the right side opens into the vena azygos major near its termination. The bronchial vein of the left side opens into the left superior intercostal vein or the left upper azygos vein. The bronchial veins are joined by veins from the trachea and mediastinum.

**The Spinal Veins.**

The numerous venous plexuses placed upon and within the spine may be arranged into four sets:

1. Those placed on the exterior of the spinal column, the **dorsi-scapal veins.**
2. Those situated in the interior of the spinal canal, between the vertebrae and the theca vertebralis, **meningo-rachidian veins.**
3. The veins of the bodies of the vertebrae, **venæ basis vertebrae.**
4. The veins of the spinal cord, **medulli-scapal veins.**

1. The **Dorsal-scapal Veins** (plexus venosi vertebralis externi) commence by small branches which receive their blood from the integument of the back of the spine and from the muscles in the vertebral grooves. They constitute two plexuses: one anterior plexus (plexus venosi vertebralis anteriores) upon the vertebral bodies and a **posterior plexus** (plexus venosi vertebralis posteriores), which surrounds the spinous processes, the laminae, and the transverse and articular processes of
all the vertebrae. At the bases of the transverse processes they communicate, by means of ascending and descending branches, with the veins surrounding the contiguous vertebrae, and they join with the veins in the spinal canal by branches which perforate the ligamenta subflava. Other branches pass obliquely forward, between the transverse processes, and communicate with the intraspinal veins through the intervertebral foramina (vv. intervertebrales). The dorsi-spinal veins terminate by joining the vertebral veins in the neck, the intercostal veins in the thorax, and the lumbar and sacral veins in the loins and pelvis.

![Diagram of the Blood-Vascular System](image)

**Fig. 465.**—Transverse section of a thoracic vertebra, showing the spinal veins.

2. The **Meningo-rachidian Veins** (*plexus venosi vertebrales interni*).—The principal veins contained in the spinal canal are situated between the theca vertebralis and the vertebrae. They consist of two longitudinal plexuses, one of which runs along the posterior surface of the bodies of the vertebrae, **anterior longitudinal spinal veins**. The other plexus, **posterior longitudinal spinal veins**, is placed on the inner or anterior surface of the laminae of the vertebrae.

![Diagram of the Blood-Vascular System](image)

**Fig. 466.**—Vertical section of two thoracic vertebrae, showing the spinal veins.

The **Anterior Longitudinal Spinal Veins** (*sinus vertebrales longitudinales*) consist of two large, tortuous veins which extend along the whole length of the vertebral column, from the foramen magnum, where they communicate by a venous ring around that opening, to the base of the coccyx, being placed one on each side of the posterior surface of the bodies of the vertebrae along the margin of the posterior common ligament. These veins communicate together opposite each vertebra by
VEINS OF LOWER EXTREMITY, ABDOMEN AND PELVIS 755

transverse trunks which pass beneath the ligament. Each transverse trunk receives the large vena basis vertebrae (v. basivertebralis) from the interior of the body of the vertebra. The anterior longitudinal spinal veins are least developed in the cervical and sacral regions. They are not of uniform size throughout, being alternately enlarged and constricted. At the intervertebral foramina they communicate with the dorsi-spinal veins, and with the vertebral veins in the neck, with the intercostal veins in the thoracic region, and with the lumbar and sacral veins in the corresponding regions.

The Posterior Longitudinal Spinal Veins, smaller than the anterior, are situated one on each side, between the inner surface of the laminae and the theca vertebralis. They communicate (like the anterior) opposite each vertebra by transverse trunks, and with the anterior longitudinal veins by lateral transverse branches which pass from behind forward. The posterior longitudinal veins, by branches which perforate the ligamenta subflava, join with the dorsi-spinal veins. From them branches are given off which pass through the intervertebral foramina and join the vertebral, intercostal, lumbar, and sacral veins. The anterior and posterior longitudinal spinal veins join by numerous branches and really constitute one plexus, the plexus venosi vertebrales interni.

The Intervertebral Veins (vv. intervertebrales) accompany the spinal nerves in the intervertebral foramina, receive veins from the spinal cord, and join the meningo-rachidian and the dorsi-spinal veins.

3. The Veins of the Bodies of the Vertebrae or the Venæ Basis Vertebrae (vv. basivertebræ) emerge from the foramen on the posterior surface of each vertebra and join the transverse trunk connecting the anterior longitudinal spinal veins. They are contained in large, tortuous channels in the substance of the bones, similar in every respect to those found in the diploe of the cranial bones. These canals lie parallel to the upper and lower surface of the bones. They commence by small openings on the front and sides of the bodies of the vertebrae, through which communicating branches from the veins external to the bone pass into its substance, and converge to the principal canal, which is sometimes double toward its posterior part. They open into the corresponding transverse branch uniting the anterior longitudinal veins. They become greatly developed in advanced age.

4. The Veins of the Spinal Cord or the Medulli-spinal Veins (vv. spinalæ) emerge from the cord substance and enter the pia plexus. The pia plexus is a minute, tortuous, venous plexus which covers the entire surface of the cord, being situated between the pia and arachnoid. “In this plexus there are six longitudinal channels—one antero-median, along the anterior fissure—two antero-lateral, immediately behind the anterior nerve roots—two postero-lateral, immediately behind the posterior nerve roots—and one postero-median, over the postero-septum” (Cunningham). These vessels are largest in the lumbar region. Near the base of the skull they unite and form two or three small trunks, which communicate with the vertebral veins, and terminate in the subcerebellar veins or in the subpetrosal sinuses. Each of the spinal nerves is accompanied by a branch as far as the intervertebral foramina, where it joins the other veins from the spinal canal.

There are no valves in the spinal veins.

VEINS OF THE LOWER EXTREMITY, ABDOMEN, AND PELVIS
(Figs. 467, 468).

The Veins of the Lower Extremity are subdivided, like those of the upper, into two sets, superficial and deep, the superficial veins being placed beneath the
integument, between the two layers of superficial fascia, the deep veins accompanying the arteries, and forming the venae comites of those vessels. Both sets of veins are provided with valves, which are more numerous in the deep than in the superficial set. These valves are also more numerous in the lower than in the upper limb.

The Superficial Veins of the Lower Extremity.

The Superficial Veins of the Foot.—On the sole of the foot there is a subcutaneous venous plexus (rete venosum plantare cutaneum), from which some branches go to the deep veins, but most of the branches pass around the margins to the dorsum of the foot. There is a transverse venous arch at the root of the toes which receives plantar vessels from the toes and sends branches between the toes (vv. intercapitulares) to the venous arch of the dorsum. On the dorsum of each toe the veins gather into two vessels, known as the dorsal digital veins (vv. digitales pedis dorsales). The dorsal digital veins from the opposed margins of two toes unite to form a dorsal interdigital vein. There are four dorsal interdigital veins (vv. digitales communes pedis), and they pass into the venous arch of the dorsum. The dorsal digital vein, from the inner surface of the great toe, passes directly into the internal saphenous vein, and the dorsal digital vein, from the outer surface of the little toe, passes directly into the external saphenous vein.

On the dorsum of the foot is a venous arch (arcus venosus dorsalis pedis [cutaneus]), situated in the superficial structures over the anterior extremities of the metatarsal bones. It has its convexity directed forward, and receives digital tributaries from the upper surface of the toes; at its concavity it is joined by numerous small veins which form a plexus on the dorsum of the foot (rete venosum dorsale pedis cutaneum). The arch terminates internally in the long saphenous, externally in the short saphenous vein.

The chief superficial veins of the lower extremity are the internal or long saphenous and the external or short saphenous.

The Internal or Long Saphenous Vein (v. saphena magna) (Figs. 467 and 470) commences at the inner side of the arch on the dorsum of the foot; it ascends in front of the inner malleolus and along the inner side of the leg, behind the inner margin of the tibia, accompanied by the internal saphenous nerve. At the knee it passes backward behind the inner condyle of the femur, ascends along the inside of the thigh, and, passing through the saphenous opening in the fascia lata, terminates in the femoral vein about an inch and a half below Poupart’s ligament. This vein receives in its course cutaneous tributaries from the leg and thigh, and at the saphenous opening receives the superficial epigastric, superficial circumflex iliac, and external pudic veins. The veins from the inner and back part of the thigh frequently unite to form a large vessel, which enters the main trunk near the saphenous opening; and sometimes those on the outer side of the thigh join to form another large vessel; so that occasionally three large veins are seen converging from different parts of the thigh toward the saphenous opening. The internal saphenous vein communicates in the foot with the internal planter vein; in the leg, with the posterior tibial veins by branches which perforate the tibial origin of the Soleus muscle, and also with the anterior tibial veins; at the knee, with the articular veins; in the thigh, with the femoral vein by one or more branches. The valves in this vein vary from two to six in number; they are more numerous in the thigh than in the leg.

The External or Short Saphenous Vein (v. saphena parva) (Fig. 468) commences at the outer side of the arch on the dorsum of the foot; it ascends behind the outer malleolus, and along the outer border of the tendon Achilles, across which it passes at an acute angle to reach the middle line of the posterior aspect of the leg.
Passing directly upward, it perforates the deep fascia in the lower part of the popliteal space, and terminates in the popliteal vein, between the heads of the Gastrocnemius muscle. It receives numerous large tributaries from the back part of the leg, and communicates with the deep veins on the dorsum of the foot and behind the outer malleolus. Before it perforates the deep fascia it gives off a communicating branch, which passes upward and inward to join the internal saphenous vein. This vein has a variable number of valves, from three to nine (Gay), one of which is always found near its termination in the popliteal vein. The external saphenous nerve lies close beside this vein.

**Surgical Anatomy.**—The saphenous veins are of considerable surgical importance, since a varicose condition of these vessels is more frequently met with than of those in other parts

---

1 Mr. Gay calls attention to the fact that the external saphenous vein often (he says invariably) penetrates the fascia at or about the point where the tendon of the Gastrocnemius commences, and runs below the fascia in the rest of its course, or sometimes among the muscular fibres, to join the popliteal vein. (See Gay on Varicose Disease of the Lower Extremities, p. 24, where there is also a careful and elaborate description of the branches of the saphena vein.)—Ed. of 15th English edition.
of the body, except perhaps the spermatic and hemorrhoidal veins. The course of the internal saphenous is in front of the tip of the inner malleolus, over the subcutaneous surface of the lower end of the tibia, and then along the internal border of this bone to the back part of the internal condyle of the femur, whence it follows the course of the Sartorius muscle, and is represented on the surface by a line drawn from the posterior border of the Sartorius on a level with the internal condyle to the saphenous opening. The external saphenous lies behind the external malleolus, and from this follows the middle line of the calf to just below the ham. It is not generally so apparent beneath the skin as the internal saphenous. Both these veins in the leg are accompanied by nerves, the internal saphenous being joined by its companion nerve just below the level of the knee-joint. No doubt much of the pain of varicose veins in the leg is due to this fact.

The Deep Veins of the Lower Extremity.

The deep veins of the lower extremity accompany the arteries and their branches and are called the *venae comites* of those vessels. The *venae comites* in the lower extremity pass into one trunk, the *popliteal vein*, whereas in the upper extremity the *venae comites* continue with the artery to the axilla.

**The Deep Veins of the Foot.**—The *plantar digital veins* (*vv. digitales plantares*) form the *plantar metatarsal veins* (*vv. metatarsaeae plantares*), which communicate with the veins of the dorsum of the foot by perforating veins and also communicate with the deep venous arch of the sole of the foot (*arcus venosus plantaris profundus*). The plantar arch gives off *lateral* or *external plantar veins*, which unite with *median* or *internal plantar veins* to form the posterior tibial veins. On the dorsum of the foot the deep veins begin as the *dorsal metatarsal veins* (*vv. metatarsaeae dorsales pedis*), which form the *venae comites* of the dorsalis pedis artery.

The *Posterior Tibial Veins* (*vv. tibiales posteriores*) accompany the posterior tibial artery and are joined by the peroneal veins.

The *Anterior Tibial Veins* (*vv. tibiales anteriores*) are formed by a continuation upward of the *venae comites* of the dorsalis pedis artery. They pass between the tibia and fibula, through the large oval aperture above the interosseous membrane, and form, by their junction with the posterior tibial, the popliteal vein.

The valves in the deep veins are very numerous.

The *Popliteal Vein* (*v. poplitea*) (Fig. 469) is formed by the junction of the anterior and posterior tibial veins; it ascends through the popliteal space to the aperture in the Adductor magnus, where it becomes the femoral vein. In the lower part of its course it is placed internal to the artery; between the heads of the Gastrocnemius it is superficial to that vessel; but above the knee-joint it is close to the outer side of the artery. It receives the *sural veins* from the Gastrocnemius muscle, the articular veins, and the external saphenous vein. The valves in this vein are usually four in number.

The *Femoral Vein* (*v. femoralis*) (Figs. 470 and 471) accompanies the femoral artery through the upper two-thirds of the thigh. In the lower part of its course it lies external to the artery; higher up it is behind it; and at Poupart’s ligament it lies to its inner side and on the same plane. It receives numerous muscular tributaries, and about an inch and a half below Poupart’s ligament it is joined by
the profunda femoris (*v. profunda femoris*); near its termination it is joined by the internal saphenous vein. The valves in this vein are four or five in number.

The **External Iliac Vein** (*v. iliaca externa*) (Figs. 464, 471, and 473) *commences* at the termination of the femoral, beneath the crural arch, and, passing upward along the brim of the pelvis, terminates opposite the sacro-iliac synchondrosis by uniting with the internal iliac to form the common iliac vein. On the right side it lies at first along the inner side of the external iliac artery, but as it passes upward gradually inclines behind it. On the left side it lies altogether on the inner side of the artery. It receives, immediately above Poupart's ligament, the deep epigastric and deep circumflex iliac veins and a small pubic vein, corresponding to the pubic branch of the obturator artery. According to Friedreich, it frequently contains one and sometimes two valves.

The **Deep Epigastric Vein** (*v. epigastrica inferior*) (Fig. 471).—Two veins accompany the deep epigastric artery; they usually unite into a single trunk before their termination in the external iliac vein.

The **Deep Circumflex Iliac Vein** (*v. circumflexa ilium profunda*) (Fig. 471).—Two veins accompany the deep circumflex iliac artery. These unite into a single trunk which crosses the external iliac artery just above Poupart's ligament and terminates in the external iliac vein.

---

**Fig. 470.**—The femoral vein and its tributaries. (Poirier and Charpy.)
The **Hypogastric or Internal Iliac Vein** (v. iliaca interna or v. hypogastrica) (Figs. 464, 471, and 473) is formed by the veins corresponding to all the branches of the internal iliac artery except the umbilical branch. It receives the blood from the exterior of the pelvis by the gluteal, sciatic, internal pudic, and obturator veins, and from the organs in the cavity of the pelvis by the middle hemorrhoidal veins, the superior vesical plexus and the prostatico-vesical plexus in the male, and the superior vesical, inferior vesical, uterine and vaginal plexuses in the female. The vessels forming these plexuses are remarkable for their large size, their frequent anastomoses, and the number of valves which they contain. The internal iliac vein lies at first on the inner side, and then behind the internal iliac artery, and terminates opposite the sacro-iliac articulation by uniting with the external iliac to form the common iliac vein. This vessel has no valves.

The **Internal Pudic Veins** (vv. pudendae internae) (Fig. 471) have the same course as the internal pudic artery. They receive tributaries corresponding to the branches of the artery, except the tributary corresponding to the dorsal artery of the penis; that is, the deep dorsal vein of the penis, which opens into the prostatico-vesical plexus.

The **Inferior or External Hemorrhoidal Veins** (vv. hemorrhoidalis inferiores) (Figs 472 and 473) collect blood from the anus. They pass outward over the External sphincter muscle, unite with numerous subcutaneous veins, and form larger vessels which join the internal pudic veins.

The **Middle Hemorrhoidal Veins** (vv. hemorrhoidalis media) (Figs. 472 and 473) help to form the hemorrhoidal plexus, perforate the rectal wall, and empty into the internal iliac vein. These veins, by their anastomoses in the hemorrhoidal plexus, establish a communication between the portal and systemic venous systems.

The **Lateral Sacral Veins** (vv. sacrales laterales) (Fig. 471) accompany the lateral sacral arteries and terminate in the internal iliac vein.
**Surgical Anatomy.**—The veins of the hemorrhoidal plexus are apt to become dilated and varicose, and form piles, *hemorrhoids*. This is due to several anatomical reasons: the vessels are contained in very loose, or connective tissue, so that they obtain less support from surrounding structures than most other veins, and are less capable of resisting increased blood pressure: the condition is favored by gravitation, being influenced by the erect posture, either sitting or standing, and by the fact that the superior hemorrhoidal and portal veins have no valves. The veins pass through muscular tissue and are liable to be compressed by its contraction, especially during the act of defecation, and they are affected by every form of portal obstruction.

The **Obturator Vein** (v. obturatoriae) (Figs. 471 and 473) follows the course of the obturator artery, lying below the artery as it passes over the side of the pelvis; this vein empties into the front part of the internal iliac vein.

The **Sciatic Veins** are two in number; they accompany the sciatic artery in the upper part of the back of the thigh, and just before their termination in the internal iliac the two veins unite.

The **Gluteal Veins** (vv. glutea) are usually two in number, and return to the internal iliac vein the blood that has been distributed by the gluteal artery and its branches.

---

![Diagram of venous anatomy](image)

**Fig. 472.**—Scheme of the anastomosis of the veins of the rectum. (Poirier and Charpy.)

The **Superior Vesical Plexus** (Fig. 473) is placed upon the fundus and lateral aspects of the bladder on the external aspect of the muscular coat. It receives vessels from the mucous membrane and from the muscular walls. It empties into the internal pudic vein: in the male it communicates with the prostatico-vesical plexus, and in the female with the inferior vesical plexus.

The **Prostatic** or the **Prostatico-vesical Plexus** (Fig. 473) surrounds the prostate gland and the neck of the bladder. It is contained between the rectovesical fascia which surrounds the base and sides of the gland and the true capsule of the gland. It communicates with the superior vesical plexus behind and above, and receives the deep dorsal vein of the penis, which enters the pelvis between the subpubic and triangular ligaments. This plexus receives veins from the seminal vesicles and vasa deferentia. On each side one or more vessels pass
from the prostatico-vesical plexus to the internal iliac vein. The veins composing the prostatic plexus are very liable to become varicose, and often contain hard, earthy concretions called **phleboliths**.

The **Inferior Vesical Plexus** exists only in the female, and corresponds to the prostatico-vesical plexus in the male, and surrounds the neck of the bladder and the upper portion of the urethra. It receives the dorsal vein of the clitoris and sends efferents to the internal iliac vein.

**Surgical Anatomy.**—The prostatico-vesical plexus is wounded in the lateral operation of lithotomy, and it is through it that septic matter finds its way into the general circulation after this operation. In enucleating the prostate the gland is shelled out from its capsule of recto-vesical fascia. The veins of the plexus remain attached to the sheath.

**The Dorsal Veins of the Penis.**—The **Superficial Dorsal Vein of the Penis** (Fig. 474) receives blood from the prepuce and runs backward beneath the skin, and divides into two branches which terminate in the superficial external pudic vein.

The **Deep Dorsal Vein of the Penis** (*v. dorsalis penis*) (Figs. 473 and 474) is a vessel of large size which returns the blood from the body of that organ. At first it con-
sists of two branches, which are contained in the groove on the dorsum of the penis, and it receives numerous superficial veins and veins from the glans penis and the corpus spongiosum. These vessels unite into a single trunk, which passes between the two parts of the suspensory ligament of the penis, and through an aperture between the subpubic ligament and the apex of the triangular ligament, and divides into two branches, which enter the prostatico-vesical plexus. The dorsal vein of the clitoris corresponds in woman to the dorsal vein of the penis in man, and runs into the inferior vesical plexus.

The Vaginal Plexuses and Veins (Fig. 475).—The vaginal plexuses are placed at the sides of the vagina, being especially developed at the orifice of the canal. They receive vessels from the vaginal walls. The plexuses communicate with the uterine plexus above, with the bulbar veins below, with the inferior vesical plexus in front and with the hemorrhoidal plexus behind. From the upper part of each vaginal plexus comes a vaginal vein which passes to the internal iliac.

The Uterine Plexuses (Fig. 475) are situated along the sides and superior angles of the uterus, between the layers of the broad ligament. They receive the veins from the uterus, which veins are without valves. During pregnancy these veins become large venous canals known as the uterine sinuses, and bring blood from the substance of the placenta. These veins join the ovarian above and the vaginal below, and Anastomose with each other. They are not tortuous like the artery.

The Uterine Veins (vv. uterinae) (Fig. 475) arise from the lower part of the plexus, and there are usually two veins on each side and they are without valves. These veins for the first portion of their course are placed in the base and inner portion of the broad ligament; they then pass back with the uterine artery in a peritoneal fold between the back of the broad ligament and the recto-uterine fold (Cunningham); they then pass upward and enter the internal iliac vein.
The Common Iliac Vein (v. iliaca communis) (Figs. 464, 471, and 473) on each side is formed by the union of the external and internal iliac veins in front of the sacro-iliac articulation: passing obliquely upward toward the right side, each vein terminates upon the intervertebral substance between the fourth and fifth lumbar vertebrae, where the veins of the two sides unite at an acute angle to form the postcava or inferior vena cava. The right common iliac (v. iliaca communis dextra) is shorter than the left, nearly vertical in its direction, and ascends behind and then to the outer side of its corresponding artery. The left common iliac (v. iliaca communis sinistra), longer and more oblique in its course, is at first situated on the inner side of the corresponding artery, and then behind the right common iliac. Each common iliac receives the ilio-lumbar, and sometimes the lateral sacral, veins. The left receives, in addition, the middle sacral vein. No valves are found in these veins.

The Middle Sacral Veins (Figs. 471 and 472) accompany the corresponding artery along the front of the sacrum, and join to form a single vein (v. sacralis media), which terminates in the left common iliac vein; occasionally in the angle of junction of the two iliac veins. The middle sacral veins communicate with the inferior hemorrhoidal.

The Ilio-lumbar Veins (vv. iliolumbales) receive branches from the iliac fossæ, spinal muscles, and spinal canal. One vein on each side runs with the artery, passes posterior to the psoas muscle, and joins the common iliac vein.

Peculiarities.—The left common iliac vein, instead of joining with the right in its usual position, occasionally ascends on the left side of the aorta as high as the kidney, where, after receiving the left renal vein, it crosses over the aorta, and then joins with the right vein to form the postcava. In these cases the two common iliacs are connected by a small communicating branch at the spot where they are usually united.1

The Postcava, Ascending, or Inferior Vena Cava (v. cava inferior) (Figs. 464 and 471) returns to the heart the blood from all the parts below the Diaphragm. It is formed by the junction of the two common iliac veins on the right side of the intervertebral substance between the fourth and fifth lumbar vertebrae. It passes upward along the front of the spine on the right side of the aorta, and, having reached the under surface of the liver, is contained in a groove on its posterior surface. It then perforates the central tendon of the Diaphragm, enters the pericardium, where it is covered for a very short distance by the serous layer of the pericardium, and terminates in the lower and back part of the right auricle. At its termination in the auricle it is provided with a valve, the Eustachian valve (valvula v. cavae inferioris [Eustachii]), which is of large size during foetal life.

Relations.—In front, from below upward, with the mesentery, right spermatic artery, transverse portion of the duodenum, the pancreas, portal vein, and the posterior surface of the liver, which, in most cases, partly and occasionally completely surrounds it; behind, with the vertebral column, the right crus of the Diaphragm, the right renal and lumbar arteries, and the right semilunar ganglion; on the left side, with the aorta.

Peculiarities. In Position.—This vessel is sometimes placed on the left side of the aorta, as high as the left renal veins, after receiving which it crosses over to its usual position on the right side; or it may be placed altogether on the left side of the aorta, as far upward as its termination in the heart: in such cases the abdominal and thoracic viscera, together with the great vessels, are all transposed.

Point of Termination.—Occasionally the postcava joins the right azygos vein, which is then of large size. In such cases the precava receives the whole of the blood from the body before transmitting it to the right auricle, except the blood from the hepatic veins, which passes directly into the right auricle.

1 See two cases which have been described by Mr. Walsham in St. Bartholomew's Hospital Reports, vols. xvi. and xvii.—Ed. of 15th English edition.
The deep veins of the lower extremity

Tributaries.—It receives in its course the following veins:

- Lumbar.
- Right Spermatic.
- Renal.
- Suprarenal.
- Phrenic.
- Hepatic.

The **Lumbar Veins** (*vv. lumbales*), four in number on each side, collect the blood by dorsal tributaries from the muscles and integument of the loins and by abdominal tributaries from the walls of the abdomen, where they communicate with the epigastric veins. At the spine they receive veins from the spinal plexuses, and then pass forward, round the sides of the bodies of the vertebrae beneath the Psoas magnus muscle, and terminate at the back part of the postcava. The left lumbar veins are longer than the right, and pass behind the aorta. The lumbar veins of a side are connected together by a longitudinal vein which passes in front of the transverse processes of the lumbar vertebrae, and is called the **ascending lumbar vein** (*v. lumbalis ascendens*) (Fig. 464). It forms the most frequent origin of the corresponding vena azygos, and serves to connect the common iliac, ilio-lumbar, lumbar, and azygos veins of the corresponding side of the body.

The **Spermatic Veins** (*vv. spermaticae*) (Fig. 476) emerge from the back of the testis, and receive tributaries from the epididymis; they unite and form a convoluted plexus called the **spermatic plexus** (*plexus pampiniformis*), which forms the chief
mass of the cord: the vessels composing this plexus are very numerous, and ascend along the cord in front of the vas deferens; below the external abdominal ring they unite to form three or four veins, which pass along the inguinal canal, and, entering the abdomen through the internal abdominal ring, coalesce to form two veins, which ascend on the Psoas muscle behind the peritoneum, lying one on each side of the spermatic artery, and unite to form a single vein, which opens on the right

Fig. 477.—Terminations of the right and left spermatic veins. (Poirier and Charpy.)

side into the postcava at an acute angle; on the left side into the left renal vein at a right angle (Fig. 477). The termination of the left spermatic vein is called the emulgent vein. Professor John H. Brinton pointed out that a valve is usually absent in the emulgent vein (Fig. 478), but regularly present in the right spermatic vein. The left spermatic vein passes behind the sigmoid flexure of the colon, and is thus exposed to pressure from the contents of that bowel.

Surgical Anatomy.—The spermatic veins are very frequently varicose, constituting the disease known as varicocele. Though it is quite possible that the originating cause of this affection may be a congenital abnormality either in the size or number of the veins of the pampiniform plexus, still it must be admitted that there are many anatomical reasons why these veins should become varicose—viz., the imperfect support afforded to them by the loose tissue of the serotum; their great length; their vertical course; their dependent position; their plexiform arrangement in the scrotum, with their termination in one small vein in the abdomen; their few and imperfect valves; and the fact that they may be subjected to pressure in their passage through the abdominal wall. The left veins more often become varicose than the right veins, probably, as Brinton suggests, because the right spermatic vein practically always has a valve and opens into the postcava at an acute angle, whereas the left spermatic vein is not unusually destitute of a valve at its opening and passes into the left renal vein at a right angle.

The Ovarian Veins (vv. ovaricae) (Fig. 475) are analogous to the spermatic in the male; they form a plexus near the ovary in the broad ligament and about the Fallopian tube, communicating with the uterine plexus. They terminate in the same way as the spermatic veins in the male. Valves are occasionally found in these veins. These vessels, like the uterine veins, become much enlarged during pregnancy.

1 See John H. Brinton in the American Journal of the Medical Sciences, and also Handbuch der Topographischen Anatomie, von Joseph Hyrtl. Rivington maintains that a valve is usually found at the orifices of both the right and left spermatic veins. When no valves exist at the opening of the left spermatic vein into the left renal vein, valves are generally present in the left renal vein within a quarter of an inch from the orifice of the spermatic vein. (Journal of Anatomy and Physiology, vol. vii, p. 163).—Ed. of 15th English edition.
The Renal Veins (vv. renales) (Fig. 465) are of large size, and are placed in front of the renal arteries. The left is longer than the right, and passes in front of the aorta, just below the origin of the superior mesenteric artery. It receives the left spermatic, the left inferior, and, generally, the left suprarenal veins. It opens into the postcava a little higher than the right. The utero-venous triangle of Robinson is formed by the ureter, the renal veins, and the ovarian veins.

The Suprarenal Veins (vv. suprarenales) (Fig. 464) are two in number: that on the right side terminates in the postcava; that on the left side, in the left renal or in the left phrenic vein.

The Phrenic Veins (vv. phrenicae) follow the course of the phrenic arteries. The two superior phrenic veins (vv. phrenicae superiores), of small size, accompany the phrenic nerve and comes nervi phrenici artery, and join the internal mammary vein. The two inferior phrenic veins (vv. phrenicae inferiores) follow the course of the phrenic arteries, and terminate, the right in the postcava, the left in the left renal vein.

The Hepatic Veins (vv. hepaticae) commence in the substance of the liver, in the capillary terminations of the portal vein and hepatic artery, intralobular veins: these tributaries, gradually uniting into sublobular veins; usually form three large hepatic veins, which converge toward the posterior surface of the liver and open into the postcava, whilst that vessel is situated in the groove at the back part of this organ. Of these three veins, one from the right and another from the left

---

1 The student may observe that all veins above the Diaphragm, which do not lie on the same plane as the arteries which they accompany, lie in front of them, and that all veins below the Diaphragm, which do not lie on the same plane as the arteries which they accompany, lie behind them, except the renal and profunda femoris vein.—Ed. of 15th English edition.
lobe open obliquely into the postcava, that from the middle of the organ and lobulus Spigellii having a straight course. The hepatic veins run singly, and are in direct contact with the hepatic tissue. They are destitute of valves.

The Portal System of Veins (Fig. 479).

The portal venous system is composed of four large veins which collect the venous blood from the viscera of digestion (stomach, intestine, and pancreas) and from the spleen. The trunk formed by their union, the portal vein, enters the liver and ramifies throughout its substance after the manner of an artery and ends in capillaries, from which the blood is collected into the hepatic veins, which terminate in the postcava. The branches of this vein are in all cases single, and destitute of valves.

The veins forming the portal system are—the

Superior Mesenteric.
Splenic.
Cystic.
Inferior Mesenteric.
Gastric.

The Superior Mesenteric Vein (v. mesenterica superior) (Fig. 479) returns the blood from the small intestines and from the cecum and ascending and transverse portions of the colon, corresponding with the distribution of the branches of the superior mesenteric artery. The large trunk formed by the union of these branches ascends along the right side and in front of the corresponding artery, passes in front of the transverse portion of the duodenum, and unites, behind the upper border of the pancreas, with the splenic vein to form the portal vein. It receives the right gastro-epiploic vein. The appendicular vein is a tributary of the superior mesenteric vein.

The Splenic Vein (v. lienalis) (Fig. 479) commences by five or six large branches which return the blood from the substance of the spleen. These, uniting, form a single vessel, which passes from left to right, grooving the upper and back part of the pancreas below the artery, and terminates at its greater end by uniting at a right angle with the superior mesenteric to form the portal vein. The splenic vein is of large size, and not tortuous like the artery. It receives the vasa brevia from the left extremity of the stomach, the left gastro-epiploic vein, pancreatic branches from the pancreas, the pancreatico-duodenal vein, and the inferior mesenteric vein.

The Inferior Mesenteric Vein (v. mesenterica inferior) (Fig. 479) returns the blood from the rectum, sigmoid flexure, and descending colon, corresponding with the ramifications of the branches of the inferior mesenteric artery. It lies to the left of the artery, and ascends beneath the peritoneum in the lumbar region; it passes behind the transverse portion of the duodenum and pancreas, and terminates in the splenic vein. Its hemorrhoidal branches, the superior hemorrhoidal veins (vv. hemorrhoidalis superior), inosculate with the middle hemorrhoidal branches of the internal iliac, and thus establish a communication between the portal and the general venous system.\(^1\)

The Gastric Veins (vv. gastricae) (Fig. 479) are two in number: one, a small vein, corresponds to the pyloric branch of the hepatic artery; the other, considerably larger, corresponds to the gastric artery. The former, the pyloric vein (v. pylorica), runs along the lesser curvature of the stomach toward the pyloric end, receives branches from the pylorus and duodenum, and ends in the portal vein. The latter, the gastric or coronary vein (v. coronaria ventriculi), begins near the pylorus.

\(^1\) Besides this anastomosis between the portal vein and the branches of the vena cava, other anastomoses between the portal and systemic veins are formed by the communication between the gastric veins and the oesophageal veins, which empty themselves into the vena azygos minor; between the left renal vein and the veins of the intestines, especially of the colon and duodenum; between the veins of the round ligament of the liver and the portal veins; and between the superficial branches of the portal veins of the liver and the phrenic veins, as pointed out by Mr. Kiernan. (See Physiological Anatomy, by Todd and Bowman, 1839, vol. ii. p. 348).—Ed. of 16th English edition.
runs along the lesser curvature of the stomach toward the oesophageal opening in the diaphragm, and then passes across the front of the spine from left to right to end in the portal vein, at a point a little above the junction of the pyloric vein.

The Cystic Vein (v. cystica) (Fig. 479).—The portal vein generally receives the cystic vein, although that vessel sometimes terminates in the right branch of the portal vein.

**NOTE.**—In this diagram the right gastro-epiploic vein opens into the splenic vein; generally it empties itself into the superior mesenteric, close to its termination.

The Portal Vein (vena portae) (Fig. 479) is formed by the junction of the superior mesenteric and splenic veins, their union taking place in front of the vena cava and behind the upper border of the head of the pancreas. Passing upward through the right border of the lesser omentum to the under surface of the liver, it enters the transverse fissure, where it is somewhat enlarged, forming the sinus of the portal vein, and divides into two branches which accompany the ramifications of the hepatic artery and hepatic duct throughout the substance of the liver. Of
these two branches, the right is the larger, but the shorter, of the two. The portal vein is about three or four inches in length, and, whilst contained in the lesser omentum, lies behind and between the common bile-duct and the hepatic artery, the former being to the right, the latter to the left. These structures are accompanied by filaments of the hepatic plexus of nerves and numerous lymphatics, and are surrounded by a quantity of loose areolar tissue, the capsule of Glisson.

The portal vein divides, in the substance of the liver, like an artery, and its minute ramifications end in capillaries, from which the blood is carried to the postcava by the hepatic veins; these veins also collect the blood which has been brought to the liver by the hepatic artery. It will therefore be seen that the blood which is carried to the liver by the portal vein passes through two sets of capillary vessels—viz.: (1) the capillaries in the stomach, intestine, pancreas, and spleen, and (2) the capillaries of the portal vein in the liver.

**THE CARDIAC VEINS** (Fig. 480).

The veins which return the blood from the substance of the heart are—the

Great Cardiac Vein.
Posterior Cardiac Vein.
Left Cardiac Veins.

Anterior Cardiac Veins.
Right or Small Coronary Vein.
Coronary Sinus.
Veæ Thebesii.

The Great Cardiac or Left Coronary Vein (v. cordis magna) is a vessel of considerable size, which commences at the apex of the heart, and ascends along the anterior interventricular groove to the base of the ventricles. It then curves to the left side, around the auriculo-ventricular groove, between the left auricle and ventricle, to the back part of the heart, and opens into the left extremity of the coronary sinus, its aperture being guarded by two valves. It receives, in
its course, tributaries from both ventricles, but especially from the left, and also from the left auricle; one of these ascending along the thick margin of the left ventricle is of considerable size, and is called the left marginal vein. The vessels joining the great cardiac vein are provided with valves.

The Posterior or Middle Cardiac Vein (v. cordis media) commences by small tributaries, at the apex of the heart, communicating with those of the preceding. It ascends along the posterior interventricular groove to the base of the heart, and terminates in the coronary sinus, its orifice being guarded by a valve. It receives veins from the posterior surface of both ventricles.

The Left Cardiac Vein (v. posterior ventriculi sinistri) receives three or four small vessels, which collect the blood from the posterior surface of the left ventricle. It opens into the lower border of the coronary sinus.

The Anterior Cardiac Veins (vv. cordis anteriores) are three or four small vessels, which collect the blood from the anterior surface of the right ventricle. One of these, the vein of Galen, larger than the rest, runs along the right border of the heart. They open separately into the lower part of the right auricle.

The Right Cardiac or Small Coronary Vein (v. cordis parva) runs along the groove between the right auricle and ventricle, to open into the right extremity of the coronary sinus. It receives blood from the back part of the right auricle and ventricle.

The Coronary Sinus (sinus coronarius) is that portion of the anterior or great cardiac vein which is situated in the posterior part of the left auriculo-ventricular groove. It is about an inch in length, presents a considerable dilatation, and is covered by the muscular fibres of the left auricle. It receives most of the veins of the heart. Besides those mentioned it receives the oblique vein of Marshall (v. obliqua atrii sinistri) from the back part of the left auricle, the remnant of the obliterated left Cuvierian duct of the foetus, described by Mr. Marshall. The great coronary sinus terminates in the right auricle, between the postcava and the auriculo-ventricular aperture, its orifice being guarded by a semilunar fold of the lining membrane of the heart, the Thebesian valve. All the veins joining this vessel, excepting the oblique vein above mentioned, are provided with valves.

The Venae Thebesii (venae cordis minimae) are numerous minute veins, which return the blood directly from the muscular substance, without entering the venous current. They open by minute orifices, foramina Thebesii (foramina venarum minarum), chiefly on the inner surface of the right auricle.
THE LYMPHATIC SYSTEM.

Lymph is obtained from the blood-plasma. From lymph the body cells obtain food, into lymph they discharge their waste materials, and there is a distinct lymphatic circulation, the constituents of the plasma passing into the perivascular lymph-spaces and returning to the heart by way of the lymphatics and certain veins.

The lymphatic system consists of lymphatic glands—large lymph-vessels, small lymph-vessels (lymphatic capillaries), the perivascular lymph-spaces, the lymph canalicular system, and the body cavities. To this system also belong the lacteal or chyliferous vessels. The lacteals are the lymphatic vessels of the small intestine, and differ in no respect from the lymphatics generally, excepting that during the process of digestion they contain a milk-white fluid, the chyle, which passes into the blood through the thoracic duct.

The lymph canalicular system is the system of spaces in areolar connective tissue. The spaces are called lymph-spaces, and are found practically in every region of the body. In these spaces lie the cells of the tissue. The larger spaces are lined with endothelium, the smaller spaces are not lined with endothelium; they form connections with each other by anastomotic channels and constitute a system of spaces and channels which many observers believe join the lymphatic capillaries. Others maintain that lymph-spaces are not direct continuations or expansions of lymph-capillaries, but that networks of lymphatic capillaries exist in the tissue immediately around each space, an arrangement which permits of interchange between the contents of a space and the contents of the surrounding capillaries. Mall seems to have proved this by his experimental injections into the portal vein. He showed that colored fluid injected into the portal vein passes through the walls of the venous capillaries, enters the lymph-spaces, and finally gets into the lymph-capillaries of the liver.

The perivascular lymph-spaces are found around certain blood-vessels. Each space is lined with endothelium, and is joined to other spaces by trabeculae of connective tissue. The spaces form a system, and the fluid in these spaces reaches the lymphatic capillaries. Perivascular lymph-spaces have been demonstrated in the Haversian canals and in the subdural space of the pia.

The pleural, pericardial, peritoneal, and synovial cavities are lined by endothelial cells. Beneath the layer of lining cells are lymph-spaces or lymph-vessels. It was long thought that these lymph-vessels communicate directly with the body cavity by means of numerous openings in the lining membrane. This view is probably incorrect. The subarachnoid space, the subdural space, the cavity for the aqueous humor of the eye, the cavity for the vitreous humor, and the space of Tenon are probably lymph-spaces.

Lymph-capillaries are arranged in networks, are larger than blood-capillaries, but the diameter of a lymph-capillary is different at different points, at some places being much larger than at others. Lymph-capillaries are formed of flattened endothelial cells. In some situations networks of lymphatic capillaries surround the blood-vessels. The lymph-vessels are called the lymphatics.

The lymphatics have derived their name from the appearance of the fluid contained in their interior (lympha, water). They are also called absorbents, from the
THE LYMPHATIC SYSTEM

property they possess of absorbing certain materials from the tissues and conveying them into the circulation. Larger lymphatics are called trunks and the largest are called ducts.

The lymphatics are exceedingly delicate vessels, the coats of which are so transparent that the fluid they contain is readily seen through them, and they appear milky-white; hence the name Ascellius gave them of lacteal veins. They retain a nearly uniform size, and may be cylindrical in shape, but usually are interrupted at intervals by constrictions which give them a knotted, beaded, or sac-like appearance. These constrictions are due to the presence of valves in the interior of the vessel. Lymphatic vessels do not invariably contain valves. Valves are absent at the starting points of lymphatics, are absent in lymphatic capillaries, are not numerous in the largest ducts (thoracic duct), and are seldom found in visceral lymphatics. The valves are not found in fixed situations and vary in number. Between the ends of the fingers and the axillary glands Sappey counted from sixty to eighty. "They are arranged in pairs and resemble the aortic semilunar valves." The lymphatic capillaries are composed purely of endothelium, but the collecting trunks possess not only an endothelial inner coat, but an investing elastico-muscular coat. Vessels in the subcutaneous connective tissue are devoid of muscle. Lymphatics have been found in nearly every texture and organ of the body which contains blood-vessels. Such non-vascular structures as cartilage, the nails, cuticle, and hair have none, but with these exceptions it is probable that eventually all parts will be found to be permeated by these vessels.

A larger lymphatic vessel is composed of three coats. The inner coat is composed of elastic tissue lined with endothelium. The middle coat is composed of elastic and muscular fibres. The external coat is composed of connective tissue intermixed with smooth muscular fibres longitudinally or obliquely placed.

The thoracic duct possesses a sub endothelial layer of connective tissue like that found in the arteries, and in the middle coat there is a longitudinal layer of connective tissue. The wall of a smaller lymphatic contains no elastic and no muscular tissue, and consists merely of connective tissue lined with endothelium.

The lymphatics are arranged in superficial and deep sets. The superficial lymphatics, on the surface of the body, are placed immediately beneath the integument, accompanying the superficial veins; they join the deep lymphatics in certain situations by perforating the deep fascia. In the interior of the body the lymphatics lie in the submucous areolar tissue throughout the whole length of the gastro-pulmonary and genito-urinary tracts, and in the subserous tissue of the thoracic and abdominal cavities. In the cranial cavity the perivascular sheaths are lymph-spaces. A plexiform network of minute, closed, capillary lymphatics may be found interspersed among the proper elements and blood-vessels of the several tissues, the vessels composing which, as well as the meshes between them, are much larger than those of the capillary blood-vessel plexus. From these networks small collecting vessels emerge, pass to a neighboring gland, and divide into a capillary network in the gland. Numerous small vessels emerge from the gland, which unite into one lymphatic vessel, which joins a larger lymphatic trunk, which empties into a branch of the precava. The deep lymphatics, fewer in number and larger than the superficial, accompany the deep blood-vessels. Their mode of origin is probably similar to that of the superficial vessels. The lymphatics of any part or organ exceed the veins in number and in capacity, but in size they are much smaller. Their anastomoses also, especially those of the large trunks, are more frequent, and are effected by vessels equal in diameter to those which they connect. The continuous trunks retain the same diameter throughout. As the lymphatic vessels

approach their point of discharge their number diminishes, but the calibre of the remainder does not increase in proportion.

The gaps in the connective tissue, the larger of which are lined with endothelium, the smaller of which are devoid of endothelial lining, are known as lymphatic spaces. (See page 772.)

The lymphatic or absorbent glands (lymphoglandulae), named also conglobate glands and lymph-nodes, are small, solid, glandular bodies situated in the course of the lymphatic and lacteal vessels. They vary from microscopic dimensions to the size of an olive, and their color, on section, is of a pinkish-gray tint, excepting the bronchial glands, which in the adult are mottled with black, the hepatic glands, which are yellow, and the splenic glands, which are brown. Each gland has a layer or capsule of cellular tissue investing it, from which prolongations dip into its substance, forming partitions. The lymphatic and lacteal vessels pass through these glands in their passage to the lymphatic ducts. A lymphatic or lacteal vessel, previous to entering a gland, divides into several small branches, which are named afferent vessels (vasa afferentia). As they enter the gland, the external coat of each becomes continuous with the capsule of the gland, and the vessels becoming much thinned, and consisting only of their internal or endothelial coat, pass into the gland, and branch out upon and in the tissue of the capsule, these branches opening into the lymph-sinuses of the gland. There is an extensive sinus beneath the capsule; from this subcapsular sinus numerous branches run inward to a central sinus. From both sinuses fine branches proceed to form a plexus, the vessels of which unite to form a single efferent vessel (vas efferens), which, on emerging from the gland, is again invested with an external coat from the gland capsule. The lymph-glands are filters through which lymph and chyle flow. Carcinoma cells are caught in them, and the dissemination of the disease is retarded. In the glands are masses of newly formed leukocytes which attack any bacteria in the lymph or chyle.

The size of the lymphatic glands decreases as age advances, and in very old individuals many glands actually disappear. It is impossible to estimate the number of macroscopic glands. Sappey estimated the number to be from 600 to 700. Glands are embedded in fat and are distinctly movable. Some of them are superficial (above the deep fascia); others are deep (below the deep fascia). Occasionally a gland exists alone, but, as a rule, they are assembled in communities or chains of from eight to twelve, or even more. They are usually arranged around vessels, and often are upon vessels. The glands have a plentiful blood-supply, and contain not only vascular nerves, but definite nerve-plexuses. Besides the glands, the body contains numerous lymphoid areas, which, in structure and function, are allied to lymph-glands (tonsils, Peyer's patches, etc.).

Hemolymph nodes exist in various regions, but are most common in the abdomen in front of the vertebrae. They are like ordinary lymph-nodes in form and also in size, but differ from them in being deep red instead of light pink. Some regard hemolymph nodes as structures like the spleen; others regard them as very vascular but otherwise ordinary nodes.
Surgical Anatomy.—In an operation for cancer it is not sufficient to cut wide of the growth and remove it; it is imperatively necessary to remove the lymphatic glands which receive lymph from the diseased area, and also, when possible, the lymphatic vessels between the cancer and the glands. Glands are diseased very early in cancer, long before they are palpably enlarged, and are usually infected by emboli of cancer cells. The rule is in any cancer, however recent, to regard the associated glands as diseased, whether enlarged or not, and to thoroughly remove them, if possible, in one piece, with the intervening lymph-vessels and the area of primary malignant growth.

THE THORACIC DUCT AND THE RIGHT LYMPHATIC DUCT.

The thoracic duct or the left lymphatic duct (ductus thoracicus) (Fig. 482) conveys the great mass of lymph and chyle into the blood. It is the common trunk of all the lymphatic vessels of the body below the Diaphragm, and usually, but not always, also receives the lymph from the left side of the body above the Diaphragm. It does not drain the right side of the head and neck, the right upper extremity, the right lung, right side of the heart, and the convex surface of the liver. It partly drains the right chest wall. It varies in length from fifteen to eighteen inches in the adult, and extends from the second lumbar vertebra to the root of the neck. The duct is formed by the union of the right and left lumbar trunks (trunci lumbales), from the lumbar lymph-nodes. The left lumbar trunk also obtains lymph from the coeliac and mesenteric nodes. A little distance above its origin the thoracic duct usually presents a triangular dilatation, the receptaculum chyli or the reservoir or cistern of Pecquet (cisterna chyli), which is situated upon the front of the bodies of the first and of the second lumbar vertebra, to the right side and behind the aorta, by the side of the right crus of the Diaphragm. The receptaculum is absent in some individuals. The thoracic duct ascends into the thorax through the aortic opening in the Diaphragm, lying to the right of the aorta, and is placed in the posterior mediastinum in front of the vertebral column, lying between the aorta and vena azygos major. Opposite the fourth thoracic vertebra it inclines
toward the left side, and ascends behind the arch of the aorta on the left side of the oesophagus, and behind the first portion of the left subclavian artery, to the upper orifice of the thorax. Opposite the seventh cervical vertebra it turns outward and then curves downward over the subclavian artery and in front of the Scalenus anticus muscle, so as to form an arch, and terminates in the left subclavian vein at its angle of junction with the left internal jugular vein. It usually opens at the apex of the angle in the superior and outer surface, but may open on the posterior surface. Sometimes it terminates by two branches. Figs. 482 and 484 show the termination of the thoracic duct. The thoracic duct, at its commencement, is about equal in diameter to that of a goose-quill, diminishes considerably in its calibre in the middle of the thorax, and is again dilated just before its termination, the ampulla. It is generally flexuous in its course, the older the person the greater the flexuosity, and it is constricted at intervals so as to present a varicose appearance. The thoracic duct not infrequently divides in the middle of its course into two branches of unequal size, which soon reunite, or divides into several branches, which form a plexiform interlacement. It occasionally divides, at its upper part, into two branches, of which the one on the left side terminates in the usual manner, while that on the right opens into the right subclavian vein, in connection with the right lymphatic duct. The thoracic duct has several valves throughout its whole course, but they are more numerous in the upper than in the lower part, and the lower valves are not competent; at its termination it is provided with a pair of competent valves, the free borders of which are turned toward the vein, so as to prevent the passage of venous blood into the duct.

The common intestinal trunk (truncus intestinalis) (Figs. 482, 483, and 509) empties into the receptaculum and brings lymph from the small intestine (lacteals), the stomach, the pancreas, and the spleen.

Radicals of Origin and Tributaries.—In most individuals the juxta-aortic glands which are placed on each side of the aorta send a vessel upward and inward, which unite to form the thoracic duct. The right vessel is known as the truncus lymphaticus lumbalis dextra. The left vessel is known as the truncus lymphaticus lumbalis sinistra. A vessel from the glands in front of (pre-aortic) and back (retro-aortic) of the aorta empties into each of the above-named vessels. In some cases a large vessel forms from the glands in front of the aorta and helps form the duct. The receptaculum chyli receives the common intestinal lymphatic trunk, which conveys lymph from the small intestine, stomach, spleen, pancreas, and a portion of the liver.

![Fig. 482.—Modes of origin of the thoracic duct. a, thoracic duct; a', receptaculum chyli; b, common trunk of the efferents of the right juxta-aortic glands; c, common trunk of the efferents of the left juxta-aortic glands; d, one of these efferents passing through the left pillar of the diaphragm; e, right juxta-aortic gland; f, left juxta-aortic gland; h, retro-aortic gland; j, common trunk of the pre-aortic glands (truncus intestinalis); j, collecting trunks of the intercostal lymphatics, which reach the receptaculum chyli by taking the downward course. (Poirier and Charpy.)](image-url)
The branches of the left lymphatic duct are: 1. A descending trunk, which collects lymph from the posterior intercostal glands of the seven lower intercostal spaces. 2. A trunk is formed by vessels coming from the superior juxta-aortic glands beneath the Diaphragm. 3. The lymphatic vessels form the upper five intercostal spaces. 4. The lymphatic vessels form the posterior mediastinal glands and retrosternal glands. 5. The left jugular trunk (truncus jugularis), although this may open directly into the junction of the subclavian and internal jugular veins. 6. In rare cases the thoracic duct receives near its termination the left subclavian trunk (truncus subclavius) and a broncho-mediastinal trunk. As a rule, however, the two last-mentioned trunks empty into the jugulo-subclavian junction separately or as one duct.

The thoracic duct receives the lymph from the extremities, the deep portion of the abdominal wall and of the pelvic wall, the pelvic viscera, the kidneys and suprarenal capsules, the large intestine, the small intestine, the walls of the thoracic cavity, the under surface and anterior portion of the liver, the stomach, the spleen, the pancreas, the sternal and intercostal glands, the left lung, left side of the heart, trachea, and oesophagus, and often, just before its termination, the lymphatics of the left side of the head and neck, and of the left upper extremity.

Structure.—The thoracic duct is composed of three coats, which differ in some respects from those of the lymphatic vessels. The internal coat consists of a single layer of flattened endothelial cells; of a subendothelial layer, similar to that found in the arteries; and an elastic fibrous coat, the fibres of which run in a longitudinal direction. Each endothelial cell is shaped like a lance-head and has serrated borders. The middle coat consists of a longitudinal layer of white connective tissue with elastic fibres, external to which are several laminae of muscular tissue, the fibres of which are for the most part disposed transversely, but some are oblique or longitudinal. The muscular fibres are intermixed with elastic fibres. The external coat is composed of arcular tissue, with elastic fibres and isolated fasciculi of muscular fibres.

The Right Lymphatic Duct (Ductus Lymphaticus Dexter) (Figs. 482, 485, 486, 509).

A right lymphatic duct is frequently present. It is a short trunk, about half an inch in length and a line or a line and a half in diameter. It is formed by the union of the right jugular, right broncho-mediastinal, and right subclavian trunks. Often on the right side the jugular, subclavian, and broncho-mediastinal trunks
are double. Usually they open into the junction of the internal jugular and subclavian veins separately. Sometimes they unite and open by one duct, and that is the right lymphatic duct. The orifice of the right lymphatic duct is guarded by two semilunar valves, which prevent the passage of venous blood into the duct.

**Tributaries.**—The right lymphatic duct, if present, receives lymph from the right side of the head and neck, the right upper extremity, the right side of the thorax, the right lung, and the right side of the heart, and from part of the convex surface of the liver.

**LYMPHATICS OF THE CRANIAL REGION, FACE, AND NECK.**

It is customary to divide the lymphatics of this region into *intracranial* and *extracranial* lymphatics. The statement is made by Poirier and Cunéo¹ that the brain and its membranes are without lymphatics. They state that there are spaces in the nervous centres comparable to lymphatic channels, but which are not truly lymphatic vessels and which are regarded by most as independent of the lymphatic system. Other writers believe that there are *cerebral* and *meningeal lymphatic vessels*. It is highly probable that the perivascular spaces around the cerebral arteries are the beginning of a cerebral lymph system, and that these perivascular lymph-channels pass out of the cranium with the arteries and the internal jugular vein and terminate in the superior deep cervical glands. It is also probable that lymph-spaces surround the dural blood-vessels and terminate in the superior deep cervical and the internal maxillary glands.

The *extracranial lymphatics* are divided into *superficial* and *deep*, and the two systems freely communicate. All of these vessels run into glands about the head and neck. The superficial lymphatics take origin in the subcutaneous tissue and superficial muscles. The deep vessels arise in the orbit, mouth, nose, pharynx, esophagus, tongue, larynx, and the muscular, ligamentous, and osseous structures.

**The Lymphatic Glands of the Head and Face.**

The lymphatic glands of the head and face are as follows:

1. The Occipital.
2. The Posterior Auricular.
3. The Parotid and Subparotid.
4. The Internal Maxillary.
5. The Facial.

¹ Article on the Lymphatics in the Treatise on Human Anatomy. By Poirier and Charpy.
The Occipital or Suboccipital Glands (lymphoglandulae occipitales) (Figs. 486 and 487).—There are only two or three of these glands on each side. They are situated beneath the deep fascia, a little in front of the anterior edge of the Trapezius muscle, near to but seldom upon the insertion of the Complexus muscle. They receive lymph from the occipital region of the scalp and from them it is sent to the upper deep cervical glands.

The Posterior Auricular Retro-auricular or Mastoid Glands (lymphoglandulae auriculares posteriores) (Figs. 486, 487, and 491).—There are two of these on each side. They are situated just beneath the lower margin of the Retrahens aurem muscle. They receive lymph from the parietal lymph-vessels, "from the internal surface of the auricle, with the exception of the lobule, and from the posterior surface of the external auditory meatus." The lymph-vessels from these glands empty into the upper deep cervical glands.

The Parotid Lymph-glands (lymphoglandulae auriculares anteriores) (Figs. 486, 487, and 488) are divided into two groups, the superficial and the deep.

The Superficial Parotid or Pre-auricular Lymph-glands.—The superficial parotid lymph-glands are not the subcutaneous lymph-glands occasionally but very rarely found in this region, and which have been described by Richet, but are lymph-nodes situated between the parotid fascia and the parotid salivary gland. There may be three glands, two glands, or only one gland.

The Deep Parotid Lymph-glands.—The deep parotid lymph-glands are situated within the parotid salivary gland. There are from fifteen to twenty of the deep glands. The parotid glands receive lymph from the eyelids, eyebrows, the root of the nose, upper portion of the cheek, frontal portion of the scalp, temporal portion of the scalp, from the outer surface of the pinna, from the external auditory meatus, from the tympanum, and possibly from the mucous membrane of the nose, the
posterior alveolar region of the superior maxillary bone, and the soft palate. Lymphatics pass from the superficial parotid glands into the superficial cervical and the upper deep cervical glands. Lymphatics pass from the deep parotid glands into the upper deep cervical glands.

The Subparotid Glands (*lymphoglandulae parotidae*).—The subparotid glands lie between the parotid salivary gland and the pharynx, and they are close to the internal carotid artery and the internal jugular vein. They receive lymph from the nasal fossae, naso-pharynx, and Eustachian tube, and send vessels to the upper deep cervical glands.

The Internal Maxillary or Zygomatic Glands (*lymphoglandulae faciales profundae*) (Fig. 486).—The internal maxillary glands lie in the course of the internal maxillary artery in the anterior pharyngeal wall. They receive vessels from the naso-pharynx, palate, zygomatic fossa, temporal fossa, and orbit. From them vessels go to the upper deep cervical glands.

The Facial Glands or Genial Glands (*lymphoglandulae faciales*) (Figs. 487, 488, and 489).—The facial glands lie in three groups in the course of the lymphatic vessels which are passing to the submaxillary glands. According to Poirier and Cunéo the supramaxillary or inferior group (Fig. 489) lies upon the outer surface of the mandible, at the anterior margin of the Masseter muscle, and beneath the Platysma myoides. There may be only one or two glands in this group, but often there are ten or twelve. These glands lie about the facial artery and vein and are not constantly present. In many cases a salivary gland, the inframaxillary (Fig. 489), is interposed between the supramaxillary and submaxillary glands. The buccinator, buccal, or middle group (Figs. 486 and 489) is present in about one-third of the subjects and lies upon the outer surface of the Buccinator muscle external to the buccal fascia. Some of these glands are situated in the region where Steno’s duct perforates the Buccinator muscle. Others are beneath the posterior fibres of the Zygomaticus major muscle.

The superior group of facial glands (Fig. 489) includes a malar gland, a suborbital gland, and a gland in the naso-genial groove.¹ An anterior gland is sometimes found, subcutaneous, on the outer surface of the Orbicularis oris muscle, the commissural gland.

The Lymphatic Vessels of the Cranial Region (Fig. 486).

The lymphatic vessels of the cranial subcutaneous tissues are divided into anterior, lateral, and posterior. The anterior or frontal terminate in the parotid

lymph-glands. The lateral or parietal terminate in the parotid and mastoid lymph-glands. The posterior or occipital terminate in the sterno-mastoid and occipital glands.

The Lymphatic Vessels of the Face, the Interior of the Nose, Tongue, Floor of the Mouth, Pharynx, Larynx, and Thyroid Gland (Figs. 486, 488, 489, 490, 491, 492).

The lymphatic vessels of the face are more numerous than those of the cranial region, and commence over its entire surface. Those from the frontal region accompany the frontal vessels; they then pass obliquely across the face, running with the facial vein, pass through the glands on the buccal surface of the Buccinator muscle, and join the submaxillary lymphatic glands. The submaxillary lymph glands receive the lymphatic vessels from the lips, and are often found enlarged in cases of malignant disease of those parts.

The lymphatics of the orbit and of the temporal and zygomatic fossae run with the branches of the internal maxillary artery to the maxillary glands, and afterward to the deep cervical glands.

![Diagram](image_url)  
**Fig. 490.—The lymphatics of the tongue; anterior view. (Poirier and Charpy.)**

The lymphatics of the nose can be injected from the subdural and subarachnoid spaces. They terminate in the retro-pharyngeal and suprahyoid glands. The lymphatics of the tongue (Fig. 490) chiefly accompany the ranine vein first to the
lingual glands and from these to the deep cervical glands. The lymphatics from the anterior part of the tongue and floor of the mouth pierce the Mylo-hyoid muscles and so reach the submaxillary lymph-glands. From the upper part of the pharynx the lymphatics pass to the retro-pharyngeal glands; from the lower part of the pharynx to the deep cervical glands. From the larynx two sets of vessels arise: an upper, piercing the thyro-hyoid membrane and joining the upper set of deep cervical glands; and a lower, perforating the crico-thyroid membrane to join the lower set of deep cervical glands. The lymphatics of the thyroid gland accompany the superior and inferior thyroid arteries, and open partly into the upper and partly into the lower set of deep cervical glands.

The Lymphatic Glands of the Neck.

The lymphatic glands of the neck are:
1. The Superficial Cervical, including the external jugular and the superficial anterior cervical.
2. The Submaxillary.
3. The Submental.
4. The Retro-pharyngeal.
5. The Deep Cervical, including the anterior deep cervical.

The Superficial Cervical Glands (lymphoglandulae cervicales superficiales) (Figs 486 and 491).—The superficial cervical glands are composed of two groups, the external jugular and the superficial anterior cervical glands.

The External Jugular Glands (Figs. 488 and 491).—The external jugular glands are superficial to the Sterno-cleido-mastoid muscle. They are four to six in number and lie along the external jugular vein upon the outer surface of the deep cervical fascia, each gland occupying a depression in the fascia. The sternocleido-mastoid muscle is beneath them. They are usually gathered in a group a little below the parotid gland, but sometimes extend to the middle of the vein. They receive vessels from the occipital, the posterior auricular, the parotid, and the submaxillary lymph-glands, from the auricle, and from the skin and subcutaneous structures of the neck. From them lymphatic vessels pass to the upper deep cervical and to the lower deep cervical glands.
The Superficial Anterior Cervical Glands.—The superficial anterior cervical glands lie along the anterior jugular vein and from them vessels pass to the deep cervical glands.

The Submaxillary or Lateral Suprahyoid Glands (lymphoglandulae submaxillares) (Figs. 486, 487, and 488).—The submaxillary glands are in the submaxillary triangle beneath the deep fascia. They number three to six; are embedded in the superficial surface of the sheath of the submaxillary gland, but are not found within the sheath. Occasionally one or two are found in the deep portion of the sheath toward the floor of the mouth. The middle gland of Stahr is situated at the point where the submaxillary group is crossed by the facial artery. This is the largest gland of the group. The submaxillary glands receive vessels from the "nose, the cheek, the upper lip, and the external part of the lower lip, almost the whole of the gums, and the anterior third of the lateral border of the tongue." They also obtain lymph from the floor of the mouth and from the sublingual and submaxillary salivary glands. They send vessels to the jugular and to the upper deep cervical glands.

The Submental or Median Suprahyoid Glands (Figs. 486, 487, and 490).—There are usually two glands situated between the anterior bellies of the two digastric muscles and upon the Mylo-hyoid muscle. They receive lymph from the cutaneous surface of the chin, from the cutaneous and mucous surfaces of the central portion of the lower lip, from the central portion of the gums, from the floor of the mouth, and from the tip of the tongue. They send some vessels to the submaxillary lymph-glands, and frequently a gland is interposed on the anterior belly of the Digastric muscle. They send other vessels to the upper deep cervical glands.

The Retro-pharyngeal or Post-pharyngeal Glands (Fig. 492).—The retro-pharyngeal glands are placed between the upper lateral portion of the posterior part of the pharynx and the first two cervical vertebrae. Leaf tells us that, as a rule, there is but one gland on each side, though two may be present. The retro-pharyngeal glands lie upon the Rectus capitis anticus major muscle, which separates them from the vertebra. They receive vessels from the muscles and fascia in front of the vertebrae, from the nasal fossæ and accessory cavities, from the naso-

---

THE LYMPHATIC GLANDS OF THE NECK

pharynx and Eustachian tube, and possibly from the cavity of the tympanum. They send vessels to the upper deep cervical glands.

The Deep Cervical, Carotid, or Sterno-mastoid Glands (lymphoglandulæ cervicæ profundæ) (Figs. 486, 487, 488, 490, 491, and 492).—The deep cervical glands are divided into the upper deep cervical and the lower deep cervical, and are associated with certain accessory glands, including the jugular and superficial anterior cervical, which have been discussed under the head of superficial cervical glands; and the anterior deep cervical and the recurrent glands, which have not yet been studied. The deep cervical chain extends from the apex of the mastoid process of the temporal bone to the junction of the internal jugular and subclavian veins.

The Upper Deep Cervical or Substernomastoid Glands (lymphoglandulæ cervicæ profundæ superiores).—The upper deep cervical glands extend from the tip of the mastoid process of the temporal bone to about the region where the common carotid artery is crossed by the Omo-hyoid muscle. One group, the external group, is placed external and posterior to the internal jugular vein. The glands are small and numerous, are embedded in the fatty tissue about the nerves from the deep cervical plexus, and at the posterior margin of the Sterno-cleido-mastoid muscle constitute a continuous mass passing to join the subclavian glands. Another group, known as the internal group or the internal jugular glands, lie directly upon or close by the outer border of the internal jugular vein. This group forms a chain along the internal jugular vein, and the glands are of larger size than those of the external group. Some glands of this group are beneath the vein. The glands of the internal jugular group communicate freely with each other and with the external group. The external group receives lymph-vessels from the posterior auricular, occipital, and external jugular glands, from the occipital region of the scalp, from the auricle, and from the skin, subcutaneous tissue, and muscles of the upper portion of the neck. The internal group receives lymph-vessels from the retro-pharyngeal, parotid, subparotid, sub-maxillary, and submental glands, the anterior cervical glands (superficial and deep), and the recurrent glands, and from the tongue, naso-pharynx, larynx, soft palate, roof of the mouth, oesophagus (cervical portion), nasal fossae, trachea (cervical portion), and the thyroid gland. The external group terminates in the supraclavicular glands. The internal jugular group terminates in the jugular trunk, which, on the right side, helps to form the right lymphatic duct or empties directly into the junction of the internal jugular and subclavian veins, and on the left side empties directly into the venous junction or into the thoracic duct.

The Lower Deep Cervical or Supraclavicular Glands (lymphoglandulæ cervicæ profundæ inferiores).—The lower deep cervical glands lie along the internal jugular vein in the lower part of its course. They receive lymph-vessels from the superficial cervical glands, the upper deep cervical glands, the axillary glands, the accessory chain, the occipital region of the scalp, the skin of the neck, the lower prevertebral muscles, the skin of the pectoral and mammary regions, and the skin of the arm. The supraclavicular glands send vessels which unite with the vessels of the upper deep glands to form the jugular lymphatic trunk. The jugular trunk on the right side may empty directly into the junction of the internal jugular and subclavian veins or may unite with the subclavian trunk to form the right lymphatic duct. On the left side it may empty into the thoracic duct or directly into the venous junction.

Accessory Chains to the Deep Cervical Glands.—The accessory chains to the deep cervical glands are: 1. The external jugular glands (p. 783). 2. The superficial anterior cervical (p. 784). 3. The prelaryngeal or infralaryngeal glands (Fig. 486)

2 Ibid.
between the Crico-thyroid muscles. They receive lymph from the trachea, larynx, and thyroid gland, and send vessels to the pretracheal glands and to the upper deep cervical glands. 4. The **tracheal or pretracheal glands** (Fig. 486) lie upon the front of the trachea, receive vessels from the trachea, thyroid body, and prelaryngeal glands, and send vessels to the lower deep cervical glands. Some anatomists speak of the prelaryngeal and the pretracheal glands as the **anterior deep cervical glands**. 5. The **recurrent glands** lie on the sides of the oesophagus and trachea, by the recurrent laryngeal nerves. They receive vessels from the larynx, trachea, oesophagus, and thyroid gland, and send vessels to the upper and lower deep cervical glands.

**The Lymphatic Vessels of the Neck** (Figs. 486, 490, 491).

The superficial and deep cervical lymphatic vessels are continuations of those already described on the cranium and face. After traversing the glands in those regions, they pass through the chain of glands which lie along the sheath of the carotid vessels, being joined by the lymphatics from the pharynx, oesophagus, larynx, trachea, and thyroid gland. At the lower part of the neck, after receiving some lymphatics from the thorax, they unite to form the **jugular trunk** (Fig. 485), which often terminates, on the left side, in the thoracic duct, and on the right side, in the right lymphatic duct, but which may on either side open directly into the vein.

**Surgical Anatomy.**—In **secondary syphilis** there is general enlargement of the lymphatic glands, and in the posterior triangle of the neck the enlarged glands are distinctly palpable. The occipital glands may enlarge because of inflammation or suppuration about the occipital region of the scalp, and the posterior-auricular glands enlarge from inflammation or suppuration of the temporal portion of the scalp, the external ear (except the lobule), and the external auditory meatus. Otorrhoea sometimes causes them to enlarge.

The cervical glands are very frequently the seat of **tuberculous disease**. This condition is usually preceded by a lesion in those parts from which they receive their lymph. The lesion may be tuberculous or inflammatory. If tuberculous it furnishes bacilli directly to the lymph. If inflammatory it lessens tissue resistance and opens the portals to infection. The glands receive the lymph from the seat of primary disease and become tuberculous. It is very desirable, therefore, for the surgeon, in dealing with these cases, to possess a knowledge of the relation of the respective groups of glands to the periphery. Some years ago Sir Frederick Treves prepared a table to show to what glandular group lymph from each region is sent. The table is practically as follows:

**Scaple.**—Posterior part = suboccipital and mastoid glands. Frontal and parietal portions = parotid glands.

Lymphatic vessels from the scalp also enter the superficial cervical set of glands.

**Skin of face and neck** = submaxillary, parotid, and superficial cervical glands.

**External ear** = superficial cervical glands.

**Lower lip** = submaxillary and submaxillary glands.

**Buccal cavity** = submaxillary and upper set of deep cervical glands.

**Gums of lower jaw** = submaxillary glands.

**Tongue.**—Anterior portion = submaxillary and submaxillary glands. Posterior portion = upper set of deep cervical glands.

**Tonsils and polate** = upper set of deep cervical glands.

**Pharynx.**—Upper part = parotid and retro-pharyngeal glands. Lower part = upper set of deep cervical glands.

**Larynx, orbit, and roof of mouth** = upper set of deep cervical glands.

**Nasal fossae** = retropharyngeal glands, upper set of deep cervical glands. Some lymphatic vessels from posterior part of the fossae enter the parotid glands.

Treves’s table indicates the glands usually involved, but the seat of primary disease cannot invariably be affirmed from the knowledge of the seat of glandular involvement, because the course of the lymphatic vessels is sometimes varied from that which usually maintains; for instance, in some cases lymphatics from the right side of the tongue pass to glands in the left side of the neck.

Glands may **enlarge** directly because of primary inflammation, injury, or tumor; but usually a glandular enlargement is secondary to a bacterial disease or to cancer involving the lymph-vessels which come to the gland. The seat of disease may be distant. Disease of the nasal fossae may cause **retropharyngeal abscess** or enlargement of the submaxillary glands. **Cancer of the breast, stomach, or oesophagus** may be followed by disease of the cervical glands. Dis-
THE LYMPHATIC GLANDS OF THE UPPER EXTREMIT Y 787

ease of the teeth, tongue, gums, floor of the mouth, and alveolar processes may cause enlargement of the submaxillary and other glands, and disease of the tonsil may lead to enlargement of the glands at the angle of the jaw.

The modern radical surgery of cancer depends on a knowledge of these glandular relations, and consists in thoroughly removing the growth and also the associated lymphatic glands, and, when possible, the lymph-vessels running from the tumor to the glands. The lower deep cervical glands occasionally enlarge secondarily to malignant growths of the abdomen or mediastinum, but this is not due to a direct flow of lymph, as the mediastinal glands do not send vessels to the supravacuicular glands. It is due to blocking of lymphatic vessels and reversal of the lymph-stream, so that lymph containing cancerous cells regurgitates.

A retropharyngeal abscess begins to the side of the pharynx. It enlarges toward the centre rather than from it, because the constrictions of the pharynx limit the outward progress of the pus.

The glands within the parotid salivary gland not unusually become tuberculous, and the surgeon may be led to believe that the salivary gland is the seat of primary disease.

Sometimes, though seldom, after the extensive removal of lymph-glands the region drained by their tributaries becomes the seat of persistent hard oedema (lymph oedema). It used to be thought that wounds of the thoracic duct were of necessity fatal, but it is now known that, unless close to the vein, they are seldom even very dangerous. It may be possible to suture a partly divided duct. In an unsutured wound of the duct recovery follows if a collateral lymphatic circulation is established.

THE LYMPHATICS OF THE UPPER EXTREMIT Y.

The Lymp thic Glands of the Upper Extremity.

The lymphatic glands of the upper extremity are divided into two sets, superficial and deep.

Superficial Lymphatic Glands (Figs. 493 and 501).—The superficial lymphatic glands of the upper extremity are few in number and small in size. They lie in the subcutaneous tissue. They are not receiving depots of great areas, but interrupt lymphatic vessels here and there. The glands in the axilla receive all of the lymphatic vessels, superficial and deep. There may be three sets of superficial glands.

One set, the ante-cubital glands, lies in front of the elbow. These glands are often absent. When these glands are present they receive vessels from the anterior portion of the forearm and the middle of the palm. The vessels from them pass upward along the front and inner aspect of the arm.

Another superficial gland lies above the internal condyle. It is the supratrochlear or supraepitrochlear gland or group of glands. There is usually but one gland, but there may be two or more. It receives vessels from the inner portion of the hand, the three inner fingers; and the inner portion of the forearm, but, because of free anastomoses, also may receive lymph from any portion of the hand and forearm. Lymph-vessels from the supratrochlear gland pass up along the basilic vein to the axillary glands.

There are sometimes several small glands by the cephalic vein in the groove between the Deltoid and great Pectoral muscles. These are called infraclavicular glands. The lymph-tract from the infraclavicular glands does not terminate in the axillary glands, but ends in the subclavian glands.

The Deep Lymphatic Glands of the Upper Extremity or the Axillary Glands (lymphoglandulae axillares) (Figs. 493, 494, 495, 496, and 501).—The chief deep glands are situated adjacent to the axillary vessels. There are also a few small glands along the radial, ulnar, and brachial arteries which receive deep lymphatics from bones, muscles, and ligaments, and send lymphatics to the axillary glands. The axillary glands number from fifteen to thirty-five in each axilla. They are embedded in the axillary fat and receive the lymphatic vessels from the upper

1 Dudley P. Allen's case. See Allen and Briggs, in American Medicine, September 21, 1901.
2 Harvey Cushing, Annals of Surgery, June, 1898.
extremity, from the skin of the upper portion of the chest, from the Pectoral muscles, and from the mammary gland. The following division of the axillary glands is made by Poirier, Cunéo, and Delamare: 1. An **external** group, the **humeral chain**, lying on the inner surface of the vessels and nerves, particularly the axillary vein, to the sheath of which they are adherent. Occasionally one or several of these glands are found beneath the vein. Some of the vessels from these glands pass into the central group of lymph-nodes; others enter the subclavian glands; others pass above the clavicle and terminate in glands situated in that region. 2. An **anterior group**, the **thoracic chain**, called also the **pectoral glands** (*lymphoglandulae pectorales*). One mass of this chain, the **supero-internal**, is situated in the second or third intercostal space in front of the long thoracic artery and beneath the lower edge of the great Pectoral muscle. Another mass, the **infero-external**, is situated in the fourth and fifth intercostal spaces along the course of the long thoracic artery. The vessels from this chain end in the central group, and some few of them in the subclavian glands. 3. A **posterior group**, the **scapular chain**, lying along the dorsalis

---

scapulae artery in the groove between the Teres major and the Subscapularis muscles. They send vessels to the humeral and central chains.

4. A central

**Fig. 495.**—Lymphatics of the antero-lateral portion of the thorax. (Sappey.)
group, the intermediate glands, placed near the base of the axilla, between the previously described chains. Their efferent vessels end in the subclavian glands. The glands of the central group in many individuals protrude through the opening in the axillary fascia known as the foramen of Langer (Fig. 312). 5. A subclavian group, situated above the upper margin of the lesser Pectoral muscle. Most of them are internal to the axillary vein, "between this vein and the first digitation of the Serratus magnus." The humeral chain and the thoracic chain come together and form the subclavian group of glands situated at the apex of the axilla. From the axillary glands come many vessels which, by anastomosing, form the infraclavicular plexus, they then unite into a trunk, the subclavian trunk, which courses between the subclavian vein and Subclavius muscle. On the right side it empties into the junction of the internal jugular and subclavian vein or unites with the jugular trunk to form the right lymphatic duct. On the left side it may empty into the venous junction or into the thoracic duct.

![Diagram of the lymphatic system](image)

**Fig. 496.—Scheme of the axillary glands.** The dotted line indicates the position of the clavicle. (Poirier and Charpy.)

### The Lymphatic Vessels of the Upper Extremity (Figs. 493, 494, 495, 496, 497).

The lymphatic vessels of the upper extremity are divided into the superficial and the deep.

**The Superficial Lymphatic Vessels of the Upper Extremity.**—The superficial vessels begin as plexuses in the skin and form vessels which ascend in the subcutaneous tissue. These plexuses are particularly plentiful in the palm and palmar surface of the digits (Fig. 497). On each side of each finger two lymph-vessels are formed; they ascend toward the hand, cross the dorsum, and anastomose frequently with each other. The vessels from the dorsum of the hand join the lymph-vessels of the forearm, which ascend chiefly along the superficial veins. The lymph-vessels which ascend with the superficial ulnar vein pass into the supratrochlear gland. The vessels which accompany the median veins pass into the ante-cubital or supratrochlear glands. Some of the lymph-vessels on the radial side of the forearm run up along the cephalic vein. All the other lymph-vessels of the upper extremity pass direct to the axillary glands. In the forearm there are about thirty vessels, in the middle of the arm there are from fifteen to eighteen (Sappey).

**The Deep Lymphatic Vessels of the Upper Extremity.**—The deep lymph-vessels convey the lymph from bone, periosteum, muscle, ligament, etc. They pass up the limb with the chief vessels, there usually being two trunks to each artery.
In the arm there are two or three vessels. Some few vessels terminate in the small glands along the radial, ulnar, and brachial arteries, but most of them pass directly to the axillary glands.

**Surgical Anatomy.**—In malignant diseases, or other affections implicating the upper part of the back and shoulder, the front of the chest and mamma, the upper part of the front and side of the abdomen, or the hand, forearm, or arm, the axillary glands are liable to be found enlarged.

In *secondary syphilis* the supratrochlear gland is found to be enlarged. This gland is subcutaneous and readily palpable when enlarged. Normal axillary glands cannot be palpated. The axilla is a passage-way for structures between the neck and the upper extremity, and purulent collections or tumors may extend from the neck into the axilla or from the axilla into the neck.

The axillary glands are involved early in cases of cancer of the mammary gland, and later the lower deep cervical glands are involved, and, as Snow has pointed out, regurgitation of lymph-containing cancer cells leads to retrosternal involvement and to secondary cancer of the head of the humerus. In operating for cancer of the breast, follow the principle of Halsted and remove the breast, the skin over it, the muscles and fascia, the lymph-vessels, and the axillary glands in one piece. By this plan thorough removal is possible, and as lymph-vessels containing carcinoma cells are not cut across, the wound is not grafted with malignant epithelial cells. Diseased axillary glands are apt to adhere to the sheath of the vein. In removing cancerous glands, always excise the sheath of the vein.

**THE LYMPHATICS OF THE LOWER EXTREMITY.**

The Lymphatic Glands of the Lower Extremity.

The lymphatic glands of the lower extremity are divided into two sets, superficial and deep. The superficial are confined to the inguinal region, forming the superficial inguinal lymphatic glands.

The **Superficial Inguinal Lymphatic Glands** (*lymphoglandulae inguinales superficiales*) (Figs. 498, 499, 500, and 501).—The superficial inguinal lymphatic glands, placed immediately beneath the integument in Scarpa's triangle, are of large size, and vary in number from ten to twenty. It is customary to divide these glands into groups according to the region in which they are found. The following division is suggested by Poirier, Cunéo, and Delamare: A horizontal line carried through the saphenous opening divides the glands into two groups, a **superior group** and an **inferior group**. A vertical line through the saphenous opening divides each of the two groups into two secondary groups, an **external** and an **internal group**. We thus have an **external and superior group**, and an **internal and superior group**, an **external and inferior group**, and an **internal and inferior group**.

---

1 The Lymphatics. Translated and edited by Cecil H. Leaf.
Directly in the saphenous opening there are often several glands constituting a central group.

Leaf points out that a gland usually exists near the saphenous opening, which is interposed between the superficial inguinal and deep inguinal glands. The superior group of glands, sometimes called the oblique group, is so placed that the
glands lie with a certain regularity along and below Poupart's ligament, the long axis of each gland corresponding with the direction of the ligament. It is now known that each group of the superficial glands does not receive with regularity the lymph from and only from a definite and accurately determined area. Hence, it is not possible, as was once taught, to determine with certainty the exact situation of a lesion by the group of superficial glands involved. The superficial inguinal
glands receive vessels from the skin of the lower extremity, gluteal region, perineum, abdominal wall, scrotum, anus, and from the prepuce of the clitoris and penis. Occasionally, though not normally, they receive vessels from the glans penis and glans clitoris. The superficial glands send vessels to the deep inguinal glands and to the external iliac glands, and these vessels penetrate the femoral sheath. The vessels which go to the iliac glands ascend with the femoral vessels. Leat figures some of the efferent vessels from these glands as terminating directly in the veins of this region.

Surgical Anatomy.—The superficial inguinal glands frequently become enlarged in diseases implicating the parts from which their lymphatics originate. Thus, in malignant or syphilitic affections of the prepuce and penis, or of the labia majora in the female, in cancer scroti, in abscess in the perineum, and in other diseases affecting the integument and superficial structures in those parts, or the subumbilical part of the abdominal wall or the gluteal region, the upper chain of glands is almost invariably enlarged, the lower chain being implicated in diseases affecting the lower limb.

The Deep Lymphatic Glands of the Lower Extremity.—The deep glands are the inguinal, anterior tibial, popliteal, gluteal, and ischiatic.

The Deep Inguinal or Deep Femoral Lymphatic Glands (lymphoglandulae inguinales profundae).—The deep inguinal lymphatic glands are beneath the deep fascia. There are only two or three of them, and they lie to the inner side of the femoral vein, the upper gland being in the crural canal and projecting into the pelvis. It is called the gland of Cloquet or the gland of Rosenmüller. The deep inguinal glands receive vessels from the superficial inguinal glands, deep lymphatics from along the femoral vessels, and vessels from the glans penis or clitoris. They send vessels to the ilio-pelvic glands.

The Anterior Tibial Gland (lymphoglandula tibialis anterior).—The anterior tibial gland is not constant in its existence. It is generally found by the side of the anterior tibial artery, upon the interosseous membrane at the upper part of the leg. Occasionally two glands are found in this situation. It receives a deep anterior tibial lymphatic trunk and sends off a vessel to the popliteal glands.

The Popliteal Glands (lymphoglandulae popliteae).—The popliteal glands are embedded in the cellular tissue and fat of the popliteal space and about the peroneal vessels. The juxta-articular gland receives lymph-vessels from the knee-joint. The popliteal glands send vessels to the superficial and deep inguinal glands.

The popliteal glands are divided into three groups:
1. A gland external to the termination of the external saphenous vein, the external saphenous gland.
2. A middle group of three or four glands on the sides of the popliteal vessels. The inferior glands of this group are the intercondylar glands of Leaf.
3. A gland adherent to the posterior ligament of the knee-joint, the juxta-articular gland of Poirier and Cunéo.

The Gluteal and Ischiatic Glands.—The gluteal and ischiatic glands are placed, the former above, the latter below, the Pyriformis muscle, resting on their corresponding blood-vessels as they pass through the great sacro-sciatic foramen.

The Lymphatic Vessels of the Lower Extremity (Figs. 500, 501).

The lymphatic vessels of the lower extremity, like the veins, may be divided into two sets, superficial and deep.

1 The Surgical Anatomy of the Lymphatic Glands, 1898.
The Superficial Lymphatic Vessels of the Lower Extremity.—The superficial lymphatic vessels are placed beneath the integument in the superficial fascia, and are divisible into three sets: trunks which follow the course of the internal saphenous vein, trunks which accompany the external saphenous vein, and trunks from the gluteal region. 1. Trunks which follow the course of the internal saphenous vein arise from a plexus on the dorsum of the foot, which plexus obtains lymphatics from all the toes, the sole, and both borders of the foot. The internal trunks, three or four in number, pass to the superficial inguinal glands. The external trunks run upward and inward and end in the internal trunks. 2. The trunks which follow the external saphenous vein number two or three, and they take origin from the heel and from the posterior half of the outer edge of the foot. They empty into the superficial inguinal glands. 3. The lymph-trunks from the gluteal region join vessels from the anus and enter the superficial inguinal glands.

The Deep Lymphatic Vessels of the Lower Extremity.—The deep lymphatic vessels of the lower extremity are few in number and accompany the deep blood-vessels. In the leg they consist of three sets, the anterior tibial, peroneal, and posterior tibial, which accompany the corresponding blood-vessels, two or three to each artery; they ascend with the blood-vessels and enter the lymphatic glands in the popliteal space; the efferent vessels from these glands accompany the femoral vein and join the deep inguinal glands; from these glands vessels pass beneath Poupart's ligament and communicate with the chain of glands surrounding the external iliac vessels. The deep lymphatic vessels of the gluteal and ischiatic regions follow the course of the blood-vessels, and join the gluteal and ischiatic glands at the great sacro-sciatic foramen.

THE LYMPHATICS OF THE PELVIS AND ABDOMEN.

The lymphatics of the pelvis and abdomen constitute a continuous chain, but for convenience of study it is customary to divide them into two groups, which we call, with Poirier and Cunéo, the ilio-pelvic glands and the abdomino-aortic glands; the first group being below and the second above the level of the bifurcation of the aorta into the two common iliac arteries.

The Iliac or Ilio-pelvic Glands (Lymphoglandulae Iliaca) (Figs. 502, 503).

The ilio-pelvic glands are at the level of the inlet of or in the cavity of the pelvis. They follow the course of the blood-vessels and are divisible into the external iliac, the internal iliac, and the common iliac chains.

The External Iliac Glands.—The external iliac glands form chains around the external iliac vessels. There are three chains of these glands. An external chain of three or four glands lies between the artery and the Psoas muscle. The lowest gland of the external chain is called by Poirier and Cunéo the external retro-crural gland (Fig. 502). A middle chain of three glands lies upon the front surface of the external iliac vein. The lowest gland of this group is called by Poirier and Cunéo the middle retro-crural gland. An internal chain of three or four glands is placed to the inner side of the external iliac vein. The lowest gland of this chain is called the internal retro-crural gland, and is close to the upper gland of the deep inguinal chain, the gland of Cloquet. The obturator gland belongs to the inner chain of external iliac glands. The external iliac glands receive vessels from the superficial and deep iliac glands, from the glans penis or glans clitoris, deep lymphatics from the umbilicus and lower part of the belly wall, vessels from the superior portion of the vagina, the uterine neck, the prostate gland, the bladder,

1 Treatise on Human Anatomy.
the membranous portion of the urethra, and the internal iliac glands, and the obturator gland receives deep lymph-vessels from along the course of the obturator vessels. The external iliac glands send vessels direct to the common iliac glands and also lymphatics to join vessels from the internal iliac glands on their way to the common iliac group. The glands along the deep epigastric artery and those along the deep circumflex iliac artery are accessory chains to the main group of external iliac glands.

**Fig. 502.—Ilio-pelvic glands.** (Poirier and Charpy.)

**The Internal Iliac or Hypogastric Glands** (lymphoglandulae hypogastricae).—The internal iliac glands are placed along the internal iliac artery and its branches. The gland on the middle hemorrhoidal artery is called the **middle hemorrhoidal gland**. The **lateral sacral gland** is on the lateral sacral artery. The internal iliac glands receive lymph from the pelvic viscera, perineum, and penile portion of the urethra, deep tissues of the posterior portion of the thigh, and from the buttocks. They send vessels to the common iliac glands and also to the external iliac glands.

**The Common Iliac Glands.**—The common iliac glands are found about the common iliac artery and are divided into an **external group**, which lies upon the inner edge of the Psoas muscle; a **middle group**, behind the artery, and an **internal group**, which lies upon the front of the body of the fifth lumbar vertebra or upon the sacro-vertebral junction. They receive vessels from the external and internal
iliac glands and from the pelvic viscera, the vessels from the pelvic viscera ascending to the promontory of the sacrum and containing perhaps, here and there, interrupting glands, known as sacral glands (lymphoglandulae sacrales) (Fig. 509). They also receive lymph-vessels from the lumbo-sacral region. They send vessels to the aortic glands. Some anatomists place the common iliac glands and the glands about the lower portion of the aorta and vena cava in a group called the lumbar glands (lymphoglandulae lumbales) (Fig. 509).

The Abdomino-aortic Glands (Figs. 483, 509).

The abdomino-aortic glands are placed about the abdominal aorta. There are twenty-five or thirty of them. They are divided by Poirier, Cunéo, and Delamaré into the right and left juxta-aortic glands, the retro-aortic glands, and the pre-aortic glands.

The Right Juxta-aortic Glands.—The right juxta-aortic glands are grouped in front of and behind the postcava, the posterior glands lying upon the Psoas muscle and the adjacent pillar of the Diaphragm. They receive lymph-vessels from the right common iliac glands, from the right testicle or the right half of the uterus, and the right tube, ovary, broad ligament, the right kidney and suprarenal capsule, and also lymph-vessels which pass along the lumbar arteries. They send vessels to the pre-aortic and the retro-aortic glands and the receptaculum chyli.

1 The Lymphatics. Translated and edited by Cecil H. Leaf.
The Left Juxta-aortic Glands.—The left juxta-aortic glands lie by the side of the abdominal aorta, upon the Psoas muscle, and the left pillar of the Diaphragm. They receive tributaries from the left side corresponding to those received by the glands of the right side, and also send out corresponding efferent vessels, and several additional vessels which pass through the left pillar of the Diaphragm and empty into the thoracic duct.

The Retro-aortic Glands.—The retro-aortic glands are placed beneath the receptaculum chyli and in front of the bodies of the fourth and fifth lumbar vertebrae. They receive lymph-vessels from both juxta-aortic groups, and also from the pre-aortic glands, and they send vessels to the receptaculum chyli.

The Pre-aortic Glands.—The pre-aortic glands lie upon the front of the aorta, and in most subjects are divisible into three groups: an inferior, lying at the origin of the inferior mesenteric artery; a middle, at the origin of the superior mesenteric artery, and a superior, about the celiac axis, the cæliac glands (lymphoglandulae coeliacae). Glands which are found along the course of all the branches of the abdominal aorta empty into and belong to the group of pre-aortic glands. The pre-aortic glands receive vessels from the juxta-aortic glands and from all the glands along the mesenteric vessels and the cæliac axis and its branches, and receive lymph from the stomach, intestines, liver, pancreas, and spleen. They anastomose with each other and send vessels to the retro-aortic glands and to the receptaculum chyli. Instead of the glands terminating in the receptaculum by separate vessels, the vessels may unite and form a common trunk, the intestinal trunk (truncus intestinalis), which runs along with the common trunk from the juxta-aortic glands, and empties into the receptaculum (Fig. 483).

1. The Glands along the Mesenteric Arteries (lymphoglandulae mesentericae) receive the lymph from the colon, cæcum, appendix, ileum, jejunum, duodenum, and perhaps also some from the stomach.

2. The Glands Connected with the Cæliac Axis and its Branches.—There are three groups of these glands: the gastric or coronary, the splenic, and the hepatic (including those of the bile-duets).

The Gastric Glands (lymphoglandulae gastricae).—One group is situated in the gastro-pancreatic fold; another group is connected with the lesser curvature of the stomach (Fig. 506). Some of them are in the lesser omentum close to insertion of the thicker part upon the stomach, and lie near the ascending branches of the gastric artery, that is to say, upon the vertical portion of the lesser curvature. Others lie within the lesser omentum and accompany the descending branches of the gastric artery, and particularly gather near the point where the gastric artery comes toward the stomach wall. The gastric glands receive lymph from most of the stomach. They send lymph to the upper group of pre-aortic glands, the cæliac glands.

The Splenic Glands (lymphoglandulae pancreaticolienales).—The splenic glands accompany the splenic artery and lie upon the posterior surface of the spleen, between the spleen and pancreas. They receive lymph from the fundus of the stomach, from the spleen, and from the pancreas, and send it to the cæliac glands.

The Hepatic Glands (lymphoglandulae hepaticae).—These glands lie along the hepatic artery, some on the level of the floor of the foramen of Winslow, others by the left side of the portal vein. The authors previously quoted point out that there is a secondary chain of hepatic glands about the right gastro-epiploic artery, the gastro-epiploic chain, and that this comprises a subpyloric group and a retro-pyloric group. The subpyloric group (Fig. 506) is placed in the great omentum below the pylorus, and is usually distinctly separated from it. The retro-pyloric group is not constant. It is placed along the gastro-duodenalis artery back of the pylorus. There is also a group of glands, secondary to the hepatic glands, to the right of

---

1 The Lymphatics. By Poirier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf.
or posterior to the cystic duct and the common bile-ducts. The hepatic glands proper receive lymph from the liver and send it to the celiac glands. The subpyloric glands receive lymph from the inferior portion of the stomach and from the superior portion of the great omentum. They send lymph to the hepatic glands proper, the retro-pyloric glands, and sometimes also to the glands about the superior mesenteric artery. The retro-pyloric glands receive lymph from the subpyloric glands, from the upper surface and from the posterior surface of the pylorus, and from the duodenum. They send lymph to the hepatic glands proper and sometimes to the glands along the superior mesenteric artery. The glands along the gall-ducts empty into the hepatic glands proper.

The Lymphatic Vessels of the Abdomen and Pelvis.

The lymphatic vessels of the abdomen and pelvis may be divided into two sets, superficial and deep.

The Superficial Lymphatic Vessels of the Walls of the Abdomen.—The superficial lymphatic vessels of the walls of the abdomen follow the course of the superficial blood-vessels. The superficial lymphatics are derived from the integument. Those of the lower part of the abdomen below the umbilicus follow the course of the superficial epigastric vessels and converge to the superior group of the superficial inguinal glands (Figs. 499 and 501). Those from the costal margins of the abdomen terminate in the axillary glands (Fig. 495). The superficial lymphatics from the sides of the lumbar part of the abdominal wall wind around the crest of the ilium, accompanying the superficial circumflex iliac vessels, to join the superficial inguinal glands (Fig. 499).

The Superficial Lymphatic Vessels of the Gluteal Region.—The superficial lymphatic vessels of the gluteal region turn horizontally around the outer side of the ischial tuberosity, and join the superficial inguinal glands.

The Superficial Lymphatic Vessels of the Scrotum and Perineum.—The superficial lymphatic vessels of the scrotum and perineum terminate in the superficial inguinal glands.

The Superficial Lymphatic Vessels of the Penis.—The superficial lymphatic vessels of the penis occupy the sides and dorsum of the organ, the latter receiving the lymphatics from the prepuce; they all converge to the superficial inguinal glands. Lymph vessels from the glans penis empty into the deep inguinal and the external iliac glands.

In the female the lymphatic vessels of the vulva and prepuce of the clitoris pass to the superficial inguinal glands; those of the glans of the clitoris pass to the deep inguinal and the external iliac glands.

The Deep Lymphatic Vessels of the Abdominal Wall.—The deep lymphatic vessels of the abdominal wall take the course of the principal blood-vessels, and arise from muscular or aponeurotic layers. One set of lymph-vessels runs along with the deep epigastric artery and terminates in the external iliac glands. Another accompanies the deep circumflex iliac artery, and also terminates in the external iliac glands. Several lymph-vessels accompany the lumbar arteries and empty into the juxta-aortic glands. A vessel accompanies the internal mammary artery and empties into the internal mammary glands. Lymph-vessels of the parietes of the pelvis, which accompany the gluteal, ischiatic, and obturator vessels, follow the course of the internal iliac artery, and ultimately join the external iliac, internal iliac, and common iliac glands, and the glands about the lower portions of the aorta and vena cava.

The Lymphatic Vessels of the Umbilicus.—The lymphatics of the umbilicus are divided into three groups: 1 The cutaneous lymphatics, which are very superficial,
and empty into the superficial inguinal glands. The lymphatics of the fibrous nucleus, which pass through the rectus sheath, reach the deep epigastric artery and join the deep lymphatics which come from the muscular and aponeurotic layers of the belly wall. The lymphatics of the aponeurotic margin are in two sets: An anterior set, some of which penetrate the rectus sheath and join the lymphatics from the fibrous nucleus; others of which pass outward, penetrate the external and internal oblique muscles, and join the posterior lymph-vessels from the aponeurotic margin. A posterior set, which forms a collection of vessels on the posterior aspect of the rectus sheath, from which several trunks emerge. One trunk passes outward, penetrates the Transversalis muscle, joins the anterior trunk from the aponeurotic margin, and empties into the external iliac glands. Other ducts run along with the deep epigastric artery and pass into the external iliac glands. Glands lie along the lower portion of these lymph-ducts, and are known as the superior epigastric glands, and a gland may exist in the subperitoneal tissue beneath the umbilicus.

The Lymphatic Vessels of the Peritoneum.—It seems probable that the peritoneal cavity is a lymph-sac and that lymphatics take origin from the peritoneum in several ways. Robinson points out three modes of origin: 1. By stomata between endothelial cells. These stomata are in direct communication with lymph-vessels. 2. By interstitial spaces in the subperitoneal tissue. 3. By a plexiform origin similar to interstitial spaces.

Surgical Anatomy.—The fact emphasized by Robinson that the peritoneum is a great lymph-sac explains the quick absorption of septic material and the rapid spread of infectious processes. If the exudate clots and blocks the lymph-channels, absorption is slow and life may be saved. If it does not clot, absorption is rapid and death is certain. Whether it clots or not depends on the nature of the bacteria present. Fowler, impressed by the fact that absorption takes place most rapidly from the diaphragmatic region and least rapidly from the pelvic region, advises placing the victim of peritonitis in bed, with his head and body elevated.

The Lymphatic Vessels of the Bladder.—No lymphatics exist in the mucous membrane of the bladder, although they do exist in the mucous membrane of the prostate. There are some lymphatics in the bladder muscle, and numerous lymphatics in the subperitoneal tissue. The network of lymph-vessels in the muscles is connected with the network beneath the peritoneum and prevesical fascia, and collecting trunks come from both the anterior and posterior surfaces of the bladder. The anterior collecting trunks are divided into two sets. One set comes from the inferior portion of the anterior surface and passes outward to terminate in an external iliac gland "between the external iliac vein and the obturator nerve." The other set comes from the superior and anterior vesical surface, runs upward and outward, and terminates in the external iliac glands. Each set of vessels possesses interrupting lymph-nodes, some of which are directly in front of the bladder.

The posterior collecting trunks are divided into four sets. The first set comes from the superior and posterior portion and passes outward, exhibiting interrupting nodes in its course. These trunks terminate in the external iliac glands. The second set runs directly back into the external iliac glands. The third set comes from the middle of the posterior portion of the bladder and terminates in the hypogastric glands. The fourth set comes from the vesical neck, passes back and then ascends and terminates in the glands in front of the sacral promontory. This fourth set joins with the lymphatics from the prostate and seminal vesicles.

The Lymphatic Vessels of the Prostate Gland.—These vessels form a peri-prostatic plexus, which receives its afferents from the gland structure. This plexus is drained by four vessels, three of which commence on the posterior surface of the

gland. Although these vessels begin on the posterior surface of the prostate, their termination in each case is different. One passes on the under surface of the bladder, crosses the superior vesical artery, runs outward, and ends in the middle chain of the external iliac group. Another passes upward, outward, and backward, and terminates in the hypogastric group. A third passes along the floor of the pelvis, runs by the side of the rectum, and ascends on the anterior surface of the sacrum to terminate in the lateral sacral glands and in the hypogastric group. Occasionally a fourth trunk is found on the anterior surface of the prostate, which descends and joins the vessels from the membranous urethra and ends in the hypogastric glands.

The Lymphatic Vessels of the Male Urethra.—These vessels are divided into two groups: First, those of the penile portion of the urethra; second, those of the bulb and membranous portion. The lymphatics of the prostatic urethra belong to those of the prostate gland. The lymph-vessels of the penile urethra in front of the sulcus all run toward the frenum, at which point they bend backward to the sulcus; here they run to the dorsal surface of the penis and terminate in the same manner as the vessels from the glans. The trunks from the remainder of the penile urethra emerge from the inferior surface, run around the corpus cavernosa, and mostly unite with the vessels from the glans penis. One vessel, though, passes over the symphysis and enters in the internal retro-crusal gland, whilst another passes beneath the symphysis and terminates with the vessels from the bulb and membranous portion of the urethra. The lymphatics of the bulb and membranous portions end in three trunks, one of which accompanies first the artery of the bulb and then the internal pudic artery, and ends in the hypogastric gland attached to the pelvic portion of this artery. A second trunk runs behind the pubes, to end in the internal retro-crusal gland. A third trunk runs on the bladder, where it joins with vessels from this organ, to end in the internal chain of external iliac glands.

The Lymphatic Vessels of the Female Urethra.—The lymphatics of the female urethra terminate in the same manner as do the lymphatics of the bulb and membranous portions of the male urethra.

The Lymphatic Vessels of the Uterus.—These consist of three sets, each of which arises by a network of capillaries. There is a mucous network, a muscular network, and a peritoneal network. The vessels from these three regions of origin are collected in the subperitoneal tissue, from which area the collecting trunks take origin. From the cervix, according to Poirier and Cunéo, come from five to eight collecting trunks, which pass toward the sides of the body of the uterus, forming on each side, by twisting and dilatation, the juxta-cervical lymphatic knot of Cunéo. The cervical connecting trunks are divisible into three groups on each side. One group is composed of two vessels, which pass to the middle chain of the external iliac glands (superior and middle glands). Another group is composed of two vessels, which enter the hypogastric glands. A third group is composed of several vessels, some of which enter the lateral sacral glands, and the balance of which terminate in the glands of the sacral promontory. From the body of the uterus come three groups on each side. One group is composed of four or five vessels which emerge below the uterine cornu, pass beneath the ovary, where they receive the ovarian lymphatics, and terminate in the juxta-aortic glands of the same side. One so-called accessory lymphatic pedicle terminates in the external iliac glands, the other in the inguinal glands.

The Lymphatic Vessels of the Fallopian Tube.—The lymphatics of the Fallopian tube join with those of the uterus and ovary and terminate in the lateral aortic glands.

The Lymphatic Vessels of the Ovary.—The ovary is extremely rich in lymphatics; they form a plexus which is superficial to the veins. The vessels leading from this plexus, four or five in number, pass upward in company with the ovarian vessels
and end in the lateral aortic glands. Above the fifth lumbar vertebra these vessels anastomose with the lymphatics from the fundus of the uterus and Fallopian tube. Quite often there is a lymph-vessel which emerges from the ovary, passes downward and outward and ends in the middle chain of the internal iliac glands.

The Lymphatic Vessels of the Vagina.—The lymphatics of the vagina are divided into those of the mucous coat and those of the muscular coat; these anastomose freely with each other and terminate in a peri-vaginal network, which is drained by three groups of trunks. One group drains the upper third of the vagina and passes to the middle chain of the external iliac glands. A second group is efferent to the middle third of the vagina and ends in the hypogastric glands. A third group carries the lymph from the lower third of the vagina to the gland of the promontory.

The Lymphatic Vessels of the Testicle.—The lymphatic vessels of the testicle consist of two sets, superficial and deep; the former commence on the visceral surface of the tunica vaginalis, the latter in the epididymis and body of the testis. They form several large trunks which ascend with the spermatic cord, and, accompanying the spermatic vessels into the abdomen, terminate in the juxta-aortic and sometimes also in the pre-aortic glands; hence the enlargement of these glands in malignant disease of the testis.

The Lymphatic Vessels of the Vas Deferens.—These lymphatics empty into the external iliac glands.

The Lymphatic Vessels of the Seminal Vesicles.—A network exists on the surface of each vesicle, formed by a collection of lymph-vessels from the mucous lining and from the muscular structure of the vesicle. The trunks from this network empty into the external and internal iliac glands.

The Lymphatic Vessels of the Kidney, Ureter, and Suprarenal Capsule.—Their courses and terminations differ on the two sides. They take origin from a superficial network just beneath the capsule of the kidney and a deep network in the interior of the organ. The superficial network is connected to the collecting vessels of the deep network at the hilum. From the superficial network numerous vessels penetrate the capsule of the kidney and join the lymphatics of the fatty capsule. According to Poirier, Cunéo, and Delamare,¹ anterior and posterior trunks come off from the deep lymphatics of the right kidney. The anterior trunk usually terminates in the right juxta-aortic glands which lie upon the vena cava. The posterior trunks terminate in the juxta-aortic glands which lie behind the vena cava. On the left side all the collecting trunks terminate in the juxta-aortic glands of the left side of the aorta.

The lymphatics of the fatty capsule of the kidney communicate with the lymphatics of the kidney, and both terminate in the same glands. The lymphatics of the suprarenal capsule terminate in the juxta-aortic glands of the same side. From the ureter lymph-vessels come off and terminate in the juxta-aortic and adjacent glands.

The Lymphatic Vessels of the Liver.—The lymphatic vessels of the liver are divisible into two sets, superficial and deep. The former arise in the lobules at the periphery of the liver and pass to the subperitoneal connective tissue over the entire organ. The latter arise from the deeper lobules, and emerge from the liver along the portal vein or the hepatic veins.

According to Poirier, Cunéo, and Delamare,² three groups of superficial collecting trunks arise from the subperitoneal network. The posterior trunks divide into three groups. The single right posterior trunk terminates in a gland about the celiac axis. The middle posterior trunks (five to seven in number) pass through the opening in the Diaphragm. The left posterior trunks pass into glands

¹ The Lymphatics. Translated and edited by Cecil H. Leaf.
² Ibid.
about the subdiaphragmatic portion of the oesophagus. The anterior collecting trunks terminate in the lymph-glands of the hilum of the liver. The superior trunks ascend. One of these trunks or a posterior trunk passes with the vena cava through the Diaphragm and terminates in glands about the vena cava. Another trunk, an anterior one, passes over the anterior border of the liver, runs for a time with the round ligament, and terminates in the hepatic glands. Numerous middle trunks ascend in the suspensory ligament, unite beneath the Diaphragm and divides into several smaller ducts, which terminate in the glands back of the xiphoid cartilage. Trunks from the superficial lymphatic network also emerge from the inferior surface of the liver. The posterior trunks from the right lobe reach the vena cava and terminate in the glands about the intra-thoracic end of that vessel. The middle and anterior trunks from the right lobe reach the glands along the cystic duct. The trunks from the left lobe terminate in the glands along the hepatic artery. The trunks from the lobus Spigelii reach the glands of the hilum and the glands about the lower intra-thoracic portion of the vena cava. The trunks from the quadrato lobe terminate in the glands of the hilum. The deep collecting trunks are divisible into two groups. One group descends along the portal vein, the other ascends along the hepatic veins.

Sappey pointed out that the deep descending trunks accompany the bile passages and the branches of the portal vein, several anastomosing vessels accompanying each branch of the portal vein. The same authority affirmed that from fifteen to eighteen trunks emerge from the hilum and terminate in the adjacent glands. The deep ascending trunks surround as a sheath the branches of the hepatic vein (Sappey). As they approach the Diaphragm they diminish in number to five or six, pass through the opening for the vena cava, and terminate in the glands about the lower portion of the intra-thoracic cava.

The Lymphatic Vessels of the Bile-ducts.—The lymphatics of the bile-ducts arise from the mucous membrane and from within the muscular tissue, and terminate in glands along the cystic and common ducts.
The Lymphatic Vessels of the Stomach (Figs. 505 and 506).—The lymphatic vessels of the stomach consist of two sets, superficial and deep. The superficial arise from the outer (serous) and the middle (muscular) coats. The deep arise from the mucous membrane and form a network in the submucous tissue. Trunks from the submucous network pass through the muscular tunic and terminate in the trunks coming from the sero-muscular layers. These latter, the musculo-serous collecting trunks, are divided into three groups. The first group is composed of six or eight vessels which pass toward the lesser curvature (Sappey). There are from three to ten glands upon the lesser curvature along the course of the gastric artery which receive these superior trunks. Vessels come to these glands from the cardia, from the body of the stomach, and from the pyloric end. In the lesser curvature the lymphatic vessels lie in the wall of the stomach. According to Cunéo, two-thirds of the stomach is drained by the lymph-vessels of group I. The second group comprises the trunks from the greater curvature which end in the subpyloric glands. The glands along the greater curvature are some distance from the stomach wall in the pyloric region, and lymph-streams flow from left to right, that is, toward the pylorus and not from it. These lymphatics drain one-third of the stomach. The first and second groups send lymph eventually to the celiac glands and juxta-aortic glands. The third group comprises trunks which come from the fundus of the stomach and enter the lymphatic glands about the spleen.

Surgical Anatomy.—Mikulicz pointed out the early infection of the glands of the lesser curvature in pyloric cancer, and insisted that in operation for pyloric cancer the entire lesser curvature must be removed. Cunéo showed us that in pyloric cancer the fundus and two-thirds of the greater curvature usually remain free from disease, because the lymph-current is toward the pylorus and not from it. Of course, if the lymphatics become blocked, the lymph-current may be reversed (regurgitation), and then infection of these parts can occur. William J. Mayo has noted the "lymphatic isolation" of the dome of the stomach. In operating for cancer of the pylorus, make the section of the stomach as directed by Hartmann, that is, a section which removes all of the lesser curvature and cuts the greater curvature well to the left of the subpyloric glands.

The Lymphatic Vessels of the Pancreas.—The lymphatics of the pancreas arise from a network about the pancreatic lobules. The collecting trunks anastomose freely on the surface of the pancreas. Some of the trunks terminate in the splenic glands, which send vessels to the celiac glands. Others terminate directly in the celiac glands. The lymphatics of the head of the pancreas communicate with the duodenal lymphatics and the lymphatics of the lower end of the common duct. The pancreatic and splenic lymphatics probably communicate.

The Lymphatic Vessels of the Spleen.—The lymphatics of the spleen consist of two sets, superficial and deep; the former are placed beneath its peritoneal covering, the latter in the substance of the organ; they accompany the blood-vessels, passing
through a series of small glands, and pass into the splenic glands which are placed in the omentum between the spleen and pancreas. The gastro-splenic omentum contains no glands.

THE LYMPHATIC SYSTEM OF THE INTESTINES.

The Lymphatic Glands of the Small Intestine (Fig. 507).—The lymphatic glands of the small intestine are placed between the layers of the mesentery, and are

---

**Fig. 506.**—General view of the subperitoneal lymphatic plexus of the stomach prepared by the method of Gerota. (Cuéno.)

called *mesentery glands* (*lymphoglandulae mesentericae*). They vary in number from a hundred to a hundred and fifty, and in size from that of a pea to that of a small almond. These glands are most numerous and largest above, the glands of the jejunum being more numerous than those of the ileum. This latter group becomes enlarged and infiltrated with deposit in cases of fever accompanied with ulceration of the intestines. The glands diminish in number as we descend until the ileocecal region is reached, when a number of glands appear about the ileo-cecal artery. The mesenteric glands receive the lacteals and send out trunks to the receptaculum chylæ. The chyle from the intestine passes through the glands on its way to the thoracic duct.

The glands may be divided into: I. A group of glands the members of which are chiefly found along the terminal vessels from the vascular loops of the intestinal branches of the superior mesenteric artery. Some glands of this group are placed upon "the anterior surface of the upper end of the jejunum." II. A group of

---

1 Leaf (Surgical Anatomy of the Lymphatic Glands) says it is very common to find not more than forty or fifty.

2 Ibid.
glands along the vascular loops of the superior mesenteric artery. Most of them are between the primary loops. Some of them are between the secondary and tertiary loops. III. A group of glands along the trunk of the superior mesenteric artery.

The Lymphatic Vessels of the Small Intestine (Fig. 507).—The lymphatic vessels of the small intestine are called lacteals, from the milk-white fluid they usually contain. They take origin in the intestinal villi and in lymphatic sinuses around the bases of the solitary glands. Lymphatic plexuses exist in the submucous tissue, the muscular coat, and the subserous tissue. The lymphatic vessels pass between the layers of the mesentery, enter the mesenteric glands, and finally unite to form two or three large trunks which terminate separately in the receptaculum chyli; frequently, however, they first unite to form a single large trunk, termed the intestinal lymphatic trunk (Figs. 483 and 509).

The Lymphatic Glands of the Large Intestine.—The lymphatic glands of the large intestine are divided into the colic glands and rectal glands.

The Colic Glands (lymphoglandulae colicae).—The colic glands are subdivided into: 1. The ileo-colic or ileo-caecal glands (Fig. 508), which lie along the course of the ileo-colic artery, one or two of the glands being placed upon the anterior surface of the caecum. The mesoappendix also contains a gland which communicates with glands in the mesocolon, and receives lymph from the appendix and, in the female, from the ovary. 2. Glands in the mesocolon along the right colic artery, which receive lymph from the ascending colon and the hepatic flexure. 3. Glands in the mesocolon along the middle colic artery, which receive lymph from the hepatic flexure and transverse colon. 4. Glands in the mesocolon along the left colic artery, which receive lymph from the descending colon and sigmoid flexure. The vessels from the colic glands pass to the pre-aortic glands.

The Rectal Glands.—The rectal glands lie in the mesorectum; they receive lymph from the anus and rectum and it passes from them to the lumbar and sacral glands.

The Lymphatic Vessels of the Large Intestine.—The lymphatic vessels of the large intestine consist of three sets: those of the caecum, ascending and transverse colon, which, after passing through their proper glands, enter the mesenteric glands; those of the descending colon and sigmoid flexure, which pass to the lumbar
glands, and those of the rectum and anus, which pass to the sacral and superficial inguinal glands.

Lymphatics of the Anus and Rectum.—These vessels take origin from two networks, one from the skin and mucous membrane and the other from the muscular coat. The lymph-vessels from the skin at the anal margin pass to the superficial inguinal glands. Some vessels from the skin of the anus ascend and reach the submucous plexus of the rectum, from which region lymph-vessels pass to the rectal glands, to the glands along the middle hemorrhoidal artery, and along the inferior hemorrhoidal artery, and to a pelvic gland near the origin of the internal pudic artery.¹ The vessels from the anal mucous membrane and from the muscular wall of the rectum penetrate the muscular wall of the rectum with the arteries and reach the rectal glands.

The thoracic lymphatics are divided into the deep lymphatics of the chest wall, the diaphragmatic lymphatics, and the visceral lymphatics.

The Lymphatic Glands of the Thoracic Wall or the Parietal Lymphatics.

The lymphatic glands of the thoracic wall include the internal mammary and intercostal glands.

The Internal Mammary Glands.—The internal mammary, retro-sternal, or sternal glands (lymphoglandulae sternalis) form a chain of five or six glands on each side of the sternum along the course of the corresponding internal mammary artery, and back of the internal intercostal muscles. The glands are separated from the pleura by cellular tissue. The internal mammary glands receive vessels from the diaphragmatic glands, the abdominal muscles above the umbilicus, the anterior

¹ The Lymphatics. By Poirier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf.
ends of the intercostal spaces, the skin over the sternum, and the mammary gland. The vessels given off by each chain from a single trunk. On the right side this trunk terminates at the junction of the internal jugular and subclavian veins, unites with the subclavian lymph-trunk to form the right lymphatic duct, or empties directly into the subclavian trunk (Fig. 485). On the left side it empties either at the junction of the subclavian and internal jugular veins or into the thoracic duct.

**The Intercostal Glands (lymphoglandulae intercostales)** (Fig. 509).—The intercostal glands are small glands lying in the intercostal spaces along the intercostal arteries. In the posterior end of each space they are constantly found. These are called the posterior glands, and there are one, two, or three in each space. These glands are opposite the neck of the rib or over the articulation of the rib with the vertebra. The pleura is in front of them, and they lie upon the external intercostal muscles. In the middle of the intercostal spaces are inconstant glands which are called lateral glands. They are merely interrupting nodes in the trunks from the intercostal muscles. The intercostal glands receive vessels from the intercostal muscles and pleura. They send vessels back toward the spine, which unite with lymphatics from the back part of the thorax and spinal canal, and which pass down the spine and terminate in the thoracic duct.

**The Diaphragmatic Lymphatics.**—The diaphragmatic lymph-glands are distinct and numerous. These glands are on the convex surface of the Diaphragm and are divided into an anterior, a middle, and a posterior group. They receive vessels from the Diaphragm and liver and send vessels to the internal mammary and posterior mediastinal glands. The lymph-vessels of the Diaphragm take origin from a capillary network contained in the spaces between the muscular and tendinous fasciculi of the Diaphragm. Numerous lymph-vessels descend until they reach the subperitoneal tissues and then ascend. Others immediately ascend to beneath the pleura. The collecting trunks are all on the convex surface of the Diaphragm. The lymphatic vessels of the Diaphragm anastomose with the lymphatic vessels of the pleura and the peritoneum. This subperitoneal network is so extensive that absorption in this region is extremely rapid. Hence, after an abdominal operation, if salt solution has been left in the abdomen, it will be very rapidly absorbed if the foot of the bed is elevated. Influenced by the knowledge that the pelvic peritoneum absorbs comparatively slowly and the peritoneum in the upper abdomen very rapidly, and that septic processes in the upper abdomen are more rapidly fatal than septic processes in the pelvis, Fowler was led to recommend the elevation of the head of the bed after operations for abdominal infections. This posture causes poisonous fluids to gravitate away from the Diaphragm.

**The Visceral Lymphatics.**—The visceral lymphatics include the anterior mediastinal glands, the posterior mediastinal glands, and the peritracheo-bronchial glands.

**The Anterior Mediastinal Glands (lymphoglandulae mediastinales anteriores).**—The anterior mediastinal glands are in the upper portion of the anterior mediastinum, a group of six or seven glands lying above and upon the front of the transverse portion of the arch of the aorta and sending glandular chains toward the neck. On the right side these glands are found between the innominate artery and vein and in front of the vein. On the left side they are in front of and behind the left common carotid and left subclavian arteries. They receive lymph from the heart, pericardium, thymus gland, and anterior mediastinum.

**The Posterior Mediastinal Glands (lymphoglandulae mediastinales posteriores)** (Fig. 509).—The posterior mediastinal glands are behind the pericardium and in front of the oesophagus. Occasionally one or two are placed back of the oesophagus. They receive vessels from the intercostal glands, aortic glands, deep cervical glands, and pleura, and send vessels to the thoracic duct.
The Peritracheo-bronchial Glands.—The peritracheo-bronchial glands are divided by Baréty into four groups. One group is in the angle formed by the junction of the trachea and right bronchus. Another group is in a corresponding situation on the left side. Another group is below the tracheal bifurcation. The glands of the fourth group are about the points of division of the larger bronchi. The peritracheo-bronchial glands receive lymph-vessels from the lung, heart, pericardium, oesophagus, trachea, and thymus.

In infancy these glands present the same appearance as the lymphatic glands in other situations. In early adult life they assume a brownish tinge, and in old age become deep black, because they arrest particles of carbon brought from the bronchi. This change is known as anthracosis, and the darkened glands are usually sclerotic. In fact, in old age these glands often lose all lymphatic characters and become fibrous masses. These glands enlarge from infection,
and when very large may compress the bronchi, the pulmonary artery, etc. They are often the seat of tuberculous deposits.

The Lymphatic Vessels of the Thoracic Wall.—The lymphatic vessels of the thoracic wall include the deep lymphatic vessels, intercostal and internal mammary, which have been described, the cutaneous lymphatics, and the lymphatics of the mammary gland.

The Cutaneous Lymphatics (Fig. 495).—The area drained by these lymphatics is very extensive. It is divided by Poirier, Cunéo, and Delamare into three regions. The anterior region extends from over the middle of the sternum to the anterior axillary line. The trunks pass to the axilla and terminate in the thoracic chain of the axillary glands. From this anterior region some accessory trunks pass above the clavicle and reach the supra-clavicular glands, and trunks may arise to one side of the mid-sternal line and pass to the opposite axilla. From the lateral region the trunks ascend to the thoracic chain of axillary glands. This region is between the anterior and posterior axillary lines. The posterior region is back of the posterior axillary line, and includes the thorax to the mid-line, and the posterior portion of the root of the neck. The trunks from the posterior area empty into the scapular group of axillary glands.

Lymphatics of the Mammary Gland (Figs. 494 and 510).—There are two sets of lymphatics in this gland, the cutaneous or superficial and the glandular or deep.

The Peripheral Cutaneous Lymphatics of the Mammary Gland.—The peripheral cutaneous lymphatics do not arise from the nipple. Their collecting trunks are arranged as are other collecting trunks of the anterior portion of the thorax, and end in the thoracic group of axillary glands of the same side. Trunks arising from the sternal margin of the skin of the breast may run to the glands of the opposite axilla.

The Central Deep Lymphatics of the Mammary Gland.—The central lymphatics form a very extensive network in the nipple and areola, and from this network numerous vessels pass into a plexus beneath the areola, Sappey's subareolar plexus; most of the trunks coming from the gland also enter the subareolar plexus.

The Glandular Lymphatics of the Mammary Gland.—The glandular lymphatics arise from spaces about the lobules and from networks about the milk-duets. We can distinguish a chief lymphatic channel and three accessory channels.

The chief lymphatic channel takes origin from collecting trunks which begin in the spaces about the lobules and in the lymph-capillaries about the milk-duets. These collectors pass toward the nipple and terminate in the subareolar plexus, which plexus also receives the vessels from the areola and nipple. Two large trunks take origin from the subareolar plexus: one from its inner side, the other from its outer side. "The internal trunk runs at first downward and then outward, turning round the inferior border of the subareolar plexus. It is thus directed toward the axilla and runs in the subcutaneous cellular tissue, along the lower border of the Pectoralis major, which it crosses at the level of the third rib to reach the base of the axilla. This collecting trunk constantly receives as afferents one or two fair-sized trunks coming directly from the inferior portion of the mammary gland. The external trunk, which is usually smaller than the preceding, runs directly outward toward the axilla. Before it reaches the latter it is augmented by a vessel coming from the superior part of the gland. At the base of the axilla these two collecting trunks perforate the axillary aponeurosis and terminate in one or two glands, placed on the inner wall of the axilla on the third digitation of the Serratus magnus muscle. These glands (the principal regional glands of the breast) may or may not be covered by the lower part of the Pectoralis major muscle according to the muscular development of the subject (Surgins)."  

1 The Lymphatics. By Poirier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf.
chain. An interrupting gland is sometimes found in the course of these two trunks, the paramammary gland.

The Accessory Channels from the Mammary Gland.—The accessory channels from the mammary gland, according to Poirier, Cuneo, and Delamare, are three. They call one the accessory axillary channel. It is not constant, and there may be interrupting glands on its collectors. Its collectors come off from the inferior portion of the mammary gland and pass directly to the axillary glands. Another channel is the subclavian channel. Neither is it constant. It comes off from the posterior surface of the mammary gland, pierces the great Pectoral muscle, and ascends between the greater and lesser Pectorals to reach the subclavian glands. There

Fig. 510.—The vessels and lymphatics of the anterior face of the mammary glands. (Sappey.)

are usually interrupting glands along this channel, the retro-pectoral glands. The subclavian channel runs along the superior thoracic artery. They call the third accessory channel the internal mammary channel. The collecting trunks arise from the inner portion of the mammary gland and pass along the vessels sent off from the internal mammary artery to the gland. They pierce the Pectoral and Intercostal muscles and reach the internal mammary glands. This channel is constant and along it there may be interrupting glands.

Lymphatics of the Great Pectoral Muscle.—The lymphatics of the great Pectoral muscle end in the subclavian glands, the thoracic group of axillary glands, and the internal mammary glands.

Surgical Anatomy.—A knowledge of the lymphatics of the breast and of the glands into which the lymphatics drain is of the first importance to a surgeon. Certain surgical deductions from the anatomy of this region are perfectly obvious—viz.: 1. If the skin of the mammary gland is involved in carcinoma, the thoracic group of axillary glands of the same side is involved. If the skin over the sternal margin of the gland is involved, the glands of the opposite axilla may be cancerous, as from this point lymph-vessels rise and pass across the mid-line. If the skin of the sternal margin is involved the prognosis is worse than if it is free, the opposite axilla may be cancerous, and the opposite breast may become diseased. 2. When lymphatic ducts become blocked by cancer cells the lymph backs up, flows backward instead of in its proper direc-
tion, and may cause infection in the most unsuspected situations. For instance, a block in the cutaneous lymphatics of a portion of the breast may lead to infection of the opposite breast and axilla, though, of course, it is not so likely to as is cancer of the skin of the sternal margin. By regurgitation of lymph the head of the humerus or the retro-sternal structures may become diseased in mammary cancer. 3. If the nipple or areola is cancerous, the entire gland is sure to be diseased, as the lymphatic network of this region empties into the subareolar plexus, and most of the trunks coming from the gland also enter this plexus. 4. If the mammary gland is cancerous, all of the axillary glands are regarded as diseased, as the main lymphatic channel from the breast reaches the glands on the inner wall of the axilla upon the third digitation of the Serratus magnus. Furthermore, in many cases an accessory lymph-channel comes off from the lower portion of the mammary gland and passes directly to the axilla. 5. The subclavian glands are to be regarded as diseased, because in a certain proportion of cases (the exact proportion being uncertain) an accessory lymph-channel comes off from the posterior surface of the mammary gland, passes through the great Pectoral muscle and ascends between the greater and lesser Pectorals to reach the subclavian glands. 6. The element which greatly interferes with the cure of mammary carcinoma is the existence of lymph-channels which arise from the inner portion of the mammary gland, pierce the greater Pectoral and Internal intercostal muscles, and reach the internal mammary glands. Mediatinal involvement is apt to be earlier in carcinoma of the inner portion of the breast than in carcinoma of other portions, and the prognosis is particularly bad in cancer of the inner portion of the breast. What is known as the sternal symptom of Snow is bulging of the sternum due to involvement of the thymus gland. 7. The sternal portion of the great Pectoral and the tissue between it and the lesser Pectoral muscle are to be regarded as diseased, because in some cases an accessory lymph-channel from the breast penetrates the greater Pectoral and ascends to the subclavian glands. This trunk has several interrupting or satellite glands, the retro-pectoral glands, in the tissue back of the great Pectoral muscle. 8. When the great Pectoral muscle is diseased, cancer cells soon spread widely through the sternal portion of the muscle, and this entire portion of the muscle becomes cancerous. The clavicular portion does not suffer early, but escapes until the cancer becomes extensive, as it is anatomically distinct from the sternal portion. If the fibres of the great Pectoral are extensively diseased, the thoracic group of axillary glands, the subclavian glands, and possibly the internal mammary glands are involved. 9. The only operation in cancer of the breast which offers any real hope of cure is one which is done early and is radical. 10. It must be done early, because delay permits involvement of the mediastinum, and if the disease has entered the mediastinum operation is hopeless. If the sternum is bulged operation is useless, and nothing short of amputation at the shoulder-joint could be of help if the head of the humerus is enlarged by the disease. Even this radical procedure is of no avail, because the mediastinum is certainly involved if the head of the humerus is diseased. 11. If the lymph-glands above the clavicle are extensively diseased operation is useless, as in such cases the mediastinum is sure to be involved. 12. A radical operation means the removal of the skin of the breast with the nipple and areola, the subcutaneous tissue of this region, the entire breast the sternal portion of the great Pectoral with its fascia, the retro-pectoral glands and tissue, all the contents of the axilla except vessels and nerves, the glands and cellular tissue beneath the anterior margin of the Latissimus dorsi, and the subclavian glands. It is probably always wisest to open above the clavicle as well as below to facilitate the removal of glands. It is seldom necessary to remove the clavicular portion of the greater Pectoral. The lesser Pectoral does not require removal, but it should be taken away, because of the added safety and speed thus obtained in cleaning the great vessels and because its retention does not improve the functional result. The surgeon must remember that the breast is a much larger organ than we used to think, and all of its irregular projections and outlying lobules must be removed (p. 791). Formerly, surgeons did not completely remove the breast, but only got rid of a large portion of it.

The Pulmonary Lymphatics.—The pulmonary lymphatics arise from networks between the lobules, around the bronchi and under the mucous membrane. The collecting trunks are in two sets, superficial and deep: the former are placed beneath the pleura, forming a minute plexus which covers the outer surface of the lung; the latter accompany the blood-vessels and run along the bronchi; they both terminate at the root of the lungs in the tracheo-bronchial glands.

The Pleural Lymphatics.—The lymphatics of the pulmonary pleura pass into the superficial pulmonary trunks; those from the costal pleura enter the intercostal trunks; those from the diaphragmatic pleura enter the diaphragmatic trunks, and those from the mediastinal pleura enter the posterior mediastinal glands.

The Cardiac Lymphatic Vessels.—The cardiac lymphatic vessels consist of two sets, superficial and deep: the former arise in the subpericardial areolar tissue of

1 The Lymphatics. By Poirier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf.
the surface, and the latter in the subendocardial tissue. From the network of deep lymphatics trunks pass to the superficial lymphatics. The superficial lymphatics follow the course of the coronary vessels. Two trunks are formed: an anterior, which lies in the anterior interventricular furrow, and an inferior, which lies in the inferior interventricular furrow. These two trunks collect the lymph from the ventricles and pass to the base of the heart, where they receive lymph from the auricles. The anterior or left trunk ascends between the left auricle and the pulmonary artery on the posterior surface of the artery, perforates the pericardium, and enters the glands about the tracheal bifurcation. The right, posterior or inferior trunk ascends between the aorta and pulmonary artery and terminates in the same group of glands as the left trunk.

**The Thymic Lymphatic Vessels.**—The thymic lymphatic vessels arise from the under surface of the thymus gland, and enter the anterior mediastinal, the internal mammary, and the peritracheo-bronchial glands.

**The Lymphatic Vessels of the Öesophagus.**—The lymphatics of the thoracic oesophagus arise from two networks, one beneath the mucous membrane and one beneath the muscular fasciculi. The connecting trunks terminate in the peri-oesophageal glands.

**The Lymphatic Vessels of the Thoracic Trachea.**—The lymphatics of the thoracic trachea take origin from a network in the submucous tissue. From this a number of collecting trunks pass through the trachea in the line of junction of the cartilaginous with the membranous portion. They terminate the peritracheo-bronchial glands.
THE NERVE SYSTEM.

THE SPINAL CORD AND BRAIN, WITH THEIR MENINGES.

REVISED AND LARGELY REWRITTEN, WITH NEW ILLUSTRATIONS.

By EDWARD ANTHONY SPITZKA, M.D.,
PROFESSOR OF GENERAL ANATOMY, JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

The nerve system of man is an apparatus by means of which he appreciates and becomes influenced by impressions from the outer world, reacts on these impressions, and hence is enabled to adapt himself to his environment. It is the organic substratum for those manifestations of nerve force engaged in the characteristic attributes of animal life—sensation and motion. Broadly stated, the nerve system connects the various parts of the body with each other and coordinates them into one harmonious whole in order to carry on the bodily functions methodically and to control the physiological division of labor throughout the organism. With the evolution of the higher forms of animal life through an immense phylogenetic past the nerve system has undergone remarkable differentiation and specialization, attaining its maximum as to dominant position and complexity of structure in the human species.

The description of the nerve system is assisted by the accommodation of physiological data to the anatomical basis in order to demonstrate more clearly and to render more practical our knowledge of the mutual relations of its structure and function. The cycle of events which accompanies nerve action is determined by impressions received by the peripheral end-organs, apperception and reflexes of these impressions in the lower nerve-centres, correlation of these with other impressions in higher centres, as well as voluntary reactions or inhibitions, liberated in compliance with the organic or higher needs of the individual.

Conventionally, the nerve system is usually considered as consisting of (1) the cerebro-spinal system, comprising (a) the central nerve-axis (brain and spinal cord) and (b) the peripheral nerves (cranial and spinal), and (2) the sympathetic nerve system. This subdivision, like others formulated by various authors, is an arbitrary one. No part of the system stands isolated, and the manifold groupings and chainings of the units of the system intimately connect the central nerve organs with the peripheral nerve-endings, the organs of special sense and the vegetative organs. The distinction between the central and the sympathetic systems has been too absolute, and the only justification for adhering to the classification given above is based upon the fact that the sympathetic system is preponderantly related to the interconnection and coördination of the nutritive (digestive, pulmonary, and vascular) apparatus, and, therefore, exercises a special control over its activities.
Structurally considered, the nerve system consists of cell-elements peculiarly differentiated from all other tissue cells in that their protoplasm is extended, often to great distances from the nuclear region, in the form of processes. The cell-elements are held in place by supporting tissues, partly of ectodermal and partly of mesodermal origin, and receive an abundant blood-supply.

The cell-element of the nerve system is called the neurone. The neurone is the developmental, structural, and functional unit of the nerve system. It is in reality a single cell presenting unusual structural modifications. It comprises not only the nerve cell-body with its numerous protoplasmic processes or dendrites, but also the axone, which may vary in length from a fraction of a millimetre to fully half a man's stature; so that, despite the delicacy of the axone; its bulk may be almost two hundred times greater than that of the cell-body from which it proceeds. The long axones serve to make a connection with a peripheral or distant nerve-cell, muscle-cell, or gland-cell, while the shorter axones of certain neurones divide into terminal branches in the immediate vicinity of its cell-body, presumably to come into relation with other nerve-cells in the same or adjacent groups.

Neurones, being devoted to the maintenance of functions manifested by various phenomena of nerve-force, are differentiated in their polarity, both structurally and dynamically. Receptive neurones are so arranged as to receive afferent nerve-impulses from other tissues; emissive or excitatory neurones give out efferent nerve-impulses. The former are generally termed sensor neurones, the latter motor (excito-motor) neurones if connected with muscle, excito-glandular if connected with gland-cells. Were the nerve system made up solely of such initial and terminal neurones the apparatus would be merely a system of reflex arcs. Such it is in low forms of animal life which, by their very organization, and because of the close juxtaposition of their sensory and motor elements, are compelled to react to stimuli from without. In higher forms, with more profoundly differentiated nerve systems, the sensory impression must pass through an interposed medium which is capable of either transmitting the molecular change in the form of an excito-motor impulse or, on the other hand, is capable of reducing or checking the impulse. In other words, reaction is not imperative; there is a freedom of choice exercised by intermediate neurones endowed with inhibitory function. The simple arc, composed of an afferent sensory neurone and an efferent motor neurone, would act independently of all other arcs were it not for the interposition of this intermediate neurone and of other association neurones which, by their relations toward similar arc-elements, produce harmony of action. The basis, then, of the nerve system is a series of neurones, with projecting and association processes, coordinated for the purpose of performing specific actions manifested either by motion, by trophic changes, or by the apperception of stimuli of a chemical, mechanical (tactile and auditory), thermal, or photic nature. When we consider the profoundly complex manifestations of nerve-phenomena in the mental and physical life of man it is not surprising to learn that his nerve system is made up of an immense multitude of aggregations of neurones.

**Fundamental Facts Regarding the Development of the Nerve System.**

The nerve system is formed by a remarkable metamorphosis of the ectodermic layer of the developing ovum. Along the mid-dorsal line of the embryonic mass a thickening of the ectoderm forms a well-defined layer of cells, the neural plate. The proliferative process passes rapidly from the cephalic toward the caudal end, and as development advances it is seen that the most intense growth-energy takes place at the cephalic end, indicative of the higher functional potentiality of what is to become the brain. The neural plate undergoes a trough-like formation as its edges become elevated cephalad and laterally to form the neural groove (Fig. 511). The edges become more and more elevated and bend toward
the median line until the margins of the groove coalesce to form a tube, the neural tube, which sinks into the subjacent mesodermal tissues. The fusion of the margins of the neural plate occurs first in the cervical region and rapidly continues both cephalad and caudad. The cephalic portion, destined to become the brain, expands and grows considerably, while the caudal portion is chiefly elongated to form the spinal cord.

Eventually the neural tube, as it sinks into the subjacent mesodermal tissues, severs all connection with the ectoderm from which it developed; but for a brief period the continuity is preserved in an attenuated septal mass, the neural crest (Fig. 511). The cell-elements of this crest subsequently become detached from the superficial ectoderm, the continuity of which is again restored to form the integu-

![Fig. 511.—Diagrams showing development of neural tube and crest.](image)

They pass ventrad to either side of the neural tube, proliferate by mitosis, and accumulate in paired masses, corresponding in number to the segments of the body, to become, in part at least, the cerebro-spinal ganglion cells of the afferent system, while other similarly paired masses migrate farther ventrad to a pre-vertebral position to form the gangliated cord and widely spread plexuses of the sympathetic system. From the tissues of the wall of the neural tube and its tem-
porary crest the entire nerve system of complex and intricate structure is developed. The cavity of the tube shares in the developmental growth-changes to become the ventricular system of the brain and central canal of the spinal cord. The major details of the development of the principal divisions will be considered in appropriate chapters.

**Development of Nerve-tissue.** 1. In the Wall of the Neural Tube.—The single layer of nucleated epithelial cells of ectodermal origin which makes up the wall of the neural tube early becomes modified into a layer of tall columnar cells called spongioblasts (Fig. 513). Their protoplasmic ends undergo differentiation in that the central ends become elongated and attenuated or collapsed to form a series of striated pillars with intervening spaces. The free ends retain their breadth, however, and form an internal limiting membrane. The ectal ends undergo differentiation to form a spongy felt-work or reticulum (*peripheral veil of His*); eventually these spongioblasts become (*a*) ciliated endymal cells and (*b*) neuroglia.

In the intercellular spaces of the central zone there appear spherical cells of different structure and destiny. These are the *germinal cells*, seen in very early stages and proliferating rapidly by karyokinesis. They soon lose their spherical form, becoming pear-shaped as a protoplasmic process extends ectad. These pear-shaped cells are now termed *neuroblasts* (Fig. 513), the protons of the neurones, and as development advances they leave the central zone and migrate into the marginal reticulum to the positions in which they are found in the gray substance of the brain and spinal cord. The protoplasmic process is at first slightly bulbous and elongates to form the axone extending toward other nerve-cells or to the peripheral tissue-elements with which they become associated by the contiguity of the terminal arborizations into which the bulbous extremity develops. The precision with which the axones travel toward their allotted goal is one of the most remarkable manifestations of organic development. An American experimenter, Ross G. Harrison, has devised a method for directly observing the living,
growing nerve. In isolated pieces of frog embryos the differentiation of the living nerve-elements could be observed from day to day during several weeks. The bulbous end of the outflowing protoplasmic fibre, showing a faint fibrillation, was seen to reveal a continuous change of form particularly in a number of fine simple and branched filaments which were in constant amoeboid movement. Harrison's demonstration\(^1\) is of great significance in connection with the "retraction theory" and other ideas related to the neurone doctrine.

2. In the Neural-crest Tissues.—The nerve-tissue elements of the sympathetic system and of the ganglia of the cranial nerves and dorsal roots of the spinal nerves are derived from the neural crest. Omitting, for the present, the development of the sympathetic system, it is found that the cells of the paired masses which eventually become the cerebro-spinal ganglia are at first somewhat spherical, then oval in form, sending out from either extremity or pole a protoplasmic process. One process migrates centrad, the other toward the tissues of the periphery. The central process penetrates the tissues of the neural tube and, assuming the typical form of an axone with its collaterals and end arborizations, comes into contiguous association with certain cells of the central axis. The peripheral process is in reality an unusually long dendrite, for it is centripetal in function; but owing to the fact that it is usually provided with a myelin sheath it is also termed the peripheral axone of an afferent (or sensor) neurone. The central processes of the cells of a single spinal nerve-ganglion form the dorsal nerve-roots; the peripheral processes constitute the afferent portion of a spinal nerve. The cells themselves are transformed from bipolar into apparently unipolar cells by the migration of the cell-body to one side and the consequent approximation of the two processes to form a common pedicle in a T-shaped manner (Fig. 533).

Structure of the Nerve System.—The whole of the nerve system is composed of nerve-tissue and supporting connective tissue. The neurones constitute the nerve-tissue, while the supportive tissue is composed of the neuroglia and of white fibrous tissue derived either from the investing membrane or from the sheaths of its numerous vascular channels.

\(^1\) American Journal of Anatomy, June 1, 1907, vii, 1. (Anatomical Record, p. 116.)
The Neurone.—The neurone or nerve cell-element, whose individuality has already been pointed out, exhibits remarkable variations as to external characters, dimensions, and form. The neurone presents a concentrated or swollen cell-mass and nucleus, formerly known as the nerve-cell (ganglion-cell) and still retaining the name. From this cell-body are given off a number of processes of two distinct kinds: (1) protoplasmic processes which are commonly branched and generally called the dendrites; (2) a single, thinner, and paler process, the axone (axis-cylinder process; Deiters' process; neuraxone; neurite).

Varied Forms of Neurones.—Bearing in mind that each neurone includes not only the cell-body and its dendritic processes, but also the axone or axis-cylinder process with all its ramifications, we may consider each of these divisions under separate heads.

1. Nerve Cell-body. External Morphology.—The bodies of nerve-cells vary much in size, measuring from 4 to 135 microns or more in diameter. The largest cells are found in the ventral horns of the spinal cord, in the spinal ganglia, in the large pyramidal cell-layer of the cerebral cortex, in the Purkinjean cell-layer of the cerebellum, and in the column of Clarke (dorsal nucleus) of the spinal cord. Very small cells are found in the olfactory bulbs, in the granular layers of the cerebral and the cerebellar cortex, and in the gliosum cornualis of the cord.

Although all nerve-cells begin in the embryonic ectoderm as spherical germinal cells, they later assume, in different regions, very different shapes. These external morphological relations have been best revealed by the methods of Ehrlich and Golgi. According to the number of processes arising from the cell-body, neurones are referred to as (1) unipolar, (2) bipolar, and (3) multipolar nerve-cells.

(1) Unipolar cells are met with frequently in early stages of embryonic development, but are rare in the adult, being found only in the retina, olfactory bulb, and within the baskets of the Purkinjean cells of the cerebellum.

(2) Bipolar cells are found almost exclusively in the peripheral sensor systems, as in the olfactory membrane, in the retina, in the cochlear and vestibular ganglia, and in the cerebro-spinal ganglia of the embryo.

(3) Multipolar cells are the most numerous and form the principal elements of nerve-centres throughout the system. They are termed multipolar because of the Purkinjean cells of the cerebellum. The cells of the cerebro-spinal ganglia (excepting the cochlear and vestibular) are apparently unipolar, but they are developmentally and functionally of bipolar nature.
of the greater or lesser number of dendrites given off in addition to the single axone.\footnote{Exceptionally, more than one axone has been observed arising from a single cell, as in the Cajal cells of the cerebral cortex.}

The terms "unipolar" and "multipolar" must be restricted to the morphological sense; dynamically all nerve-cells are bipolar.

According to the relations of the axone we distinguish, after Golgi, two kinds of neurones.

I. Neurones with long axones which become the axis-cylinder of a central or peripheral nerve-fibre. The axones give off several collaterals which, like the parent stem, break into finely branched terminals or telodendria.

II. Neurones with relatively short axones which do not go into the formation of a nerve-fibre, but break up into terminal twigs in the vicinity of the cell-bodies from which they arise.

Type II is generally termed, for brevity's sake, the \textit{Golgi cell}.

\begin{figure}
\centering
\includegraphics[width=\textwidth]{fig516.png}
\caption{Purkinjean cell from human cerebellum. \textit{a}, axone; \textit{clt}, collaterals. (Golgi method.)}
\end{figure}

According to the morphological relations of the dendrites, neurones are classified as follows:

\begin{enumerate}[leftmargin=*, label=(\alph*)]
\item \textbf{Stellate cells}, the dendrites of which spring at intervals from the whole circumference of the cell-body and pass toward all directions (motor cells in ventral horn and tract-cells of the cord).
\item Cells with one principal stout dendrite (among other lesser dendrites) which gives off side branches and ends in fine terminal twigs (pyramidal cells of cerebral cortex; mitral cells of olfactory bulb).
\item \textbf{Arboriform cells}, giving off branched dendrites from both base and apex, resembling the roots and the branches of a tree; the axone often springs from the base of one of the root-like dendrites (pyramidal cells of the hippocampus).
\item Cells with \textbf{monopolar dendrites}. Several main dendritic stems spring from one pole of the cell and, undergoing frequent subdivision, break up into a fine terminal arborization. The axone springs from the opposite pole (Purkinjean cells of the cerebellum; granular cells of the fasciola).
\end{enumerate}
2. Nerve Cell-body. Internal Morphology.—The nucleus of the nerve-cell differs in no essential from the typical nuclear structure. Regarding the organization of the cytoplasm several conflicting views exist. In the present state of our knowledge concerning this still obscure field of investigation it may be said that the nerve-cell protoplasm is roughly divided into a peripheral exoplasmic portion and a central endoplasmic portion. There is shown throughout the cytoplasm a tendency to fibrillary structure, more pronounced in the exoplasmic portion. Within the meshes of a more or less homogeneous ground-substance, which pervades the whole, are deposited larger and smaller masses of a granular substance. Nerve-cells fixed and stained by the methods of Nissl and Held show that the granule-masses are "stainable" (chromatophiles; tigroid bodies; Nissl bodies), probably of the nature of a nucleo-proteid (MacCallum) and looked upon as a sort of nutritive reserve. Many of the larger cells possess more or less pigmented material, adjacent to the nucleus. The cells of the intercalatum (substantia nigra) and of the locus ceruleus contain an abundance of such pigment-granules.

The "unstainable" homogeneous ground-substance of the cytoplasm is probably the more important functionally, for numerous delicate neuro-fibrils have, by special methods, been shown to traverse the cell-body and its processes, crossing and interlacing, perhaps anastomosing with each other, and traceable into the axone.\(^1\) Nissl, after years of painstaking investigation has classified nerve-cells into a great many different species in accordance with their reaction to staining agents.

The Dendrites.—The dendrites are usually numerous attenuated processes resembling in structure and staining reactions the cytoplasm and, being extensions thereof, represent an increase in the surface of the cell-body. Emerging by a broad base they become narrower as they divide into many branches in a dichotomous or arborescent manner to end free, according to most observers, or to be joined with the dendrites of other neurones by means of minute fibrille (as claimed by Apathy) or by concrescence (Held). The contour of the dendrite is usually irregular in some specimens, revealing varicosities along its course; in others, and more constantly, being seen to be beset with numerous lateral buds called

\(^1\) That the neuro-fibrils form such an intracellular network and that the axones arise therefrom is disputed by Ramon y Cajal, Bielschowsky, and others.
gemmules. Various hypotheses have been advanced in explanation of these appearances, it being held by some investigators that they are related to conditions of activity as contrasted to those of repose, while others believe them to be artifacts produced by the fixing and staining methods at present employed. However, it is no longer disputed that the function of the dendrites is receptive and conductive (or celluli-petal) for nerve-impulses, although they probably serve the nutritional requirements of the cell-body as well.

This functional distinction gives the clue to the correct interpretation of the central and peripheral prolongations of the cerebro-spinal ganglionic neurones. The cells of these ganglia are at first bipolar in form, but gradually undergo transformation into apparently unipolar cells by the migration of the cell-body to one side and the consequent approximation of the two processes to form a common pedicle in a T-shaped manner so typical of the spinal ganglion cell of the adult. The central branch invariably remains cellulifugal, the peripheral branch invariably remains celluli-petal, and as such is equivalent to the dendrites of all other neurones. It is merely a modified dendrite in that it courses a longer distance without branching until it reaches the periphery and is usually myelinic. Such a peripheral prolongation of the ganglion cell is also termed a centripetal nerve-fibre or medullated (myelinic) peripheral axone of a peripheral centripetal neurone.

The Axone.—The axone is usually much longer than any of the dendrites, thin, pale, smooth, emerging from the nerve-cell as a direct continuation of the neuro-fibrillar ground-substance of the cell-body, and devoid, so far as at present known, of chromatophile granules. Its calibre varies for the different cells, corresponding in general to the length of its course, but it is practically of uniform diameter throughout its extent. Axones may be extremely short or fully a metre in length. Most cells give rise to only one axone (monaxonic neurones), but in certain localities diaxonic (two axones) and polyaxonic (several axones) neurones are found. In a Golgi preparation axones stand out like pieces of black thread, taking a more direct course than do the irregular dendrites, and rarely branching before reaching the ultimate termination, although giving off collaterals along their course. The central axones of spinal ganglion (sensor) neurones are the principal exception to this rule in that they bifurcate in a Y-shaped manner after their entrance into the central nervous axis. In the case of another group of neurones, Golgi's Cell, Type II, the axone is observed to break up into numerous branches soon after its departure from the cell; such axones are called dendraxones. The axones and their collaterals end in terminal arborizations, the telodendria.

The axone is the distributive or emissive (cellulifugal) conductor of nerve-impulses. There is, therefore, a functional opposition attributable to the two extremities of the neurone, based upon its dynamic polarity and upon a physiological principle which is established by all experiments to which the nerve system is submitted; namely, that nerve-impulses pass through the neurone in a definite direction which is invariably and admitting of anatomical localization.

The majority of the peripheral spinal and cerebral axones as well as those constituting the white matter of the brain and cord are invested by a myelinic sheath.

The Collaterals (paraxones; cylindro-dendrites; side fibrils).—The collaterals are accessory branchings of the axones which are more numerous in the cytoproximal portion and are usually directed at right angles to the parent stem. Some axones possess few or no collaterals, while others possess many. The collaterals, especially those in the gray substance of the central axis, are frequently myelinic. They unquestionably play an important part in the grouping and chaining of neurones within the system, in yielding up to neighboring neurones a portion of the impulse that the cell has received by its dendrites and transmits along its axone to a distance.

STRUCTURE OF THE NERVE SYSTEM
Varieties of Axones.—Axones are divided into two main groups depending upon the presence or absence of a myelin sheath—myelinic axones and amyelinic axones, or medullated and non-medullated axones.

Myelinic axones or medullated axis-cylinder processes are axones enveloped by a relatively thick sheath composed of semifluid phosphorized fat which gives to the bundles of these structures their opaque, white appearance. The myelin sheath is in turn invested by a delicate membrane (neurilemma) in one group, while another group is devoid of such covering, giving rise to the further subdivision into (a) myelinic axones with a neurilemma; (b) myelinic axones without a neurilemma.

Myelinic axones with a neurilemma constitute the bulk of the cerebro-spinal nerves and, in lesser proportion, of the sympathetic nerves. The myelin sheath (medullary sheath of Schwann) does not invest the axone throughout its course nor in a uniform manner. The axone after its emergence from the cell-body and likewise in its preterminal portion is naked; and the delicate external membrane or neurilemma comes in contact with the axone. The myelin sheath consists of a number of tubular segments demarcated by nodal intersections which are only 0.08 mm. apart in the very small myelinic axones, while for larger axones the intervals may be 1 mm. or more. At the internodes (nodes or constrictions of Ranvier) the neurilemma dips into the constriction to come in contact with the axone, and any branches of the axone are invariably given off at such points. The interruptions in the continuity of the myelin sheath have been assumed to be provisions facilitating nutritive diffusion between the axone and the surrounding lymph. Each internodal myelinic segment is further characterized by oblique clefts, irregularly distributed—the incisures of Schmidt-Lautermann—seen only in fixed specimens and probably artifacts. Extraction of the fatty substance of the myelin sheath by boiling alcohol and ether brings out a fine network which

Fig. 519.—A, myelinic axones in fresh state, showing a few internodes; B, portion of a myelinic axone treated with boiling ether and alcohol to remove the myelin and leaving the neurokeratin network; a, axone.
resists trypsin digestion, and termed neurokeratin on account of its resemblance to the keratin of epidermal structures.

The neurilemma (primitive sheath of Schwann; neurolemma), a delicate structureless membrane, encloses the myelin and the axone, wherever the myelin sheath is wanting. Against the inner surface of the neurilemma, and embedded as it were in the myelin, usually midway between two nodes, lies the oval-shaped nucleus of the neurilemma.

Myelinic axones are usually from 4 to 10 microns in diameter; the extremes range from 2 to 20 microns.

Myelinic axones without a neurilemma constitute the white substance of the brain and spinal cord as well as the optic nerves. They differ from the axones just described in two particulars: the neurilemma is absent and there are no internodes interrupting the continuity of the myelin sheath. A network of neuroglia replaces the neurilemma as a supporting tissue.

Amyelinic axones with a neurilemma (Remak's fibres; sympathetic nerve-fibres) constitute the majority of the sympathetic axones and the axones of the olfactory nerves. The myelin sheath is absent and the axone is invested, more or less completely, by a nucleated cellular sheath or neurilemma.

Amyelinic axones without a neurilemma are naked axones, most numerous in the central ganglia. Most axones of longer course are devoid of any sheath in the cytoproximal and preterminal portions, whatever investment they may receive in the intermediate portion.

"NERVE-FIBRES" AND NERVES.

Prior to the general adoption of the neurone concept it was customary to designate the conducting elements of the nerve system by the term nerve-fibres in distinction from the nerve-cells. As has been pointed out above, the distinction no longer holds, but the designation "nerve-fibre" is still retained in anatomical vocabulary and recurs so frequently in common parlance that, even with the new conception which has been formed of the architecture of the nerve system, the term cannot yet be discarded in favor of "axone," although it probably will eventually.

Nerves are round or flattened bundles of axones which serve to bring the central axis into relation with the periphery and other tissues of the body. The nerves of the body are subdivided into two great classes—the cerebro-spinal, which are
attached to the cerebro-spinal axis, and the sympathetic or ganglionic nerves, which are attached to the ganglia of the sympathetic. The cerebro-spinal nerves consist of numerous nerve-fibres (myelinic axones) collected together into small or large bundles or fasciculi and enclosed in a membranous sheath.

In structure the common membranous investment, or sheath of the whole nerve, which is called the epineurium, as well as the septa given off from it, and which separate the fasciculi, consists of connective tissue, composed of white and yellow elastic fibres, the latter existing in great abundance. The tubular sheath of the smaller fasciculi composing the nerve-trunk, called the perineurium, consists of a fine, smooth, transparent membrane, which may be easily separated, in the form of a tube, from the fibres it encloses; in structure it consists of connective tissue which has a distinctly lamellar arrangement, being composed of several lamellae, separated from each other by spaces containing lymph. The nerve-fibres are held together and supported within the fasciculus by delicate connective tissue called the endoneurium (sheath of Henle). It is continuous with septa which pass inward from the innermost layer of the perineurium, and consists of a ground-substance in which are embedded fine bundles of fibrous connective tissue which run for the most part longitudinally. It serves to support the capillary vessels, which are arranged so as to form a network with elongated meshes. The cerebro-spinal nerves consist almost exclusively of myelinic axones, the myelinic axones existing in very small proportions.

The blood-vessels supplying a nerve terminate in a minute capillary plexus, the vessels composing which pierce the perineurium and run, for the most part, parallel with the fibres; they are connected together by short, transverse vessels, forming narrow, oblong meshes, similar to the capillary system of muscle. Fine myelinic axones accompanying these capillary vessels, the vasomotor fibres, and break up into elementary fibrils, which form a network around the vessel. Horsley has also demonstrated certain myelinic fibres as running in the epineurium and terminating in small bulboid tactile corpuscles or end-bulbs of Krause. These nerve-fibres, believed to be sensor, and termed nervi nervorum, are considered to have an important bearing upon certain neuralgic pains.

Nerves, in their course, subdivide into branches, and these frequently communicate with branches of a neighboring nerve.

The axones, as far as is at present known, do not coalesce, but pursue an uninterrupted course from the centre to the periphery. In separating a nerve, however, into its component fasciculi, it may be seen that they do not pursue a perfectly insulated course, but occasionally join at a very acute angle with other fasciculi proceeding in the same direction; from this branches are given off, to join again in like manner with other fasciculi. It must be distinctly understood, however, that in these communications the axones do not coalesce, but merely pass into the sheath of the adjacent nerve, become intermixed with its axones, and again pass on, to become blended with the axones in some adjoining fasciculus.

The communications which take place between two or more nerves form what is called a plexus. Sometimes a plexus is formed by the primary branches of the trunks of the nerves—as the cervical, brachial, lumbar, and sacral plexuses—and occasionally by the terminal fasciculi, as in the plexuses formed at the periphery of the body. In the formation of a plexus the component nerves divide, then join, and again subdivide in such a complex manner that the individual fasciculi become interlaced most intricately; so that each branch leaving a plexus may contain filaments from each of the primary nerve-trunks which form it. In the formation also of smaller plexuses at the periphery of the body there is a free interchange of the fasciculi and primitive fibres. In each case, however, the individual filaments or axones remain separate and distinct, and do not inosculate with one another.
It is probable that through this interchange of fibres the different branches passing off from a plexus have a more extensive connection with the spinal cord than if they each had proceeded to be distributed without such connection with other nerves. Consequently the parts supplied by these nerves have more extended relations with the nerve-centres; by this means, also, groups of muscles may be associated for combined action, as is best exemplified in the formation of the limb-plexuses.

The sympathetic nerves are constructed in the same manner as the cerebro-spinal nerves, but consist mainly of myelinic axones, collected into fasciculi and enclosed in a sheath of connective tissue. There is, however, in these nerves a certain admixture of myelinic axones, and the amount varies in different nerves, and may be known by their color. Those branches of the sympathetic which present a well-marked reddish-gray color are composed more especially of myelinic axones, intermixed with a few myelinic axones; while those of a white color contain more of the latter and a few of the former. Occasionally, the gray and white cords run together in a single nerve, without any intermixture, as in the branches of communication between the sympathetic ganglia and the spinal nerves, or in the communicating cords between the ganglia.

The nerves, both of the cerebro-spinal and sympathetic systems, convey impressions of a twofold kind. The afferent or centripetal nerves, generally called sensor, transmit to the nerve-centres impressions made upon the peripheral ends of their components, to produce reflexes in the lower centres while the mind, through the medium of the brain, becomes conscious of environmental conditions or changes. The efferent or centrifugal (in large part "motor") nerves transmit impulses from the centres to the parts to which the nerves are distributed; these impulses either excite muscular contraction or influence the processes of nutrition, growth, and secretion.

The Ganglia may be regarded as separate small aggregations of nerve-cells, connected with each other, with the cerebro-spinal axis, and with the nerves in various situations. They are found on the dorsal root of each of the spinal nerves; on the sensor root of the trigeminus; on the facial and auditory nerves; and on the glosso-pharyngeal and vagus nerves. They are also found in a connected series along each side of the vertebral column, forming the gangliated cord or trunk of the sympathetic; and on the branches of that nerve, generally in the plexuses or at the point of junction of two or more nerves with each other or with branches of the cerebro-spinal system. On section they are seen to consist of a reddish-gray substance, traversed by numerous white nerve-fibres; they vary considerably in form and size; the largest are found on the sensor root of the trigeminus and in the cavity of the abdomen; the smallest, not visible to the naked eye, exist in considerable numbers upon the nerves distributed to the different viscera. The ganglia are invested by a smooth and firm, closely adhering membranous envelope, consisting of dense areolar tissue; this sheath is continuous with the perineurium of the nerves, and sends numerous processes into the interior of the ganglion, which support the blood-vessels supplying its substance.

Origin and Termination of Nerves.—To the central and the peripheral ending of a nerve are usually given the names of "origin" and "termination." These designations have been rendered inappropriate, in many cases, by the newer concept of neuronic arrangement. They have not yet become obsolete, however, particularly in dissecting-room anatomy, and warrant description here with a certain degree of reserve alluded to above.

Origin.—The origin in some cases is single—that is to say, the whole nerve emerges from the nerve-centre by a single root; in other instances the nerve arises by two or more roots, which come off from different parts of the nerve-centre, sometimes widely apart from each other; and it often happens, when a
nerve arises in this way by two roots, that the functions of these two roots are

different; as, for example, in the spinal nerves, each of which arises by two
roots, the ventral of which is motor and the dorsal sensor. The point where
the nerve-root or roots emerge from the nerve-centre is named the superficial or
apparent origin, but the axones of which the nerve consists can be traced for
a certain distance into the nerve-centre to some portion of the gray substance,
which constitutes the deep or real origin of the nerve.

The manner in which these fibres arise at their deep origin varies with their
functions. The centrifugal or efferent nerve-fibres originate in the nerve-cells
of the gray substance, the axones of these cells being prolonged to form the fibres.
In the case of the centripetal or afferent nerves the axones grow inward either from
nerve-cells in the organs of special sense (e.g., the retina) or from nerve-cells
in the ganglia. Having entered the nerve-centre, they branch and send their
ultimate twigs among the cells, without, however, uniting with them.

![Diagrams of motor nerve-endings](image)

**Fig. 521.**—Diagrams of motor nerve-endings in A, striated muscle; B, cardiac muscle; C, unstriated muscle
a, axone; t, telodendria. (After Huber, Böhm and Davidoff, and others.)

**Termination.**—Axones terminate peripherally in various ways and may be most
conveniently studied in the efferent and afferent systems respectively. The
so-called peripheral terminations of afferent neurones are better called peripheral
nerve-beginnings, on account of their functional relations; the impulse is excited
in the peripheral end and conducted centrad through the rest of the neurone.

**Modes of Termination of Axones.**—The ultimate terminals of the axones and their
collaterals are called telodendrions (or telodendria). As far as can be determined
by present methods they invariably end “free,” commonly by exhaustion through
multiple division. This manifold branching presumably puts the neurone in a
condition to influence the processes of many other neurones (“avalanche conduc-
tion” of Ramón y Cajal). In some localities the formation by axonic terminals
of pericellular and peridendritic networks has been observed. Upon muscle-
fibres the axone terminals form chains of flattened disks, the motor end-plates.
Among gland-cells the terminal fibrils form more or less intricate plexuses.

**Peripheral Nerve-beginnings of Centripetal Neurones.**—Nerve-beginnings of the
centripetal (sensor) fibres are found in nearly all the tissues of the body. They
are peculiarly differentiated and of various forms in different localities and their function is apparently the conversion of mechanical, thermal, chemical, and other stimuli into nerve-impulses. The organs of vision, hearing, smell, and taste possess variously modified nerve-beginnings which are described under appropriate titles in the chapter on the Organs of Special Sense. The end-organs of the centripetal neurones collecting bodily impressions (tactile sense, muscular sense) and connected with the central axis are often very complicated structures. The principal varieties are:

Terminal fibrillae.
Tactile corpuscles (Meissner’s).
“Ruffini’s endings.”

I. Lamellated corpuscles (Pacini’s).
   Bulboid corpuscles (Krause’s).
   Genital (nerve) corpuscles.
   Articular (nerve) corpuscles.

II. Neuro-muscular spindles (Ruffini).
    Neuro-tendinous spindles (Golgi).

Fig. 522.—Showing some varieties of peripheral terminations of afferent neurones (or "peripheral nerve beginnings"): A, terminal fibrille in epithelium (after Retzius); B, tactile corpuscle (Meissner’s, after Dogiel); C, bulboid corpuscle (Krause’s, after Dogiel); D, lamellated corpuscle (Pacini’s, after Dogiel, Sala, and others); E, genital nerve corpuscle from human glans penis (after Dogiel); a, axone; t, telodendria.
**Terminal Fibrillae** are best demonstrable in the epithelium of the skin, mucous membranes, and cornea. The axone is seen to break up into its constituent fibrillae, which often present regular varicosities and Anastomose with each other in a plexiform manner.

**Tactile Corpuscles** (*corpuscula tactus; touch corpuscles of Meissner and Wagner*) consist of elongated oval lobules of delicate epithelioid tissue invaded by one or more axones which divide into their primitive fibrils, each terminal branch ending free usually as a somewhat flattened, disk-like plate in among the wedge-shaped cells of the corpuscle. Tactile corpuscles occur in large numbers in the cutaneous papillae of the finger-tips, in the conjunctiva, and, less abundantly, in the rest of the skin; they appear to be concerned with the finer tactile sensations.

Ruffini has described a special variety of sensor nerve-beginning in the subcutaneous tissue of the human finger (Fig. 523). They are principally situated at the junction of the corium with the subcutaneous tissue; they are of oval shape, and consist of a strong connective-tissue sheath within which the axone divides into numerous varicose fibrils ending in small, free knobs.

**Lamellated Corpuscles** (*corpuscula lamellosa; Pacinian corpuscles; Vater's corpuscles; Herbst's corpuscles*) are among the largest of the tactile end-organs and are found chiefly in the palmar surface of the hand, the sole of the foot, the genital organs, the serous membranes, and many other structures. Each corpuscle

![Diagram of a nerve-ending of Ruffini.](After A. Ruffini, Arch. Ital. de Biol., Turin, 1894, t. xxI.)

consists of a number of capsular connective-tissue lamellae arranged more or less concentrically around a central granular protoplasmic core, pierced by a single axone which usually divides into two or more branches giving off collaterals of beaded appearance and terminating in rounded knobs.

**Bulboid Corpuscles** (*corpuscula bulboidea; Krause's end-bulbs*) are minute cylindrical or oval bodies, consisting of a capsule continuous with the perineurium enclosing a core (inner bulb) of semifluid, finely granular protoplasm in which an axone runs out to end quite free at the distal end, usually terminates in a bulbous extremity, or, as is frequently observed, the axone divides into a number of branches of which each one terminates in an end-bulb.

The *genital corpuscles* (*corpuscula nervorum genitalia*) and the *articular corpuscles* (*corpuscula nervorum articularia*) very much resemble the bulboid corpuscles just described.

The genital corpuscles form aggregations of from two to six knob-like masses in the penis and clitoris. The articular corpuscles are found in the synovial membranes of the joints.

**Neuro-muscular Spindles** (*muscle-spindle of Kühne*).—These are found in nearly all the skeletal muscles and are most numerous in the extrinsic muscles of the tongue, in the small muscles of the hand and foot, and in the intercostal muscles. Most elaborate investigations upon these spindles have been conducted recently by Ruffini in Italy, Sihler, Huber, and De Witt in America. Neuro-muscular
spindles are usually found in the fibrous septa of the perimysium and consist of the flattened nerve-fibrils of centripetal axones arranged in one or all of three ways: (1) annular, where the fibrils surround the muscle-fibres in rings; (2) spiral, and (3) dendritic or branched (Fig. 524). They are doubtlessly concerned with the so-called muscle-sense.

**Neuro-tendinous Spindles (Organ of Golgi).**—The nerves conveying sensory impulses from the tendons have a special modification of the terminal fibres, in the form of numerous fibrils with branching end-plates or of an annular and spiral arrangement resembling the neuro-muscular spindles. They usually occur at the junction of the tendon bundles with the muscle-fibres (Fig. 525).

**The Neurone Doctrine.**—The results of the investigations of Golgi, Cajal, Forel, and others prompted Waldeyer to enunciate a theory with regard to the nerve mechanism of the neurone. This hypothesis is generally known as the neurone theory and assumes that (1) each neurone is a distinct and separate entity; (2) the collaterals and other terminals of the neurone form no connections among themselves; (3) neurones are associated, and impulses conveyed, by contact or contiguity of the axonic terminals of one axone with the cell-body or dendrites of
another neurone. The theory postulates a nerve-cell amœbism analogous to the extension and retraction of the pseudopodia of an amœba, and the "retraction theory" has been propounded in explanation of certain functional dissociation phenomena attending nerve-force manifestations.

Opposed to the "neurone theory" or "contact theory" is the more recent continuity theory which is being earnestly advocated by Apáthy, Bethe, and Nissl. In behalf of this theory it is claimed that the neurofibrils are continuous not only within the cell and its processes, but through an extracellular network as well. The dispute now being waged does not, however, affect our fundamental ideas regarding the individuality of neurones with regard to their dynamic condition.

The Supporting Tissue Elements of the Nerve System.—A fine meshwork of non-nerve tissue, more or less dense in different localities, but apparently restricted to the central axis, serves to support the neurones. This sustentacular tissue is of two kinds: (1) the neuroglia; (2) connective-tissue trabeculae derived from (a) the pia or (b) vascular channels.

The Neuroglia.—The neuroglia consists of glia-cells of varied forms and glia-fibres. Glia-cells are divisible into two species: endymal cells and astrocytes of long-rayed and short-rayed type.

Endymal cells are the columnar epithelial cells which line the neural canal throughout. In the embryonic condition each cell is seen to project a long multi-branched filament toward the periphery of the neural tube, while the free end carries a tuft of cilia. In adult life both the cilia and the radial filament are apparently lost or very much reduced.

Regarding the structure of the glia-cells proper as well as of the glia-fibres there is a variance of opinion among different investigators. The astrocytes, as they are commonly revealed in Golgi preparations, may, as pointed out by Weigert and others, be due to an extension of the silver deposit upon glia-cell nuclei as well as upon adjacent filaments. Huber, 1 Hardesty, 2 and others regard neuroglia tissue as a syncitium resulting from an early fusion of the protoplasm of the cells of the neural tube which at first were individual and definitely bounded. The filamentous reticulum of glia-fibres ordinarily seen in adult tissues seems to result

---

1 American Journal of Anatomy, 1901, pp. 45-61.
2 Ibid., 1904, pp. 229-268.
from an increase of the fine threads of the spongio-plasmic network of the original cell-protoplasm. Neuroglia occurs in both gray and white substance as an all-pervading supporting tissue. In certain localities, as upon the surface of the brain and cord, the neuroglia tissue is disposed in the form of a thin layer.

Besides the neuroglia, the central nerve system contains as supporting tissues numerous fine and coarse septa or trabeculae derived from the investing pia, or from the sheaths of blood-vessels.

**Chemical Composition.—**The amount of water in nerve-tissue varies with the situation. Thus in the gray substance of the cerebrum it constitutes about 83 per cent., in the white substance from the same region about 70 per cent., while in the peripheral nerves, such as the sciatic, it may fall to 60 per cent.

The solids consist of neuro-albumins, neuro-globulins, nucleo-proteins, neuro-keratin (in the gray substance proteins constitute about one-third of the total solids), lecithins, cerebrosides (chiefly phrenosin), cholesterol, unidentified organic sulpho-compounds, amino-fatty substances, nitrogenous extractives and inorganic salts, with some collagen, fat, etc., in the adherent connective tissue (W. J. Gies).

THE CENTRAL NERVE SYSTEM.

The central nerve system, as it is conventionally distinguished from the sympathetic system, is composed of a central axial aggregation of ganglia forming the brain and spinal cord, which are connected with the other tissues of the body by 43 pairs of nerves, of which 12 pairs are attached to the brain and 31 pairs to the spinal cord. The functional relations of the central mechanisms with the periphery are maintained by the essential cell-elements of the nerve-tissues, the neurones. The chief task in the study and analysis of the structure of the nerve system lies in the dovetailing of features visible to the naked eye with those visible only under high magnifying powers. By the combination of macroscopic with microscopic features the attentive student is enabled to resolve or reconstruct, in the three dimensions of space, and see with his mental eye the opaque interior transparently resolved into intricate yet well-defined projecting and associating mechanisms. Assistance in such study may be derived from illustrations depicting hidden structures in accordance with this principle.

**Preliminary Considerations. Gray Substance and White Substance.**—The central axis of the nerve system contains two categories of substance, their difference to the eye being one of color. They are conventionally designated the gray and white substance. The white substance (alba), which forms about two-thirds of the neuraxis, is the conducting substance and its characteristic appearance is due to the myelin sheaths which invest the axones in it. The gray substance (cinerea; grisea) is the sentient and reacting mass containing the cell-bodies of neurones. Its color is due to its translucency, its greater vascularity, and to a certain amount of pigmented material in the cell-elements. The white and the gray substance is not sharply demarcated everywhere, for although the white substance is exclusively conducting substance, the gray is not exclusively ganglionic, for the former encroaches on the latter; in some localities, as in the ventral horns of the spinal gray, in parts of the cerebral cortex, in the reticular formation of the pons and oblongata, and in the column of Clarke (dorsal nucleus), the admixture of myelinic fibres is considerable. Both white and gray substance is pervaded by the neuroglia.

The specific gravity of the cortical gray is 1.021, of the great ganglia 1.034, of the gray substance in the cerebellum and mesencephalon 1.050, and of the white substance 1.028.

For convenience of study, and somewhat in correspondence with phyletic
development, the central axis of the nerve system is divided into (1) the spinal cord and (2) the brain, grossly sub-divided into (a) oblongata, pons, and cerebellum; (b) mid-brain and (c) fore-brain. This gross subdivision is arbitrary and the inter-relations of the parts would be obscured were too much stress laid upon any mode of separation.

THE SPINAL CORD (MYELON; MEDULLA SPINALIS).

The spinal cord is the attenuated, nearly cylindrical part of the cerebro-spinal axis which lies in the vertebral canal, occupying its upper two-thirds in the adult. It extends from about the level of the atlo-occipital articulation (or lower border of the pyramid decussation) to the level of the lower border of the body of the first lumbar vertebra, where it terminates in a slender filament of gray substance enveloped by pia, and, further caudad, by a sheath of dura which is attached to the dorsum of the coccyx. The spinal cord is continuous cephalad with the oblongata. Its length is 45 cm. (44 to 50 cm.) in the male and 43.5 cm. (39.5 to 47 cm.) in the female. In the course of foetal development, the spinal cord occupies the entire length of the vertebral canal up to the third month, but after this period it gradually recedes cephalad owing to the more rapid growth of the vertebral column, so that at birth the caudal end of the spinal cord has risen to the level of the third lumbar vertebra.

The spinal cord does not entirely fill the vertebral canal. A wide space, or rather a concentric series of spaces intervene between its surface and the walls
of the canal, affording a marked freedom of movement of the vertebral column without exerting undue tension upon the spinal cord. These spaces, three in number, which concentrically surround the cord, are demarcated by the three protective membranes: (1) **pia**, (2) **arachnoid**, and (3) **dura**, which are continuous with the like meninges of the brain. The arrangement of the spaces and the membranes may be shown thus:

<table>
<thead>
<tr>
<th>Bony and ligamentous wall of vertebral canal.</th>
<th>Epidural space.</th>
<th>Dura.</th>
<th>Subdural space.</th>
<th>Arachnoid.</th>
<th>Subarachnoid space and subarachnoid reticulum.</th>
<th>(Pia investing spinal cord.)</th>
<th>(Spinal cord.)</th>
</tr>
</thead>
</table>

The pia closely invests the entire surface of the spinal cord and sends septal ingrowths into its substance as well as a fold occupying the ventro-median fissure. A leaf-like, serrated fold of pia, the **ligamentum denticulatum**, passes from each lateral border to the inner surface of the dural sheath and helps to support the cord within the subarachnoid space. The arachnoid and the pia are not separable in gross dissection as they merge insensibly, though usually described as distinct membranes. The arachnoid is in reality an exceedingly delicate and transparent web-like reticulum whose meshes constitute a relatively wide cavity filled with cerebro-spinal fluid. The dura constitutes the outermost and thickest sheath, while the narrow interval between the dura and the vertebral canal is filled by a fine venous plexus, together with soft, areolo-fatty tissue. Of the three spaces which surround the cord, only the two innermost contain fluid, and that of a serous character; the amount in the sub-dural space is very small, just sufficient to moisten the contiguous endothelial surfaces of the dura and arachnoid; that in the sub-arachnoid space is considerable. (For detailed description see section on the Meninges.)

**Weight.**—The weight of the spinal cord, exclusive of all nerve-roots, averages 28 grams, or 1 ounce avoirdupois, being slightly less in the female. Including the nerve-roots as ordinarily cut in postmortem procedure, the weight averages 45 grams in the male and 40 grams in the female. The ratio of weight in proportion to that of the brain is lowest in the human species, being 1 to 51 in the male and 1 to 49.8 in the female. In the newborn the ratio is 1 to 115. Its specific gravity is 1.038.

**External Morphology.**—*In situ* the spinal cord exhibits slight curvatures in the sagittal plane, being convex ventrad in the transition from cervical to thoracic portion and slightly concave ventrad to the lumbar portion. Its position varies also according to the degree of curvature of the spinal column, being raised slightly (a few millimetres only) in flexion of the spine.
The intrinsically segmental nature of the spinal cord is expressed by the association of each definite segment with the somatic segment supplied by its nerves. Thirty-one pairs of spinal nerves are commonly enumerated, although two additional, rudimentary pairs, relics of a tailed vertebrate ancestry, are demonstrable microscopically.

The first pair of spinal nerves emerges between the occiput and atlas, and is designated the first cervical; the other cervical pairs are named after the lower of the two vertebra which form the intervertebral foramen through which the nerve emerges. Very inconsistently the pair emerging between the seventh cervical and first thoracic vertebra is called the eighth cervical pair. The remaining spinal nerves are named after the upper of the two vertebra forming the corresponding foramen. In all there are:

- Cervical pairs: 8
- Thoracic pairs: 12
- Lumbar pairs: 5
- Sacral pairs: 5
- Coccygeal pairs: 1

Total: 31
All spinal nerves are made up of two roots by which they spring from the lateral aspects of the cord, symmetrically arranged, and these nerve-root attachments are the only guides to the demarcation of the various segments of the spinal cord. The two roots are generally termed the dorsal (afferent or sensor) root, which enters the cord along the dorso-lateral fissure and the ventral (afferent or motor) root which emerges along the ventro-lateral fissure.

Although the cervical nerves pass outward through the intervertebral foramina at nearly a right angle to the long axis of the cord, those of the lower series slope more and more downward, so that the fifth lumbar pair emerges six vertebral bodies lower than it originates. In fact, the lumbar and sacral nerves descend as parallel bundles in a brush-like manner to form the cauda equina, enclosed by the dural sheath as far as about the middle of the sacral canal. The topographical relations of the levels of origin and exit of the spinal nerves to the spinous processes of the vertebra is shown in Fig. 529.

Corresponding with the degree of development of the periphery, the spinal cord is more massive in those segments which are associated with the limb. Thus, in the ground-mole, the cervical portion is very much enlarged in conformity with the powerfully developed fore-limbs, while in the kangaroo or the ostrich, with powerful legs, the lumbar portion of the spinal cord is proportionately enlarged. In man, both the cervical and lumbar portions are enlarged, and while the bulk of the lower limbs exceeds that of the upper, the cervical portion of the spinal cord is more redundant because it innervates a limb which is functionally more differentiated, capable of much more skilful and complex movements and endowed with more acutely developed tactile sensibility.

The Enlargements of the Spinal Cord.—The spinal cord is marked by two spindle-shaped enlargements in its cervical and lumbar portions, while the intervening thoracic portion is nearly cylindrical, being slightly reduced in its dorso-ventral diameter. The cervical enlargement (intumescentia cervicalis) extends from the first or second cervical segment to the level of the second thoracic vertebra, acquiring a maximum breadth (13 to 14 mm.) at the sixth cervical vertebra. At its junction with the oblongata its breadth is about 11 mm. The thoracic portion is about 10 mm. in breadth (minimum at a little below its middle) while its sagittal diameter is 8 mm. The lumbar enlargement (intumescentia lumbalis) begins at the level of the tenth thoracic vertebra,
acquires its maximum breadth (12 mm.; sagittal diameter = 9 mm.) opposite the twelfth thoracic vertebra. Below the lumbar enlargement the cord gradually tapers to form a cone (conus), the apex of which, at the level of the lower border of the body of the first lumbar vertebra, is continuous with the attenuated filum.

The cervical enlargement is characterized by a relatively greater breadth than the remaining portions of the cord which, on section, appear nearly circular.

Conus (conus medullaris).—The conus is the conical extremity of the cord. The lower three sacral segments and the coccygeal segment are usually included under this term. Its diameter becomes reduced to 2 mm., to be continued below as the filum.

Filum (filum terminale; nervus impar).—The delicate terminal thread called the filum, continuous with the tapered end of the conus, is about 24 cm. in length. As far as the level of the second sacral vertebral segment it is enclosed, together with the cauda equina, in the tapering sheath of the dura. Within the dural sac it is called the filum internum, in contradistinction to the filum externum, which is an attenuated process of connective and nerve-tissue invested by a prolongation of the dura, which finally attaches to the periosteum of the dorsum of the coccyx. The filum externum occupies one-third of the total length of the filum. Morphologically, the filum is the caudal representative of the cord, and its intradural portion is usually accompanied by slender fascicles of nerve-fibres, which are rudimentary second and third coccygeal pairs of spinal nerves.

Fissures and Grooves.—The spinal cord is a bilaterally sym-
metrical structure and exhibits a deep ventral fissure and a slight dorsal groove partially subdividing the cord into right and left halves. The ventral fissure extends throughout the entire length of the cord, being shallower in the cervical and dorsal portions (less than one-third of the sagittal diameter) than in the lumbar portion. It is lined by a fold of pia which conveys the more important nutritive vessels to the depths of the cord substance. In the depth of this fissure lies the white ventral commissure of the cord. The dorsal groove has been regarded, erroneously, as being analogous to the ventral fissure. Unlike the ventral fissure, however, the pia does not descend into its depths, but passes continuously over it. The shallow groove marks the site of a septum made up of neuroglial and endynal elements. An actual groove is best demonstrable in some of the lumbar cord and in the oblongata, where it constitutes a veritable fissure between the clavæ.

Each lateral half is marked by the lines of root-attachment of the spinal nerves. The dorsal nerve-root fascicles enter the cord in linear series and in a depression or true sulcus termed the dorso-lateral fissure. The ventral nerve-root fascicles emerge, irregularly scattered, out of a greater circumferential area and no true ventro-lateral fissure can be said to exist. The line of emergence of the outermost fascicles is usually taken as an arbitrary boundary between the ventral and lateral districts of the cord, while the dorso-lateral fissure more distinctly maps off the lateral from the dorsal district. An additional fissure, observed most distinctly in the cervical and upper thoracic portions, termed the dorso-paramedian fissure, demarcates the two principal divisions of the dorsal columns, the dorso-median and the dorso-lateral columns. The dorso-paramedian fissure is an exceedingly shallow groove and is best denoted in sections of the cord by its continuance as a connective-tissue (glia) septum into the substance of the dorsal column. An analogous ventro-paramedian fissure is sometimes observable close to the ventral fissure, demarcating the ventral (or direct) pyramidal fasciculus.

Columns of the Cord (funiculi medullae spinalis).—Each half of the spinal cord is thus divided, with respect to its white substance, into three chief columns or funiculi. The dorsal column occupies the area between the dorsal septum and groove and the line of attachment of the dorsal nerve-roots; this column in its turn is generally subdivided into the dorso-median (funiculus gracilis; column of

![Diagram](image_url)
Goll's column and the dorso-lateral (funiculus cuneatus; column of Burdach) by the shallow dorso-paramedian groove and glia-septum referred to above. The ventral column (funiculus anterior) occupies the area between the ventral fissure and the outermost fascicles of the ventral nerve-roots—an arbitrary boundary line. The lateral column (funiculus lateralis) constitutes the remainder of the cord, between the dorsal and ventral nerve-root attachments. Each of these columns is subdivided into its component bundles or fasciculi, best studied in sections of the cord.

**Development of the Spinal Cord.**—The elongated postcranial portion of the neural tube becomes the spinal cord, while the primitive cavity within is preserved
as the central canal of the cord. The metamorphosis of the neuro-epithelial columnar cells has been described (p. 818). The lateral walls thicken considerably, the central slit-like canal widens as the walls bulge outward in an angular manner, and the central tubular gray becomes a fluted column with dorsal and ventral ridges (or horns) enveloped by a rapidly growing mantle of axone bundles which

Fig. 536.—Explanation of abbreviations: tr. olf., olfactory tract; c. q. l., lateral geniculate body; p. r. cr. A., indicate approximately the location of the reflex centres for the pupillary (p), the respiratory (r), cremasteric (cr.), patellar (pat), and tendo-Achillias (A.) reflexes. The vesical centre lies in the third and fourth sacral segments; the anal centre in the fourth and fifth (represented by circles); the centres for erection, ejaculation, labor pains (?) are probably also situated in this region. In reality, the divisions between the various segments are, of course, not so sharp as they are shown in the diagram, so that a given muscle or cutaneous region derives some of its controlling nerve-roots from the segments lying immediately above and below the principal segment. The sensor segment for any given region is regularly somewhat higher than the corresponding motor segment. (Jakob.)

become myelinic in successive stages. The bulging of the thickening walls in the dorsal and ventral as well as lateral directions produces the ventral fissure and the post-septum.

The segmental nature of the spinal cord has been alluded to before with regard to the segmental derivation of the cerebro-spinal ganglia and the disposition of the out-growing nerve-bundles. There is a further mode of division into longitudinal
systems based upon functional relationships. Two main categories of activity characterize the mechanism of the nervous system and find somatic expression in its architectural plan: First, actions in relation to the external world (somatic—involving skin, muscle, skeleton, etc.); second, internal activities concerned with the processes of nutrition and reproduction (visceral—involving the alimentary tract, circulatory, excretory, and reproductive systems). In each there is a twofold activity on the part of the nerve system: reception of stimuli and motor responses. In the cord (and to some extent in the brain as well) the following functional divisions may be distinguished and located anatomically (Fig. 534):

Somatic sensor elements.
Somatic motor elements.
Visceral sensor elements.
Visceral motor elements.

This functional differentiation of the neural axis into sensor and motor divisions apparently finds organic expression in an important modification of the developing neural tube. Each lateral wall of the neural tube is early demarcated
into a **dorsal** and a **ventral strip** or **lamina** and the slit-like central canal becomes more or less lozenge-shaped on trans-section, owing to the formation of a lateral longitudinal furrow within. The dorsal lamina or zone is preponderatingly sensor in function, while the ventral zone is principally motor in function. This fundamental fact has been of the greatest aid in the correct interpretation of many hitherto obscure facts regarding the mechanism of the nerve system, and will be found to underlie our method of description throughout.

**Muscular Supply from Motor Segments of the Cord.**—This is shown in Fig. 536.

**Internal Structure of the Spinal Cord.**—If a transverse section of the spinal cord be made, it will be seen to consist of white and gray nerve substance. The white substance is made up of myelinated axones; the gray contains the cell-bodies of neurones and non-myelinated axones. The color of the gray substance, so called, varies according to the degree of capillary injection and the age of the individual. It is usually of a faint reddish-gray tinge, the gray preponderating in older persons, but various shades of red, yellow, and light-slate color may be noted.

Nor is the color uniform even in the same section. Around the central canal and at the periphery of the dorsal horn the gray substance is very translucent and is termed, according to its situation, the **gloisa centralis** (gelatinosa centralis) and **gloisa cornualis** (gelatinosa Rolandi or caput glosum). The white substance surrounds the gray column as a variously thickened tunic, closely invested by the pia, which sends numerous delicate, vessel-bearing ingrowths into the substance of the cord. The relative area of the white substance, as seen on section, increases cephalad; the absolute area of both white and gray is largest in the region of the enlargements (Fig. 539).

**Gray Substance of the Cord** (entocinerea; substantia grisea centralis).—A plastic conception of the gray substance of the cord is essential to an understanding of the internal architecture. The gray core must be imagined not alone in the relations in which it is conventionally studied, as exposed in trans-sections, but also as a fluted column having a continuous extent throughout the cord. This gray column is drawn into ventral and dorsal ridges, connected respectively with the ventral and dorsal nerve-roots, while the white substance fills out the
irregularities and completes the nearly cylindrical outline of the cord (Figs. 540 and 541).

On viewing a trans-section, it is seen that the gray substance is so arranged as to present, in each lateral half of the cord, a crescentic or comma-shaped mass, the concavity of which is directed laterad. The two lateral masses are connected by a transverse bar or band of gray substance, termed the gray commissure (commissura cinerea [grisea]), and containing the central canal, which extends the entire length of the cord. The dorsal septum of the cord reaches quite to the gray commissure, there being but a few white commissural fibres in the dorsal zone. Ventrad, however, a lamina of white substance, the commissura ventralis alba, separates the gray commissure from the ventral fissure (Fig. 538).

In trans-sections of the cord it is seen that the lateral crescentic gray masses, united across the middle line by a gray commissure, have the aggregate appearance of the letter H. Each crescentic mass presents projections which are more or less pronounced according to the segment of the cord under consideration. Broadly stated and without reference to special levels, the most marked projections are the dorsal and ventral horns or cornua.

The Dorsal Horn, directed dorso-laterad, is elongated and narrow, and its apex is composed of a translucent V-shaped mass termed the gliosa cornualis (caput gelatinosa Rolandi [caput gliosum would be a better term]).

The attenuated apex of the dorsal cornu approaches the surface of the cord along the line of entrance of the dorsal nerve-roots. The apex of the dorsal horn is wider in the regions of the enlargements and the gliosa is most marked in the higher cervical segments. The base or cervix of the dorsal horn is constricted somewhat except in the thoracic portion, where its greater breadth is due to the presence of the nucleus dorsalis (Clarke's column). The Ventral Horn is shorter, thicker, and more blunt, and is separated from the ventral and lateral surfaces of the cord by a tolerably thick lamina of white
substance. Its margin, in trans-sections, presents a dentate or stellate appearance due to the emergence of fascicles of efferent or ventral root-axones on their way to the ventral surface of the cord.

What is known as the lateral horn projects as a lateral peninsular extension of the central gray nearly on the line of the gray commissure. It is best marked as a triangular projection in the upper thoracic segments. In the cervical enlargement it is merged with the greatly expanded ventral horn, but it again becomes prominent in the upper cervical segments.

The gray substance of the cord is not everywhere sharply demarcated from the white owing to the invasion of myelinic and amyelinic nerve-fibres. Facing the lateral column, in the angle between the dorsal and ventral horns, small fascicles of white fibres are embedded in the gray so that it is broken up in a peculiar basket-work pattern termed the reticula or reticular formation. This gray network is best marked in the cervical region and becomes more abundant in the oblongata.

The mode of arrangement of the gray substance and its amount in proportion to the white vary in different parts of the cord. Thus, the posterior horns are long and narrow in the cervical region; short and narrower in the thoracic; short but wider in the lumbar region. In the cervical region the crescentic portions are small, and the white substance more abundant than in any other region of the cord. In the thoracic region the gray substance is least developed, the white substance being also small in quantity. In the lumbar region the gray substance is more abundant than in any other region of the cord. Toward the lower end of the cord the white substance gradually ceases. The crescentic portions of the gray substance soon blend into a single mass, which forms the only constituent of the extreme point of the cord.

The Gray Commissure which connects the two crescentic masses of gray substance consists of myelinic and amyelinic nerve-fibres and neuroglia. The fibres pass transversely, spreading out at various angles, into the lateral gray masses. In the gray commissure, and extending the whole length of the cord, is a minute channel, the central canal (myelocele; canalis centralis), which is barely visible to the naked eye, but is proportionately larger in some of the lower vertebrates. Cephalad, in the oblongata, it opens out into the fourth ventricle; caudad it is continued for a short distance into the filum, in which it ends blindly. The canal is very minute, less than 0.1 mm., except in the terminal part of the conus, where it expands into a fusiform dilatation, the sinus terminalis (rhombocaele; ventriculus terminalis [Krause]). The central canal is lined by a layer of columnar cells which
are seen to be ciliated in the embryo and are in all respects identical with the endymal cells lining the ventricles of the brain. Surrounding the endymal lining of the central canal and gradually merging into the spongy substance which constitutes the remainder of the gray commissure is a finely granular and reticulated of the central canal and gradually merging into the spongy substance which constitutes the remainder of the gray commissure is a finely granular and reticulated
The gray substance of the cord is composed of (1) the gliosa, which envelops the head of the dorsal horn and which encircles the central canal of the cord; (2) the spongiosa, which forms the crescentic horns (except the heads of the posterior horns and the envelope of the central canal). Further, it may be stated that the gray substance consists of nerve-fibres of variable but smaller average diameter than those of the white column; (3) nerve-cells of various shapes and sizes, with few or many processes; (4) blood-vessels, lymphatic channels, and connective tissue.

The nerve-fibres of the gray substance of the posterior horn are for the most part composed of a dense interlacement of minute fibrils, intermingled with nerves of a larger size. This interlacement is formed partly by the axones and dendrites of the cells of the gray substance, and partly by fibrils which enter the gray substance and which come from various sources.

The nerve-cells of the gray substance are collected into groups as seen on transverse section, but they really form columns of cells placed longitudinally; or else they are found scattered throughout the whole of the gray substance (Fig. 542).

In the ventral horn four main groups of cells may be distinguished which are not wholly represented, however, in all regions of the cord: (1) A ventral group of cells, separable in the cervical and lumbar regions into ventro-medial and ventro-lateral sub-groups; (2) a dorso-medial group, situated in the cervix of the ventral horn, usually demonstrable in the thoracic portion as well as a few contiguous cervical and lumbar segments; (3) a lateral group, separable in the lower cervical and lumbar regions into ventro-lateral and dorso-lateral sub-groups, and supplying the muscles of the extremities; (4) a central group of cells in the lumbar and sacral regions.

In the lateral horn, which is most prominent in the thoracic and upper cervical segments, lies an intermediate group of cells, a long, slender column which is nearly restricted to the thoracic portion of the cord, but is seen to reappear in the upper three cervical and in the third and fourth sacral segments. The axones from these cells probably do not pass out with the ventral nerve-roots, but rather course within the cord to terminate at various levels on the same as well as on the opposite side. A close connection with the sympathetic nerve system, and with vasomotor and sweat-gland nerves, has been suggested.

In the dorsal horn the most conspicuous group of cells is a columniform nucleus commonly termed Clarke’s column (nucleus dorsalis), which extends between the seventh cervical and second (or third) lumbar segments of the cord. The cells are large and the group presents an oval outline in trans-sections, lying in the medial part of the cervix of the dorsal horn. The axones of these cells pass out of the gray into the lateral column of the cord to form the spino-cerebellar tract, and convey tactile impulses to the cerebellum.

Just ventrad of Clarke’s nucleus, and extending through a greater length of the cord, scattered cells constitute the nucleus of Stilling, represented in the oblongata by the accessory cuneate nucleus. Aside from these nuclear columns, the cells of the dorsal horn are not grouped very definitely, and for the purposes of description they are sub-divided according to their location. The cells vary much in form and size and their branched axones pass toward other regions within the gray substance at various levels on the same or on opposite sides, or via the ground-bundles. Many fibres of the dorsal nerve-roots are in relation with the dorsal-horn cells.

The various groups of cells enumerated above are frequently demarcated from neighboring groups by nerve-fibre intervals which may be straight, curved, interlaced, or loop-shaped.
Through the gliosa cornualis pass numerous fine fibrils, chiefly the afferent dorsal nerve-root fibres, but in addition this peculiar, gelatinous, and semitranslucent substance contains numerous small stellate cells; the region is so densely filled with axones and collaterals, as well as neuroglia-cells that until staining-methods became sufficiently developed the importance of this substance remained in dispute. In man the gliosa cornualis shows convolutions feebly imitating those of the olive, and its structure is analogous. Dorsad of the gliosa lies the ultimate zone of the dorsal horn; this gray substance resembles the spongiosa in its essential characters.

The White Substance of the Cord (substantia alba).—The white substance of the cord, consisting chiefly of longitudinally disposed myelinic fibres, with blood-vessels, neuroglia, and connective-tissue septa, forms a thick mantle which invests the central gray column. When stained with carmine, a transverse section of the white substance is seen to be studded all over with minute dots surrounded by unstained circular areas. The dots are the transversely cut axones; the lighter areas are the myelin sheaths. The mass of white substance is closely invested by a sheath of neuroglia immediately beneath the pia. Numerous septa, derived from the pia, but always coated by a thin layer of neuroglia, pass into the white substance to separate the respective bundles of fibres and are often interwoven between individual nerve-fibres, acting as a supporting framework in which they are embedded. In addition to the longitudinal fibres—there are shorter and less numerous transverse fibres collected into the so-called commissural bundle or white commissure.

Longitudinal Fibres.—The longitudinal fibres constitute the conducting tracts. Although a purely anatomical examination fails to reveal the functional relations of these fibre-bundles, the structural alterations which ensue (in accordance with the laws of Waller) in the distal portion of a neurone whose proximal portion has been destroyed, the progressive myelinization of separate tracts in the embryo and infant (as proved by the researches of Meynert and Flechsig), the comparative anatomy method and electro-physiological experimentation have rendered possible the demonstration of the origin and destination of the various conducting systems or tracts with almost mathematic accuracy. While some fibres pursue a lengthy course, serving as conduction paths between the brain-centres and the various spinal centres, others are shorter and serve to associate different spinal levels—in juxtaposition or relatively not far distant. It must be borne in mind that the gray substance, intercalated as it is in the course of the impulses which pass to and fro in the cord, contains the neural elements which are either (a) the source or (b) the destination of these impulses, and thus complete the nerve-cycle requisite for the organization of the functions belonging to the cord. The motor and sensor phenomena, though interacting, depend upon distinct nerve elements.
which, because of their functional relationship, or because of the direction in which they convey impulses, are generally referred to as motor or sensor, efferent or afferent neurones; and in the spinal cord usage has sanctioned the employment of the terms descending and ascending for tracts conveying motor and sensor impulses, respectively. Anatomically speaking, however, it is preferable to describe the tracts with reference to their origins and termini (as cerebro-spinal, spino-thalamic, etc.), when known, or to their topographical relations as studied in trans-sections of the cord.

For the purposes of description it is convenient to classify the longitudinal fibres into three general systems: (1) The cerebro-spinal system of axones forming conduction paths for efferent impulses from the cerebrum to the spinal centres for peripheral organs, and axones for afferent impulses received in the spinal centres from the periphery and conveyed in turn to the cerebrum.

(2) The spino-cerebellar system, consisting of conduction paths, afferent and efferent, between the cerebellum and the spinal centres.

(3) Numberless association systems strictly confined within the cord (or only extending into the oblongata), composed of shorter or longer axones which serve to associate not only different levels of the same spinal segment, but also the different segments, that are in juxtaposition or more remotely situated. These spinal association axones form bundles in close contact with the central gray column and are termed the fasciculi proprii or ground-bundles.

The columns of white substance have already been enumerated (p. 539) as the dorsal, lateral, and ventral columns or funiculi.

In the dorsal column there are described the following tracts:

Ascending:

(1) Fasciculus gracilis (Golli).

(2) Fasciculus cuneatus (Burdachi).

Descending:

(1) Comma tract (Schultze).

(2) Median oval tract (Flechsig).

Associating:

(1) Fasciculus dorsalis proprius.

(2) Dorsal cornu-commissural tract.

(3) Septo-marginal tract (Bruce).

Another tract, usually described as belonging to the lateral column, but functionally more intimately related to the sensor neurone-system of the dorsal column is the fasciculus marginalis (of Spitzka and Lissauer).

The great majority of the axones constituting the dorsal column are the afferent (sensor) axones arising from the spinal ganglion cells, entering the cord by the dorsal roots. These dorsal root-axones bifurcate in the region of the dorsal horn, one branch ascending a little obliquely at first, then vertical, while the other branch takes a similar downward course for a shorter distance (Fig. 544). As additional groups of fibres are contributed by each successive dorsal nerve-root the mass of white substance in the dorsal column accumulates as the cord is ascended, though it must be noted that not all of these afferent fibres traverse the whole of the cord above, but end in relation with cells in the gray substance at various levels. The successive accessions of afferent fibres are disposed in a laminated manner so that the lumbar fibres come to lie lateral to the sacral bundle, the thoracic lateral of the lumbar, and so on as the cord is ascended. A section of the cord at its highest level would therefore traverse a collection of bundles derived from all of the dorsal-nerve roots of the cord, arranged as shown in Fig. 544.

In the upper segments of the cord it is possible to distinguish a division of the dorsal column into two principal fasciculi owing to the presence of a distinct connective-tissue septum which passes into the substance of the dorsal column.
along the dorso-paramedian groove. These fasciculi are termed, according to their position, the dorso-median and dorso-lateral fasciculi or Goll's column and

Burdach's column; in the consideration of the external morphology of the cord, these have already been referred to as the funiculus gracilis and funiculus cuneatus, respectively.
It has been noted that even in the fresh cord, when sectioned, the gracile bundle has a different tinge and stains more deeply with carmine than does the cuneate bundle.

The caudad or descending branches of the bifurcate dorsal-root axones are considerably shorter than the ascending branches. They terminate in the gray substance in relation with its cells and, by numerous collaterals which are shorter or larger and given off at various intervals, serve to associate different levels of the cord. Some of these collaterals cross the median line in the dorsal commissure to come into relation with neurones of the opposite side. Certain of the longer descending branches show a tendency to collect into a feebly marked bundle along the mesal border of the dorso-lateral fasciculus, called because of its outline in trans-sections—as seen in cases of descending degeneration from injury at a higher level—the comma tract of Schultze. A similar bundle, situated along the dorsal septum, best demonstrable in the lumbar cord, and with its fellow of the opposite side of oval outline as seen on section, is called the oval bundle of Flechsig (tractus cervicolumbatis [Edinger]; dorsomediales Sakralfeld [Obersteiner]).

Marginal Tract.—Not all the axones of the dorsal-nerve root enter the dorsal column. Another group elsewhere described passes into the dorsal horn as
THE NERVE SYSTEM

well as toward Clarke's column, while a third group of fibres forms the so-called marginal tract, situated close to or among the entering fibres of the dorsal roots, but frequently described as lying in the lateral column. The tract is demonstrable in all levels and is made up of successive increments of relatively short axones (traversing not more than three or four segments) to end in relation with the cells of the glosa cornualis. It has been assumed that the tract is concerned with the transmission of pain-sense.

Ground-bundle of the Dorsal Column.—A zone of fibres contiguous with the dorsal face of the gray column, and termed the fasciculus dorsalis proprius or dorsal ground-bundle, is composed of axones arising from the smaller cells of the dorsal horn, which, after entering the white substance and bifurcating into ascending and descending branches, come into relation with other levels of the gray column by means of collaterals and terminating in it after a comparatively short course. They are therefore to be regarded purely as association or “longitudinal commissural” fibres. The dorsal cornu-commissural tract (ventrales hinterstrangsbündel [Strümpell]; zone cornucommissurale [Marie]), occupying a triangular interval at the apex of the trans-sected dorsal column, and the septo-marginal tract [of Bruce], in apposition with the post-septum, belong to this category of association bundles. Both tracts are most evident in the lumbar portion of the cord.

In the lateral column the following tracts may be enumerated:

Ascending:

1. Dorso-lateral spino-cerebellar tract (Flechsig).
2. Superficial ventro-lateral spino-cerebellar tract (Gowers).
4. Spino-mesencephalic tract.
5. Spino-olivary tract (Hellweg).

Descending:

1. Crossed pyramidal tract.
2. Rubro-spinal tract.
3. Cerebello-spinal tract (Marchi and Löwenthal).
4. Vestibulo-spinal tract.
5. Olivo-spinal tract.

Associating:

1. Fasciculus lateralis proprius.

The dorso-lateral spino-cerebellar or direct cerebellar tract (of Gratiolet and Flechsig) lies at the periphery, laterad of the crossed pyramidal tract. Its axones arise from the cells of Clarke’s column and ascend uninterruptedly to the oblongata, and thence to the vermis of the cerebellum in its post-peduncle. The tract becomes more massive as the cord is ascended (Fig. 543).

The superficial ventro-lateral spino-cerebellar tract also courses along the periphery, but farther ventrad. The origin of its axones is yet in dispute; they probably arise from cells in the gray column of both sides, in the zone between the dorsal and ventral horns as well as from some of the ventral-horn cells. The destination of the axones of this tract is equally uncertain, but most of the fibres have been traced through the dorso-lateral region of the oblongata and the pontile reticula, whence it turns dorsi-mesad, to enter the cerebellum through the valvula and ending in the dorsal vermis. A lesser portion of the tract has been traced to the quadrigemina, while other groups of axones end in various levels of the gray column.

The spino-thalamic and spino-mesencephalic (tractus spinotectalis) tracts are not gathered into compact bundles, but are rather scattered among the fibres of

1 First described by F. C. Spitzka (in 1885) and Lissauer (1886) and usually bearing the name of the latter.
the lateral column just mesad of the superficial ventro-lateral spino-cerebellar tract (Gowers). The axones of both systems arise from cells in the dorsal horn and its cervix of the opposite side, coursing through the white ventral commissure and ascending the cord, the spino-thalamic fibres ending in the thalamus, the spino-mesencephalic fibres ending in the region of the quadrigemina. The two tracts are collectively called *tractus spino-tecalis et thalamicus*.

The spino-olivary tract (Helweg’s Dreikantenbahn; Bechterew’s Olivenbündel) is found only in the higher segments of the cord, at its periphery and just laterad of the emergence of the ventral nerve-roots.

Its connections and functional direction are uncertain; some investigators have traced its fibres between the olive and certain ventral-horn cells; Obersteiner suggests a relationship with the pyramidal tract. The coincidence, in point of time, of the myelinization of both tracts is significant in this connection.

The crossed pyramidal tract (lateral cerebro-spinal fasciculus) occupies an approximately triangular or oval area in the dorsal portion of the lateral column, just mesad of the direct cerebellar tract, except in the lumbar cord, where it lies at the surface. The axones of this tract arise from the pyramidal cells of the cerebral cortex (motor area) of the opposite side. After having descended through the internal capsule, crusta, pons, to the pyramis of the oblongata, the major portion of the fibres derived from one-half of the brain decussate with those of the other half, crossing the median line to descend in the lateral column of the cord. The fibres which do not decussate constitute the direct pyramidal tract in the ventral column. As the crossed pyramidal tract descends it diminishes in size as its axones become distributed to the ventral horn, where they terminate in contiguity with the ventral motor cells which give rise to the fibres of the ventral (motor) nerve roots. The bundle becomes exhausted as a distinct strand at the level of the fourth sacral segment.

The rubro-spinal, cerebello-spinal, lateral vestibulo-spinal, and olivo-spinal tracts consist of descending axones which are intermingled so that their mutual topographical relations cannot at present be described. Collectively they constitute the *fasciculus intermedius* of Löwenthal and Bechterew (intermedio-lateral tract of Bruce and Campbell) and they lie ventral of the crossed pyramidal tract and mesad of the combined spino-thalamic and spino-mesencephalic tracts.

The rubro-spinal tract (Monakow’s tract; prepyramidal tract) originates in the rubrum (red nucleus in the tegmentum of the mid-brain) of the opposite side and its axones terminate in relation with ventral-horn cells. In their course these fibres are seen to invade the area of the crossed pyramidal tract. The cerebello-spinal tract (Marchi’s tract) is supposed to arise in the cortex of the cerebellar hemispheres; to become distributed to the motor centres in the ventral horn.

The lateral vestibulo-spinal tract arises in the lateral nucleus of the vestibular nerve (Deiters’ nucleus) and by its relations with spinal centres establishes a connection with the equilibratory apparatus.

The olivo-spinal tract, according to Kölliker, is a crossed tract whose axones arise in the olive and terminate in relation with the motor cells of the ventral horn.

Several other descending tracts ending in the spinal cord and arising in higher centres like the quadrigemina, central gray of the mesencephalon, and the cerebellum have been recently described by Held, Boyce, and Bechterew.

**Ground-bundle of the Lateral Column** (*fasciculus lateralis proprius*).—This lies in the concavity of the lateral aspect of the gray column and consists of axones having a purely commissural function. In the regions where the reticula is best marked it is subdivided into a group of smaller bundles by numerous glial septa.
In the ventral column are described the following tracts:

**Descending:**

1. Direct pyramidal tract.
2. Sulco-marginal tract.
3. Ventral vestibulo-spinal tract.

**Associating:**

1. Association-axones between spinal centres and several cranial nerve nuclei.
2. Fasciculus ventralis proprius.

The **direct pyramidal tract** (fasciculus cerebrospinalis ventralis; fasciculus of Türek) is the uncrossed portion of the pyramidal tract below the decussation in the oblongata, and constituting only 10 to 15 per cent. of the fibre system arising in the motor cortex of the same side. It is a small, oblong bundle, as seen on trans-section, lying parallel with the ventral fissure, from which it is separated in the higher segments by the relatively narrow sulco-marginal tract. The tract diminishes in bulk as the cord is descended, to disappear in the thoracic portion of the cord; though, in rare instances, it has been observed to extend throughout the lumbar portion as well. This diminution and eventual disappearance of the tract is due to the successive decussations of its fibres throughout its course, for, with a few exceptions, these cross in the ventral white commissure to come into relation with the ventral-horn cells (motor cells) of the opposite side. This partial longitudinal extension of the pyramidal decussation and consequent formation of an uncrossed, ventrally situated pyramidal tract is peculiar to the primate order of vertebrates.

The **sulco-marginal tract** (tractus tectospinalis) is a thin bundle whose axones arise in the quadrigemina of the opposite side, immediately decussating and descending through the oblongata, to be distributed to various spinal centres in a manner not yet accurately ascertained. The system is assumed to be concerned in the coördination of movements of the head, with optic and acoustic reflexes.

The **ventral vestibulo-spinal tract** (Löwenthal’s tract; anterior marginal fasciculus; ventral cerebello-spinal tract) lies at the periphery of the ventral column, extending, as seen on trans-section, from the ventral-root zone to the ventral fissure. Its axones arise from (1) the lateral (Deiters’) and (2) superior (Beechterew’s) nuclei of the vestibular nerve; (3) from the fastigium of the cerebellum. Their termination about the ventral-horn cells has been traced as far as the sacral region of the cord.

As in the lateral column, and continuous with the like formation, there is in the ventral column an intermediate zone of mixed systems of axones which serve to associate various levels of the cord with ganglionic masses in the oblongata as well as with the cerebellum and quadrigemina. The nuclei of the trigeminus, facial, auditory, glosso-pharyngeal, and vagus nerves, together with the olive and the cerebellum, seem most intimately associated with the spinal centres for movements of the head and neck.

**Ground-bundle of the Ventral Column.**—The white substance of the ventral column contiguous with the central gray is made up of intersegmental axones of association connecting different levels of the cord.

The **ventral white commissure** (commissura ventralis alba) is composed of myelinic fibres which decussate with or cross each other and, on trans-section, are seen to form a narrow band connecting the ventral columns of the two sides. The axones composing it are chiefly (1) those arising from ventral-horn cells, which after crossing the mid-line, course horizontally or cephalad and caudad to come into relation with neurones at the same or at different levels of the gray substance; (2) the decussating axones of the direct pyramidal tract; (3) numerous collaterals from the ventral and lateral column axones. The white commissure is most
massive in the enlargements where the associations of the limb-centres are necessarily greater in number.

**Myelinization of the Axones of the Cord.**—The acquisition of the myelin sheath is not contemporary for all axones in the cord, but is characterized by a regular progression in the myelinization of separate fasciculi. As a rule, those axone systems which are concerned with simpler or intrinsically spinal reflexes become myelinic or "mature" at an earlier stage of fetal development than do those concerned in the more elaborate connections of the cord with the brain. Thus, the efferent and afferent axones, and those of associating neurones, become myelinic in the fifth and sixth months of fetal life, while the pyramidal tracts and the spino-olivary tract (of Helweg) are observed to be the last to mature at the time of birth, in correspondence, apparently, with the inception of the functional use of these tracts. The order of myelinization of the separate fasciculi is indicated in Fig. 546.

![Diagram showing the order of myelinization of the various tracts in the spinal cord (cervical level). The tracts are named on the right side; the Roman numerals on the left side correspond with the enumeration given in the text. H, Helweg's tract; M, marginal tract.](image-url)

**Summary.** **The Gray Substance.**—The gray substance consists, aside from its supporting tissues, of sentient and reacting nerve-cells, with their dendrites and axones, and of the terminals of axones entering from without. These nerve-cells may be classified as follows:

(a) Nerve-cells whose axones pass directly out of the cord. These lie in the ventral horn, are "motor" in function, and their axones form the ventral-nerve roots.

(b) Nerve-cells whose axones pass into the white substance, usually bifurcating into a shorter descending and a longer ascending branch. Two kinds of cells are distinguished:

1. Strand- or tract-cells whose axones (ascending branches) traverse the cord, to come into relation with higher centres in the brain.

2. Association-cells whose axones, after a comparatively brief course in the white substance, reenter the gray substance and serve to coordinate different levels of the cord.

The tract-cells may be further divided into two categories: **homo-lateral** and **contra-lateral tract-cells.** Homo-lateral cells are those whose axones enter the white...
columns of the same side; contra-lateral cells are those whose axones traverse the white ventral commissure to the other side. Tract-cells exist in all parts of the gray substance and are termed, according to their situation: ventral-, lateral-, and dorsal-horn cells. The contra-lateral tract-cells preponderate in the dorsal horn, its cervix, and in the intermediate zone, and, on account of their course, are also called commissural cells.

c) Nerve-cells of Golgi's type II, or cells with short, multi-branched axones.

The motor ventral-horn cells differ, therefore, from the other categories in that they alone send their axones out of the central axis to the periphery. The tract-cells, commissural cells, and the Golgi type II cells are strictly confined to the central axis; the tract-cells serve to coordinate the separate units of the spinal neurone system with higher centres; the association-cells maintain the paths of conduction between higher and lower cell-complexes; while the cells of Golgi's type II are limited to a narrower field of nerve-activity as nerve links in the chaining together of neurones.

White Substance.—The white substance consists essentially of axones the great majority of which are disposed longitudinally. These axones comprise:

a) Axones arising in the cerebral cortex, the gray ganglionic masses in the mid-brain, pons, and cerebellum, and descending to their terminations in different levels of the cord.

b) Axones which, conversely, arise in the gray substance of the cord (tract-cell axones), to terminate in the higher brain-centres.

c) Axones which coordinate different levels of the cord with each other (association-cell axones.)

d) Axones which, arising from the spinal-ganglion cells of the dorsal-nerve roots, enter the cord and ascend in the dorsal columns.

Dissection.—To dissect the cord and its membranes it will be necessary to lay open the whole length of the vertebral canal. For this purpose the muscles must be separated from the vertebral grooves, so as to expose the spinous processes and lamina of the vertebrae; and the latter must be sawed through on each side, close to the roots of the transverse processes, from the third or fourth cervical vertebra above to the sacrum below. The vertebral arches having been displaced by means of a chisel and the separate fragments removed, the dura will be exposed, covered by a plexus of veins and a quantity of loose areolar tissue, often infiltrated with serous fluid. The arches of the upper vertebrae are best divided by means of a strong pair of cutting bone-forceps or by a rachitome.

MEMBRANES OF THE CORD.

The membranes which envelop the spinal cord are three in number. The most external is the dura, a strong fibrous membrane which forms a loose sheath around the cord. The most internal is the pia, a cellulo-vascular membrane which closely invests the entire surface of the cord. Between the two is the arachnoid, a non-vascular membrane which envelops the cord and is connected to the pia by slender filaments of connective tissue.

The Spinal Dura (Dura Spinalis) (Figs. 528, 530, 547, 549).

The spinal dura represents only the meningeal or supporting layer of the cranial dura. The endocranial or endosteal layer ceases at the foramen magnum dorsally, but reaches as low as the third cervical vertebra ventrally; below these levels its place is taken by the periosteum. The dura forms a loose sheath which surrounds the cord and the cauda equina, and is loosely connected with the vertebral periosteum and the ligaments by a quantity of lax areolar tissue and a plexus of veins, the meningo-rachidian veins (plexus venosi vertebrales interni). The
space containing the fat and veins is called the **epidural space** *(cavum epidurale)*. The situation of the veins between the dura and the periosteum of the vertebrae corresponds therefore to that of the cranial sinuses between the endocranial and supporting layers. The dura is attached to the circumference of the foramen magnum and to the axis and third cervical vertebra; it is also fixed to the posterior common ligament, especially near the lower end of the spinal canal, by fibrous slips; it extends below as far as the second or third piece of the sacrum; here it becomes impervious, and, ensheathing the filum terminale, constitutes the **filum durae spinalis** *(Fig. 530)*, and descends to the dorsum of the coccyx, to blend with the periosteum. This part of the dura is called the **coccygeal ligament** *(Fig. 549)*. The dura is much larger than is necessary for its contents, and its size is greater in the cervical and lumbar regions than in the thoracic. Its inner surface is smooth. On each side may be seen the double openings, which transmit the two roots of the corresponding spinal nerve, the fibrous layer of the dura being continued in the form of a tubular prolongation on them as they pass through these apertures. These prolongations of the dura are short in the upper part of the spine, but become gradually longer below, forming a number of tubes of fibrous membrane, which enclose the sacral nerves, and are contained in the vertebral canal.

The chief peculiarities of the dura of the cord, as compared with that investing the brain, are the following:

- The dura of the cord is not closely adherent to the bones of the vertebral canal, and is not, as is the cranial dura, the internal periosteum of the vertebrae. The vertebrae have an independent periosteum.
- It does not send partitions into the fissures of the cord, as the cranial dura sends partitions into certain fissures of the brain.
- Its fibrous laminae do not separate to form venous sinuses, as in the cranium.
- It contains no Pacchionian bodies.
Structure.—The dura consists of white fibrous and elastic tissue arranged in bands or lamellae, which, for the most part, are parallel with one another and have a longitudinal arrangement. Each surface is covered by a layer of endothelial cells. It is sparingly supplied with vessels, and some few nerves have been traced into it.

The Arachnoid (Arachnoidea Spinalis) (Figs. 528, 547).

The arachnoid is exposed by slitting the dura and reflecting that membrane to either side. It is a thin, delicate, tubular membrane which invests the surface of the cord, and is connected to the pia by slender filaments of connective tissue. Above, it is continuous with the cranial arachnoid; on each side it is continued on the various nerves, so as to form a sheath for them as they pass outward to the intervertebral foramina. The outer surface of the arachnoid is in contact with the inner surface of the dura, and the two are, here and there, joined together by isolated connective-tissue trabeculae. These trabeculae are especially numerous on the posterior surface of the cord. For the most part, however, the membranes are not connected together, and the interval between them is named the subdural space (cavum subdurale). The subdural space contains a very small amount of lymph-like fluid. There is no communication between the subdural and the subarachnoid spaces. The subdural space is prolonged outward for a short distance on each emerging nerve and communicates with the lymph tract of the nerve. The inner surface of the arachnoid is separated
THE PIA OF THE CORD

from the pia by a considerable interval, which is called the subarachnoid space (cavum subarachnoideale). The space is largest at the lower part of the spinal canal, and encloses the mass of nerves which forms the cauda equina. Cephalad it is continuous with the cranial subarachnoid space, and communicates with the general ventricular cavity of the brain by means of openings in the pia, in the roof of the fourth ventricle, the metapore or foramen of Majendie and foramina of Key and Retzius. It contains an abundant serous secretion, the cerebrospinal fluid (liquor cerebrospinalis). This secretion is sufficient in amount to expand the arachnoid, and thus to distend completely the whole of the space included in the dura. The subarachnoid space is occupied by trabeculae of delicate endothelial covered connective tissue, connecting the pia on the one hand with the arachnoid on the other. This is named subarachnoid tissue.

In addition to this the space is partially subdivided by a longitudinal membranous partition, the septum posticum or the posterior fenestrated septum (septum subarachnoideale), which serves to connect the arachnoid with the pia, opposite the dorso-median fissure of the spinal cord. It is a partition, but an incomplete and cribriform partition, consists of bundles of white fibrous tissue interlacing with each other, and is coated with endothelium. The dentate ligament (ligamentum denticulatum), which run from the pia to the dura on either side of the cord, divide the subarachnoid space into an anterior and a posterior space (cavum subarachnoideale anterius et posterius), which join like spaces in the cavity of the cranium. The external spinal veins (venae spinales externae) lie in the subarachnoid space.

Structure.—The arachnoid is a delicate membrane made up of closely arranged interlacing bundles of connective tissue in several layers. It contains many elastic fibres, and is covered on each side by endothelial cells. The arachnoid contains neither vessels nor nerves.

The Pia of the Cord (Pia Spinalis).

The pia of the cord is exposed on the removal of the arachnoid (Figs. 547 and 548). It covers the entire surface of the cord, to which it is very intimately adherent, forming its neurilemma, and sending a process downward into its ventral fissure. It also forms a sheath for each of the filaments of the spinal nerves, and invests the nerves themselves. A longitudinal fibrous band extends along the middle line on its ventral surface, called by Haller the linea splendens; and a somewhat similar band, the ligamentum denticulatum, is situated on each side. At the point where the cord terminates the pia becomes contracted, and is continued caudad as a long, slender filament, the filum terminale (Fig. 549), which descends within the sheath of the dura and the arachnoid and through the centre of the mass of nerves forming the cauda equina.

It unites with the dura and arachnoid about the level of the third sacral vertebra, and as the central ligament of the spinal cord, the coccygeal ligament, or the filum durae spinalis the fused membranes extend caudad as far as the base of the coccyx, where they blend with the periosteum. It assists in maintaining the cord in its position during the movements of the trunk. It contains a little gray nerve substance, which may be traced for some distance into its upper part, and is
accompanied by a small artery and vein. At the upper part of the cord the pia presents a grayish, mottled tint, which is owing to yellow or brown pigment-cells scattered among the elastic fibres.

**Structure.**—The pia of the cord is less vascular in structure, but thicker and denser, than the pia of the brain, with which it is continuous. It consists of two layers: an outer, resembling the arachnoid, composed of bundles of connective-tissue fibres, arranged for the most part longitudinally; and an inner (intima pia), consisting of stiff circular bundles of the same tissue, which present peculiar angular bends. It is covered on both surfaces by a layer of endothelium. Between the two layers are a number of cleft-like lymphatic spaces which communicate with the subarachnoid cavity, and a number of blood-vessels which are enclosed in a perivascular sheath, derived from the inner layer of the pia, into which the lymphatic spaces open. The pia contains the anterior spinal artery and its branches, the two posterior spinal arteries, and numerous veins which pass to the external spinal veins. It is also supplied with nerves, which are derived in part from the sympathetic and in part from the cerebro-spinal nerves. These nerves supply the walls of the blood-vessels and enter the cord with the vessels.

The **Dentate Ligament** (*ligamentum denticulatum*) (Figs. 528 and 548) is a narrow, fibrous band, situated on each side of the spinal cord, throughout its entire length, running from the pia to the dura, and separating the ventral from the dorsal roots of the spinal nerves. It has received its name from the serrated appearance which it presents. Its inner border is continuous with the pia at the side of the cord. Its outer border presents a series of triangular, dentated serrations, the points of which are fixed at intervals to the dura. These serrations are twenty-one in number on each side, the first being attached to the dura opposite the margin of the foramen magnum between the vertebral artery and the hypoglossal nerve, and the last near the lower end of the cord. Its use is to support the cord.

**Surgical Anatomy.**—Evidence of value in the diagnosis of meningitis may be obtained by the operation of lumbar puncture, that is, by puncturing the theca of the cord and withdrawing some of the cerebro-spinal fluid, and the operation is regarded by some as curative, under the supposition that the draining away of the cerebro-spinal fluid relieves the patient by diminishing the intracranial pressure. Lumbar puncture may give important diagnostic aid after a head injury by disclosing bloody cerebro-spinal fluid. The operation is performed by inserting a trocar, of the smallest size, below the level of the fourth lumbar vertebra. In an adult the cord terminates at the lower border of the first lumbar vertebra, and in a child opposite the body of the third lumbar vertebra. The canal may be punctured below the fourth vertebra without any risk of injuring its contents. The point of puncture is indicated by laying the child on its side and dropping a perpendicular line from the highest point of the crest of the ilium; this will cross the upper border of the spine of the fourth lumbar vertebra. In a child the puncture is made just below the vertebral spine. In adults one-half an inch to one side of the end of the vertebral spine. However the preliminary puncture is made, the needle penetrates the dura in the middle line. In entering the needle it should be directed upward and forward in a child; upward, forward, and slightly inward in an adult.

**THE BRAIN OR ENCEPHALON.**

The brain is that greatly modified and enlarged portion of the cerebro-spinal axis which, with its membranes, almost completely fills the cavity of the cranium. It is a complex organ in which reside the highest functions—consciousness, ideation, judgment, volition, and intellect—together with the centres of special sense and for the mechanism of life (respiration and circulation), and it is the agent of the will.

**General Appearance and Topography of the Brain.** Corresponding to the varieties of cranial form, the shape of the fresh or the successfully preserved brain
varies from the ovoid to the nearly spherical form, as viewed dorsally. The frontal pole is usually narrower, though more squarely formed; while the parieto-occipital portion is more massive, but more sharply pointed in each half. The outline is often rather that of an irregular pentagon with its angles rounded off. A dorsal view shows only the extensive convex surface of the two great convoluted hemicerebra (cerebral hemispheres) separated by a median cleft, the intercerebral fissure (fissura longitudinalis cerebri). On divaricating the cerebral halves it is seen that the separation is not a total one, for in the depths of the fissure a broad commissural mass of white fibres—the callosum—joins the hemicerebra. Frontad the intercerebral fissure is continued to the ventral or basal aspect of the brain; caudad it passes into the tentorial hiatus (fissura transversa cerebri) or interval, separating the cerebrum from the cerebellum.

In a lateral view the continuity of the spinal cord with the oblongata, then the pons and cerebellum are seen in part, overlapped by the cerebrum. Prominent is the temporal lobe with its rounded pole, separated from the frontal and parietal lobes by a deep cleft, the sylvian fissure, in whose depths—overlapped by the opercula of the adjacent lobes—lies the insula.

A ventral view presents many of the subdivisions of the brain. Here is seen the continuity of the spinal cord, with the short and slightly expanding oblongata lying ventrad of the cerebellum and somewhat buried in its vallecula or depression between the lateral hemispheres, which alone are visible. The cerebellum is a grayish-colored mass of considerable size and easily recognized by its foliated appearance, due to the numerous parallel and closely-set curved fissures. A mass of white fibres, the pons, passes transversely from one cerebellar hemisphere to the other, ventrad of the upper portion of the oblongata. Above the pons are seen two large bundles, the crura, one on either side, diverging to pass into the cerebral halves. The interval between the divergent crura and temporal poles laterad and the orbital portions of the cerebrum frontad contains a number of important structures. Encircling the crura and meeting in the fore-part of the fossa are the optic tracts, decussating in the median plane to form the chiasm and continuing frontad as the optic nerves. The arch of the optic tracts and chiasm and the crura enclose the intercural space, in which may be seen (1) the postperforatum (substantia perforata posterior); (2) the albicantia (corpora albicantia; c. mammillaria; c. candidantia); (3) the tuber (tuber cinereum), and the stalk of the hypophysis. A groove marking the lateral boundary of the fossa along each crus is termed the oculomotor sulcus, as the root-fibres of the oculomotor nerve have their superficial origin therein. The postperforatum is a gray area with numerous minute apertures for the entrance of postperforant branches of the post-cerebral artery. The albicantia are two small, pea-like, white eminences closely set side by side. The tuber is a conical projection between the albicantia and the chiasm, to which the hypophysis (pituitary body), resting in the sella of the sphenoid, is attached. In the removal of the brain from the skull the stalk of the hypophysis is usually torn through and an orifice, the lura, leading to the infundibular recess of the third ventricle, is thus exposed.

In the interval between the optic tract and the orbital surface of each hemicerebrum a small, depressed, triangular area of gray substance leading laterad into the basisylvian fissure and dotted with numerous apertures for the minute basal branches of the medicerebral artery and called the preperforatum.

If the chiasm be drawn somewhat ventrad, a delicate gray lamina, the terma (lamina terminalis; lamina cinerea) is seen attached to the dorsal surface of the chiasm and passing dorsad into the intercerebral cleft to the region of the precommissure.

Parallel to the medial border of the orbital surface of each hemicerebrum lie the olfactory tract and bulb, torn away from the fila olfactoria as these pass through
the cribosa of the ethmoid. The olfactory tract may be traced to its root-area, the **olfactory trigone**, just frontad of the preperforatum.

The superficial origin of nearly all of the **cranial nerves** may be seen upon the basal aspect of the brain (Fig. 551). These nerves, their superficial attachments to the brain, and the foramina of exit in the skull are enumerated in the following table:

**Tabulation of the Cranial Nerves, Their Superficial Attachments to the Brain, and the Foramina of Exit in the Skull.**

The olfactory, optic, and acoustic nerves are **afferent** or sensory nerves.

The trigeminal, glosso-pharyngeal, and vagus nerves are **mixed nerves**.

The oculomotor, trochlear, abducent, facial, accessory, and hypoglossal nerves are **efferent** or motor nerves.

**Dimensions.**—The sagittal or fronto-occipital diameter of the white male adult brain averages 16 to 17 cm.; the maximum width in the parietal region averages 13 to 14 cm., while the maximum height is about 12.5 cm. The dimensions of the female brain are usually somewhat less. The brains of dolichocephalic
individuals are naturally longer and narrower than those of brachycephalic, and other differences in size and shape are found in conformity with the cranial configuration and other factors.

The Development of the Brain and the Usual Classifications of its Subdivisions.—The cephalic region of the embryonic neural plate is characterized, as already pointed out (p. 816), by a rapid process of expansion and intensity of growth-energy which seems to indicate the higher functional potentiality of what is to become the brain. The fusion of the margins of the neural plate, proceeding rapidly cephalad and caudal from about the cervical region, soon effects the complete closing in of the brain portion of the neural tube and its complete separation from the overlying ectoderm. For a brief period prior to the completion of the tube-formation there exists a minute opening affording communication between the interior of the neural tube and the surrounding amniotic cavity; this temporary passage is called the neonule (Fig. 542), and is morphologically the cephalic end of the tube. Its adult position is probably in the hypophysial region.

The simple neuroblast expands very early in intra-uterine life in a sac-like manner proximal to it and is divided into three dilatations or pouches—the primary

![Diagram of the brain showing the superficial origin of the cranial nerves. The Roman numerals indicate the nerves.](image-url)
The nerve system of the human body is demarcated by two constrictions. The vesicles are designated respectively the Fore-brain (Prosencephalon), Mid-brain (Mesencephalon), and Hind-brain (Rhombencephalon or Metencephalon).

The constriction between mid- and hind-brain has been called the *isthmus rhombencephali* by Prof. His, and he regards it as coordinate with the other segments recognized by him; the region, however, no more deserves a definitive segmental value than would the cephalic constriction even if it were dignified by the term *isthmus prosencephali*. This classification has been found acceptable from every comparative standpoint in brain morphology, but attempts have been made to establish a further segmentation into definite anatomical divisions regarding which opinions and usages differ widely and have proven to be a hindrance rather than an aid to the homologization of brain-structures in the vertebrate series. The difficulties in formul-
ting a satisfactory schema of the segmental divisions of the brain will be overcome, perhaps, only by distinguishing the neuromeres or neural segments conforming to the general segmental plan of the vertebrate body. The existence of a neuromerism that is akin to the metameric or serial segmentation of the body, or to the branchiomerism characterizing the arrangement of the branchial arches, is indicated in several ways, but thus far only the earliest embryonic stages and the disposition of certain of the cranial nerves afford a clue to the definitive segmentation of the brain. According to the most recent researches, as many as eleven, sixteen, and even more neuromeres have been established in various vertebrate brains. The hind-brain alone shows from six to eight such neural segments (Figs. 552 and 553). The whole matter is yet so obscure that confusion will be avoided by restricting our description to the three primary divisions and their derivatives without insisting upon the recognition of further definitive segments proposed by various authors in consequence of preconceived ideas obtained from the complicated adult structure of the brain. At this transitional period the student is, however, obliged to be familiar with the commonly accepted—yet provisional—schemes of segmentation and a comparative view is given in the following table:

**Brief Consideration of the Phases of Development of the Brain-tube.**—

1. **Fore-brain.**—The cephalic or fore-brain vesicle widens and expands most rapidly and attains to a comparatively large size even before the mid- and hind-brain vesicles become markedly defined. A series of remarkable developmental changes ensue in the following order: (a) **Optic vesicles** appear as two diverticula, each budding from either side of the primary fore-brain vesicle, their distal ends growing considerably and coming into contact with the overlying epidermis, while the proximal or attached ends assume a stalk-like shape. The distal
sac-like end becomes invaginated and forms the retina of the eye, while the stalk upon obliteration of its cavity forms the optic nerve. It is necessary to state here that as development proceeds the optic stalks become relatively shifted caudad and form more intimate connections with the thalamus and mid-brain.

(b) A second pair of budding vesicles arises cephalad in the dorsal portion of the fore-brain vesicle and are destined to develop into the ponderous hemicerebra with their great ganglia, growing with great rapidity and exceeding in this respect all other parts of the brain. The growth of these secondary fore-brain vesicles is principally in the distal parts, and in this manner each forms a great pouch whose interior communicates with the primary neural cavity through a small opening, the porta, or foramen of Monro. It must be remembered that in these initial
stages the vesicles are all extremely thin-walled, but later the walls thicken or hypertrophy to a marked degree, so that the neural cavity becomes relatively small.

(c) Meanwhile (in the fourth week) the most cephalic portion of the fore-brain also becomes differentiated. As the enlarging hemispherical vesicles crowd upon the median, slower-growing portion, there is observed, on either side, the development of a groove or furrow, the primary arcuate fissure, which demarcates the olfactory region (rhinencephalon) into a cephalic and a caudal portion. The cephalic portion develops into a blind tubular diverticulum, which grows cephalad to form the olfactory bulb and tract, its central cavity becoming obliterated (persistent in certain other mammals), while the caudal portion forms the roots of the olfactory nerve, the preperforatum and the subcallosal gyre.

(d) At the ventral margin of the hemicerebral or secondary fore-brain vesicle an excessive proliferation of cells results in the production of several ganglionic masses—the basal ganglia, of which the largest are the lenticula and caudatum

(e) The median-cephalic terminal wall intervening between the large hemispherical vesicles persists as a thin and relatively undeveloped lamina, the terma.

(f) The remainder of the fore-brain undergoes great hypertrophy in its lateral walls to form the thalami, while the ventral portion develops moderately to form the hypothalamus, tuber, post-hypophysis, and albicantia. The dorsal wall fails to develop and remains epithelial except at a point immediately adjacent to the quadrigeminal lamina of the mid-brain; here a diverticulum grows out to form the epiphysis (a rudimentary structure in man, but undoubtedly of functional use in ancestral vertebrates).
(q) The cavity of the primary fore-brain vesicle undergoes alterations in form as the secondary metamorphoses of its walls proceed in the course of development.

The hollow cerebral buds so rapidly outstrip all other parts of the brain that their internal cavities, the lateral ventricles, become the most spacious of the ventricular
system. The great hypertrophy of the thalamic ganglia in the lateral walls of the primary fore-brain determine the sagittally placed, slit-like form of the so-called third ventricle. The cavities of the optic and olfactory buds become obliterated.

II. Mid-brain.—The second primary vesicle becomes somewhat later differentiated and takes a less prominent part in the adult brain. Its dorsal wall goes into the formation of four eminences, the quadrigemina, while the lateral and ventral sections grow considerably to form the crura. The neural cavity within the mid-brain persists as the narrow aqueduct joining the third and fourth ventricles.

III. Hind-brain.—The third primary brain-vesicle is demarcated from the mid-brain by a marked constriction to which has been given the term isthmus rhombencephali. The hind-brain is specially characterized by the great expansion of its thinned-out, membranous dorsal wall caudad, while cephalad the dorsal wall becomes very much thickened as the proton or fundament of the cerebellum.

The ventral and lateral parts undergo thickening to form the pons and oblongata.

**Flexures of the Brain-tube.**—The difference in growth-rate of the different parts of the brain-tube and the marked disproportion between the rapid brain-growth and slower head-growth causes the encephalic neural tube to become sharply bent upon itself at certain points. The first flexure to occur is involved in a bending of the entire head and takes place in the region of the mid-brain; this flexure is termed the cephalic flexure. A second bending of the tube occurs at the junction of the spinal cord and hind-brain; this is termed the cervical flexure and is so pronounced in the fifth week of intra-uterine life that the brain-tube and spinal cord form a right angle with each other. A third flexure is produced, in consequence of the other two, in the region of the future pons, and is therefore called the pontile flexure. Subsequently the cervical and pontile flexures are obliterated by a gradual straightening of this portion of the brain axis.
Dorsal and Ventral Laminae or Longitudinal Zones of the Brain.—Quite like the longitudinal division of the developing spinal cord, there is a differentiation of the brain-tube into dorsal and ventral zones, though much less clearly shown. The limiting furrow between the two is not demonstrable in the forebrain; at least it is disputed, on good grounds, that it exists there. It is claimed, even, that three such longitudinal divisions exist on each side (Kupffer) and the formation of the cranial nerves is not quite comparable to the spinal nerves, although there is a fair homology with their dorsal-sensor and ventral-motor functional differentiation, despite their frequent admixture in some cranial nerves or the

![Diagram of brain development stages](image)

**Fig. 560.—Three stages in the development of the oblongata, showing the metamorphosis of the rhomboidal lip.** (Modified after His.)

The total absence of the one category in others. Thus the motor elements do not extend higher than the mid-brain and the dorsal division preponderates in the more highly organized parts of the brain, becoming predominant in the higher vertebrate species—particularly in man.

In its simplest expression the brain is a tube like the rest of the central nervous axis, but a remarkably modified one. There is the same primitive endymal lining throughout its interior; there is likewise a central tubular gray mass of ganglionic tissue which, however, undergoes nuclear differentiation in some portions, atrophies in others, while in certain localities it is crowded away from
the central cavity by the intrusion of white-fibre masses which are chiefly commissural. A total atrophy occurs in a part of the dorsal wall of both fore-brain and hind-brain; partial atrophy is observable in the floor of the third ventricle, near the chiasm, once perhaps the optic centre in the earliest of the ancestral vertebrates, but atrophied in higher forms as the visual tract became secondarily projected in the mid-brain. Great hypertrophy characterizes the growth of the ganglionic gray in the floor of the lateral ventricle (cerebral vesicle), resulting in the formation of nugget-like masses, the caudatum, lenticula, and amygdala. The central gray of the primary fore-brain also undergoes great hypertrophy, but in the lateral walls only, to form the large, compact thalami.

As in the cord, fibre masses develop ectad of the central tubular gray in some localities, while in other regions the ganglionic gray remains at the surface and the white conducting substance is developed on its inner aspect. Thus we have, secondarily, the formation of superficial gray matter as the cortex (or rind) of the cerebrum and cerebellum. The isolation of ganglionic gray masses from the primitive central tubular gray and their differentiation into cell-nests (nidi or nuclei) is also observable in the reticular ganglionic formation of the oblongata and pons as well as in the roof of the mid-brain. Certain aggregations of gray ganglionic tissue are intercalated in the course of fibre strands, receive an admixture of these, and are regarded as terminal, interrupting, or as condensing
stations not unlike some very complex relay telegraph system. The olive, dentatum, rubrum, the nuclei of the gracile and cuneate funiculi, the basketwork intercalations of the reticular and lemniscus fields belong to this intrrafascicular type of ganglionic structures.

The plan of structure of the brain differs, therefore, from the comparatively simple arrangement of the gray and white substance in the spinal cord. In the brain the gray substance is not centrally situated throughout, and there is a tendency to nuclear differentiation of great and small ganglionic masses. These are connected with each other and with the centres in the cord by longitudinal strands of fibres of greater and lesser length, as well as by transverse associating fibres uniting the bilateral nuclei of the same ganglionic category; with the periphery they gain connection through the cranial nerves and (via the spinal cord) the spinal nerves.

In tracing the various structures of the brain from the oblongata to the cerebral cortex we follow anatomically what nature has done in the evolution of the highest type of brain from that of the simplest and most ancient vertebrate. In the oblongata lie the centres which exert a very direct influence over those of the entire cord. The striate bodies and the thalamri form a connecting link between the higher cerebral cortex and the oblongata and cord below. The extensive cerebral cortex, an aggregation of psychic centres and therefore the seat of the will, controls the activities of the fore-brain ganglia (striatum, thalamus) and the cerebellar cortex, and these in turn preside over the functions of lower centres, as in the way of motor responses to external impressions; such reactions may be delayed or immediate according to the exercise of the will-power residing in the cerebral cortex.

This control by the will is intensified the higher we ascend the animal scale; the pyramidal tract, which originates in the cerebral cortex and threads its way to the motor centres of the spinal cord without interruption along the brain-axis, is better developed in man than in any other animal. In the course of evolution the lower or more automatic ganglia and tracts remain relatively about the same in mass as in other mammalia, but the higher, more intellectual ganglia surpass these in growth so that there is an apparent but not real diminution of the automatic systems observed in the human brain.

It has been seen from the foregoing brief accounts of the development of the nervous system that the most prominent feature is the redundant growth of the

---

**Fig. 562.**—Scheme showing the connections of the several parts of the brain.
cephalic or brain end of the neural tube. Comparative neuro-anatomic researches have thrown much light upon the probable genesis of this remarkable characteristic. The ancestral vertebrate, built upon the segmental type, was a swimming animal, and its locomotion took place in the direction of its long axis. In its progress through the water the cephalic (or anterior) segments were those which first encountered the foreign objects floating in the same medium. It was for these segments to determine the quality of the objects encountered—whether they were inimical or indifferent or beneficial to its individual ends. The sensory periphery, in consequence of the demands of evolution, underwent specialization in the development of olfactory and gustatory end-organs for testing the quality of the food and of the surrounding medium; optical organs for perceiving rays of light; auditory organs for the appreciation of certain oscillations of the surroundings; while others, strictly tactile in nature, underwent elaboration as such in the development of sensitive antenna or tentacles. Motor contrivances, useful in the quest for food or in encounters with the enemy, were developed in the way of powerful jaws and masticatory muscles. In brief, a remarkable specialization and differentiation of structure attended the development of the head-end and with it the central organ of control kept pace. In the human species we find certain of these structural characteristics in a highly developed condition, while others have dwindled or disappeared in the course of evolution. Thus in the myxinoide fishes and the lamprey the cerebral hemispheres themselves are mere appendages of the olfactory lobes; the sense of smell was probably the most important in lower animals. In the brain of man conditions are reversed and the olfactory system is seen to have dwindled to an extreme degree as compared with the immense size of the cerebrum; this in conformity with the relatively slight use made of the smell-sense in the mental life of man. Other organs of special sense, however, became augmented and these, together with the nerve-mechanisms controlling the vital functions (respiration, circulation), required a more and more elaborate central nervous organ for the harmonious interaction of the several elements. This central organ or brain developed, in bulk and complexity, hand in hand with the increase of the intellectual faculties. Man’s most manifest distinction from other animals has resulted from a remarkable evolutionary growth in brain-size and brain-power; and as the brain is the material organ of mental and moral manifestations, we find in mankind the highest degree of superiority and culture—not only as compared with the nearest related apes, but of the civilized and progressive races as compared with the primitive and unprogressive races.

DESCRIPTIVE ANATOMY OF THE ADULT HUMAN BRAIN.

Morphologically considered, the brain consists of a common trunk (or brain-axis) from which the two cerebral hemispheres crop out like swollen terminal buds, while the cerebellum is an excrescence of the trunk itself. The axially situated brain-axis or "brain-stem" \(^1\) comprises, roughly speaking, the axial parts of all three primary divisions of the brain-tube: (a) oblongata, (b) pons, (c) mid-brain, (d) thalamic division of fore-brain. In this brain-stem lie the majority of the ganglionic masses enumerated above, together with the nerve-tracts uniting the various cell-nests in (presumably) automatic coördination as well as the great nerve-tracts connecting the spinal gray with the cerebral hemispheres, the thalami,

---

\(^1\) Also "brain-isthmus." a loosely used term. It may here be remarked that most extant accounts of the anatomy of the brain over-emphasize the distinction of brain-parts from each other. Some authors follow one or another system based upon the theories of the segmentation of the brain-tube; others divide the brain into (a) rhombencephalon or hind-brain and (b) cerebrum, comprising mid- and fore-brain. None of the classifications proposed are, as already pointed out, quite satisfactory. The continuity of the parts can only be interrupted arbitrarily, and such procedure leads to a too narrow conception of brain-structures single and apart rather than serial and connected.
cerebellum, and the ganglia of the oblongata (including the cranial-nerve nuclei), and still other tracts connecting the oblongata with the cerebral hemispheres, the cerebellum, and the special ganglia of the pons and mid-brain.

**Parts Derived from the Hind-brain (Rhombencephalon). External Morphology.**

The Oblongata (Medulla Oblongata; Spinal Bulb; Post-oblongata of Wilder; Myelencephalon).

The oblongata is the continuation cephalad of the spinal cord, the transition lying at the level of the foramen magnum and marked by the decussation of the pyramids. Its cephalic limit is sharply defined ventrad by the rounded margin of the pons, while its dorsal surface is sunk into the cerebellar vallecula. The length of the oblongata along its ventral surface is 20 to 25 mm.; its maximum width at the pontile end is 17 to 18 mm., and half as much at its transition into the spinal cord; its maximum thickness is about 15 mm. Its expansion as it approaches the pons gives it the form of a truncated cone. The ventral surface rests upon the basilar groove of the occipital.

**Fissures.**—The ventral and dorsal fissures of the cord are continued upon the oblongata, making it a bilaterally symmetrical structure. The ventral or ventro-median fissure (*fissura mediana anterior*), at the level of the foramen magnum is interrupted by a number of obliquely intercrossing fibres, called the decussation of the pyramids. Beyond this interruption the ventral fissure passes cephalad to end at the ventro-caudal border of the pons in a recess called the postpontile recess or foramen caecum.
The dorsal or dorso-median fissure (fissura mediana posterior) is of short extent upon the oblongata, for the neural cavity is here expanded into a rhomboideal fossa whose dorsal wall, profoundly atrophied, is represented only by a delicate membranous lamina; the dorsal fissure rapidly becomes shallower as it ascends to cease at the caudal apex of the "fourth ventricle."

Like the spinal cord, the surface of each half of the oblongata is divided into three longitudinal districts by fissures called the ventro-lateral and dorso-lateral fissures. Of these the latter only is a continuation of the fissure of the same name in the spinal cord.

The ventro-lateral fissure (sulcus lateralis anterior) of the oblongata demarcates the ventral column (pyramid) from the lateral column as well as the olive, and the roots of the hypoglossal nerve, arranged in linear order, emerge from this fissure. (The ventro-lateral fissure of the spinal cord becomes obscured as it ascends into the oblongatal region, for cephalad of the emergence of the ventral roots of the first cervical nerve a band of superficial arcuate fibres usually obliterates all traces of the furrow.)

The dorso-lateral fissure (sulcus lateralis posterior) of the oblongata is directly continuous with the same-named fissure of the spinal cord, and the root-bundles of the accessory, vagus, and glosso-pharyngeal nerves are attached along the bottom of this fissure. Unlike the dorsal roots of the spinal nerves, the root-bundles of these three cranial nerves are not all composed of afferent fibres arising in extraneous ganglionic cells and entering the oblongata, for the accessory nerve is purely efferent and the vagus contains both afferent and efferent fibres.

Areas.—The ventro-lateral and dorso-lateral fissures with their rows of nerve-fascicles divide the surface of the oblongata on each side into three districts which appear to be continuous with the three columns of the spinal cord; they are not so in reality, however, owing to the rearrangement of the fibre-tracts and the central ganglionic mass in the myel-oblongatal transition. This portion of the brain-axis is sculptured into several eminences and depressions; of the eminences, some, like the olives, the tubercula cinerea, and the claves are due to the accumulation of gray substance beneath the surface at that point; others, like the pyramids and restes, are due to the prominence at certain points of the surface of the great nerve-tracts.

Areas of the Oblongata.

I. Ventral Area:
   Pyramid.

II. Lateral Area:
   (a) Lateral Tract.
   (b) Olive.

III. Dorsal Area, marked by slight furrows dividing it into:
   (a) Funiculus gracilis.
   (b) Funiculus cuneatus.
   (c) Funiculus lateralis and tuberculum cinereum.

The last three structures mentioned appear to become fused cephalad to continue as the restis; in reality the restis is formed in a different manner.

I. The Pyramids (pyramis medullae oblongatae).—The pyramids constitute the oblongatal portion of the direct cerebro-spinal efferent tracts conveying (voluntary) motor impulses from the precentral cortex, through the internal capsule, crusla, and ventral pons to descend in the crossed and direct pyramidal tracts to the efferent (motor) cell-groups in the ventral horns of the spinal gray. In their external appearance in the oblongata they are moderately constricted at their pontile ends, appear to become somewhat expanded, to again taper as they pass, partly into the ventral columns of the cord, partly, by decussation, into the lateral
columns. The pyramids are separated from each other by the ventral (or ventromedian) fissure except where this is more or less completely obliterated by the decussating bundles. Each pyramid is bounded laterally by a slight furrow, the ventro-lateral or pyramido-olivary groove, in which arise the hypoglossal nerve-roots and which separates the pyramid from the olive. The pontile end of each pyramid is frequently traversed by a band of arched fibres (fibræ arcuatae etales; ponticulus of Arnold (not the ponticulus of Heune), the ecal arcuate fibres.

The Decussation of the Pyramids (decussatio pyramidum) is a term given to the obliquely intercrossing bundles seen at the oblongata-myelon transition. The extent to which this decussation occurs and the degree of its visibility varies in different individuals. While in most cases the majority (90 per cent.) of the fibres cross the median line in this decussation to continue as the crossed or lateral pyramidal tract, it is sometimes observed that a larger share of the fibres pass into the direct or uncrossed pyramidal tract with a corresponding reduction of the crossed tract. Occasionally the decussating bundles are so deeply situated in the ventral fissure as not to be visible.

II. Lateral Area.—The lateral area of the oblongata is continuous with that of the spinal cord and is bounded by the dorso-lateral and ventro-lateral fissures. It is composed of the ventro-lateral spino-cerebellar tract (fasciculus anterolateralis superficialis), the ventro-lateral ground-bundle (fasciculus proprius anterolateralis), and the direct spino-cerebellar tract (fasciculus cerebellospinalis [Flechsig]), while it is invaded from above by the crossed pyramidal tract. The olive is interpolated in the cephalic part of this area.

The Olive (oliva; olivary body) is a prominent, elongated oval mass bulging from the cephalic part of the lateral area of the oblongata, bounded by shallow grooves, of which one, for the hypoglossal nerve-roots (ventro-lateral fissure) separates it from the pyramid, while the other, containing the nerve-fascicles of the vagus, glosso-pharyngeal and accessory nerves, separates the olive from the restis. From the pons it is separated by a shallow groove in which a band of arched fibres is sometimes seen. Numerous white fibres (ectal arcuate fibres) emerging from the ventral fissure and traversing the pyramid loop across the lower parts of the olive to enter the restis. The olive is formed by the olivary nucleus, embedded in a thin layer of white matter.

The olive is about 12 mm. in length and 5 mm. in breadth.

III. Dorsal Area. (a) Funiculus Gracilis.—The funiculus gracilis is the direct continuation of the tract of the same name in the spinal cord. It is a narrow white band placed along the dorso-median fissure, and separated from the funiculus cuneatus by the dorso-paramedian furrow (sulcus intermedius posterior). At the apex of the rhomboidal fossa (fourth ventricle) each funiculus gracilis diverges from the median plane, presenting at this point a club-like enlargement, the clava. The prominence of the funiculus gracilis (and clava) is due to the gray nucleus funiculi gracilis beneath.

(b) Funiculus Cuneatus.—The funiculus cuneatus is the direct continuation of the tract of the same name in the spinal cord. It enlarges as it ascends, exhibiting a slight eminence or enlargement, the cuneate tubercle (tuberculum cinereum), which is marked only in the oblongata of young individuals, and is due to the nucleus funiculi cuneati beneath.

(c) Funiculus Lateralis and Tuberculum Cinereum.—The funiculus lateralis is a longitudinal prominence which gradually enlarges cephalad into a slight tubercle, the tuberculum cinereum (tubereulum Rolandi), marking the approach of the gliosa to the surface so as to form a prominence at a level with the lower border of the olive.

The Restis (corpus restiforme) occupies the upper dorso-lateral area of the oblongata on each side, lying between the floor of the fourth ventricle and the roots.
of the vagus and glosso-pharyngeal nerves. This structure might at first glance appear to be the continuation of the three funiculi just described. But as a matter of fact it is made up of the direct spino-cerebellar tract, a set of ectal arcuate fibres (fibrae arcuatae externae) and a set of ental arcuate fibres (fibrae arcuatae internae). Each rests assists in forming the lower part of the lateral boundaries of the fourth ventricle and then enters the cerebellum as the postpeduncle of that body.

The Pons and Pre-oblongata (Pons Varolii; Protuberantia Annularis).

The pons is a prominent white mass on the ventral aspect of the brain-stem which is interposed between the oblongata and the crura. It is convex from side to side and its fibres, running chiefly in a transverse arched direction, are gathered into rounded, compact strands on either side, to continue as the medipeduncles into the white substance of the corresponding cerebellar hemisphere. The fibre-bundles of the pyramidal tracts thread their way through the pons on either side of the median plane and small aggregations of gray substance (nuclei pontis) are packed in the intervals between the transverse pontile and longitudinal pyramidal fibre-bundles.

The Ventral Surface (pars basilaris pontis).—The ventral surface of the pons is in relation with the basilar process of the occipital and the dorsum sellae of the sphenoid. A shallow mesal groove lies between the eminences produced by the pyramidal tracts in their course through the pons. The groove is called the basilar groove (sulcus basilaris), as the basilar artery is usually accommodated in it; the artery is not, however, a factor in the production of the groove. The large sensor and small motor-root bundles of the trigeminal nerve pierce the mass of the pons near the prepiriform border, and a line drawn from this nerve-
root to that of the facial nerve is usually employed as an arbitrary boundary between the pons proper and the medipeduncle of the cerebellum. The abducent nerve emerges from the postpetontile border (prepyramidal part); the facial and acoustic nerves are attached farther laterad.

While most of the superficial fibre-bundles of the pons are seen to arch transversely, certain small compact bundles1 are seen to extend in an obliquely longitudinal direction from the region of the trigeminal nerve-root to and among the roots of the facial and acoustic nerves.

The Pre-oblongata (pars dorsalis pontis; pars metencephalica medullae oblongatae).—The pre-oblongata is not sharply demarcated from the oblongata or the tegmentum and crusta of the mid-brain and the margins of the pons on the ventral surface afford only arbitrary boundary lines; for in the vertebrate series the pons varies greatly in width and its margins can hardly be accepted as the boundaries of a definitive brain-segment. The dorsal surface of the pre-oblongata is continuous with that of the oblongatal ventricular surface, and its description more properly belongs to a consideration of the anatomy of the fossa rhomboidalis or “floor of the fourth ventricle.”

Fourth Ventricle of the Brain (Ventriculus Quartus).

In a previous section on brain-development it has been pointed out how the growth-changes and differentiations in the hind-brain differ from those of the rest of the neural tube in that there is a marked disproportion in the degree of growth in the dorsal and ventral walls. While the ventral wall thickens greatly throughout to form the pons-oblongata, the dorsal wall hypertrophies in its cephalic portion to form the cerebellum, while caudad thereof the roof atrophies and expands and becomes so attenuated as to be represented merely by a thin epithelial membrane. The outward folding of the walls of the neural tube in this region creates an expansion of the central cavity in the form of a rhomboidal fossa roofed in by the cerebellum and a thin epithelial layer. A time-honored custom enumerates this as the fourth of a system of ventricles of which the other three lie in the forebrain.

A cast of the cavity (Fig. 565) shows it to be irregularly pyramidal, with a lozenge-shaped base and ridge-like apex extending from side to side, corresponding to the acute-angled recessus tecti in the fastigium (“gable roof”) formed by the valvula and velum. Such a cast also indicates the ventral extension of the cavity from the lateral angles of the rhomboidal base in the form of the lateral recesses.

It is customary to describe for the fourth ventricle a roof and a floor, although an

---

1 Called the inter-radicular pons tract by E. C. Spitzka (1884) and more recently described as part of the corpus ponto-bulbare by Essick (American Journal of Anatomy, vii, 1).
FOURTH VENTRICLE OF THE BRAIN

examination of a sagittal section of a brain hardened in situ shows the floor to be in a vertical plane in the erect attitude. Caudal the cavity is continuous with the minute central canal of the spinal cord and postoblongata (in part); cephalad it passes into the aqueduct or mesocle. The dorsal wall or "roof" is formed by the valvula, the prepeduncles, metatela, and fastigium of the cerebellum. The ventral wall or "floor" is the rhomboidal fossa occupied by the expanded central gray of the pre- and postoblongatal portions of the hind-brain.

"Floor" of the Fourth Ventricle (fossa rhomboidea).—The "floor" of the fourth ventricle is lozenge-shaped and exhibits regional elevations, depressions, and color differences which are in relation with the deep anatomy of the oblongata and tegmentum (of pre-oblongata). It is divided longitudinally into symmetrical halves by a median groove and each lateral half is subdivided into a larger cephalic and a smaller caudal triangle by white, transverse stria, composed of bundles of myelinic fibres connected with the acoustic tract and appearing to sink beneath the surface near the median groove. The portion occupied by these striae acusticae (striae medullares; striae transversales) is termed by His the pars intermedia as distinguished from the pars superior and pars inferior or frontal and caudal triangles respectively. Much variation is met with in regard to the course and degree of prominence of the striae acusticae (Fig. 566). There may be none visible or as many as twelve distinct bundles; bilateral symmetry is the exception and not infrequently one or more bundles run obliquely cephalo-laterad—the striae oblique (conductor sonorus). This irregularity of the acoustic striae has led to another mode of division of the "floor" for descriptive purposes—each side to be divided into a median and a lateral area, indicated by a more or less well-marked groove, the lateral furrow (sulcus limitans), connecting the superior and inferior (ala cinerea) foveae. This groove probably corresponds to one of the interzonal sulci of the embryonic tube and in a gross way it separates the motor and sensor fields of the "floor." The median area is usually a continuous ridge which is quite accentuated in the cephalic division as the eminentia abducentis, while caudal it becomes narrowed as it approaches the closed part of the oblongata. The convergence of the median and lateral furrows at the caudal apex of the rhomboidal fossa gives the appearance of the point of an ancient writing reed- or quill-pen; hence the term calamus scriptorius.

In the caudal quarter-triangle a middle area is occupied by an elongated triangular field whose depressed apex is directed frontad. A slight oblique ridge, the funiculus separans, composed chiefly of neuroglia, separates the area postrema

![Varieties of fourth ventricle](image-url)
caudal from the *ala cinerea* or *trigonum vagi* of a pronounced grayish color. The apical depression has been termed the *fovea inferior*. Mesally lies a narrow triangular field with its apex directed caudal and with slightly raised surface—the *trigonum hypoglossi*. This area is resolved into two fields by a single or double formation of oblique rugae affording a "feathered" appearance to the lateral field, *area plumiformis*. Laterad of the trigonum vagi lies the caudal portion of the lateral area of the "floor," also called (in part) the *area vestibularis* (*area acustica*) and crossed over its middle by the *stria acusticae* when these are present. The area vestibularis is an irregularly triangular raised surface with its convex base toward the median line, and extending laterally to the attachment of the metatela and into the lateral recess. In the fovea and in certain lower vertebrates the area is more prominent and is designated the *tuberculum acusticum* s. *vestibularis.*

![Diagram](image)

**Fig. 567.—Surface markings and topography of the principal nuclei of the floor of the fourth ventricle.** (Modified from Streeter.)

The "frontal" division of the floor or triangular quarter-field is marked by a depression at about its middle, the *superior fovea*, from which the slight "lateral furrow" runs caudal, and but for the intervention of the strie would reach the inferior fovea. Cephalad of the superior fovea, and continuing some distance along the aqueduct, is the *locus ceruleus*, which owes its color to the refraction of the pigmented cells, the *substantia ferruginea*, by the milky-white endyma. At this altitude, the medial elevation between the superior fovea and the median sulcus is accentuated into a fairly pronounced eminence, the *eminencia abducentis* (*eminencia teres*), overlying the nucleus of the abducent nerve and the genu of the root of the facial nerve. The portion of the median sulcus intervening between the eminencia abducentis is correspondingly depressed to form the *fovea mediana*.

The ventricular features enumerated above correspond in a crude way to the deep structures of the pons-oblongata, and most of the cranial nerve nuclei are held in a rhomboidal frame formed by the pre- and postpeduncles. The surface-markings are only imperfect replicas of the subjacent structures; the various cell-
FOURTH VENTRICLE OF THE BRAIN

nests overlap each other more or less and their relations can best be studied in the projection drawing in Fig. 567.

Membranous Portion of the "Roof" of the Fourth Ventricle.—The caudal extension of the hypertrophied cerebellum hides from view the whole of the rhomboidal fossa, but this structure, as before stated, forms but a part of the actual dorsal wall or "roof." This includes the converging prepeduncles, the valvula intervening between these, the fastigium of the cerebellum, the velum, and the metatela.

The Velum (velum medullare posterior).—The velum is a thin and narrow lamina of white substance, continued lateral as the floroculi of the cerebellum. At its caudal edge, i. e., where nerve-tissue ceases, the endyma or ventricular lining epithelium and the pia over this portion coalesce to form a delicate membrane—the metatela—attached along the caudo-lateral boundary-line of the rhomboidal fossa. Along this attachment there is another intrusion of nerve matter between the endymal and pial layers; this reenforced lamina is usually termed the ligula and may be traced on the clava and cuneate tubercle, thence lateral over the restis to bound the lateral recess. The structure is probably a vestige of the secondary rhomboidal lip and has actually been found to be a part of the ponto-bulbar body referred to above. Another small semilunar lamina of nerve tissue bridges the caudal apex of the fourth ventricle and is called the obex. This structure is often devoid of nerve tissue and is then a mere membranous lamina.

Except in rare instances, the metatela is perforated a short distance from the calamus region. The opening is of variable shape and size; it permits of communication between the ventricular cavity and the subarachnoid space and is termed the metapore (apertura medialis ventriculi quarti) or foramen of Majendie.

Similar apertures at the extremities of the lateral recesses, and called the foramina Luschke (apertura lateralis ventriculi quarti) also permit of a tidal flow of the cerebro-spinal fluid.

The metaplexuses or choroid plexuses of the fourth ventricle are highly vascular infoldings of the metatela, one on either side of the median plane, from each of which shoots extend lateral into the lateral recesses. As the choroid plexuses of the brain are always formed by infoldings or invaginations of the membranous portions of the brain-tube, the endymal continuity is nowhere interrupted.

Internal Structure of the Postoblongata.—While the spinal cord remains a closed tube with centrally situated gray, the oblongata opens out on the dorsal aspect so as to uncover its part of the neural canal as the "floor" of the fourth ventricle. This involves a tilting of the functionally differentiated gray segments and, after a gradual transition in the post-oblongata, the motor gray is to be sought nearest the middle line, the mixed gray just ektad, while the sensor is the outermost of all. Instead of the ventral, lateral, and dorsal horns of each half of the spinal cord, we have an ental, middle, and ectal cornu in each half of the oblongata. The positions alone have changed; the functional relations to nerve-roots having corresponding functions are homologous. Thus the motor hypoglossal nucleus is placed in the mesal part of the ventricular floor, while the terminal nuclei of the afferent vagus, glosso-pharyngeal, and auditory nerves lie in the lateral part.

Another cardinal change in the internal structure of the oblongata, accompanying the preponderating development of the cerebrum and great basal ganglia, is caused by interrupting and decussating fibre systems which seek passage through the brain-stem and encroach more or less on its primitive architecture. While in the spinal cord there is a perfect continuity of the central tubular gray, we find in the oblongata more pronounced peninsular and isolated insular nuclei or ganglionic gray masses.

Pyramidal Decussation (decussatio pyramidum).—An important change in the internal structure is caused by the passage of the fibres of the pyramidal tract as these pass to the same and opposite sides of the cord, the latter category forming
the pyramidal decussation. In consequence of this passage of white (crossed pyramidal) fibres through its substance the ventral gray horn is broken up into a coarse network, while one portion of it, the caput cornu, is entirely separated from the rest; only a small portion of the base of the cornu remains intact close to the ventro-lateral aspect of the central canal. The caput cornu, thus separated, is displaced laterally, and comes to lie close to the caput cornu dorsalis, which has also shifted its position. In consequence of this breaking up of the greater part of the ventral gray cornu by white fibres a coarse network is formed in the anterior and lateral areas of the medulla, which is named the formatio reticularis.

The gliosa (gelatinosa Rolandi) of the dorsal horn is continued into the oblongata, but becomes insignificant, relatively, in the pre-oblongata. The spinal root of the trigeminal nerve is in ectal relation with the gliosa; at higher levels the spinal root of the vestibular nerve intervenes.

**Decussation of the Lemnisci.**—A similar change, dorsad and cephalad of the pyramidal decussation, is caused by the decussation of axone bundles arising in the nuclei of the gracile and cuneate fasciculi (Goll and Burdach). At this level the base of the dorsal gray cornu undergoes change in the form of two thick dorsal peninsular outgrowths which form the nuclei of termination of the axones in the gracile and cuneate fasciculi; externally these gray masses produce the eminences of the clava and cuneate tuberde. The axones from these nuclei stream mesad and cephalad in a series of con-
centric arches, decussating in the raphé with the bundles of the opposite side to form the decussion of the lemnisci or sensor decussion. Cephalad of this decussion the lemnisci are two bundles of fibres coursing on either side of

the raphé between the olives, and just dorsal of the pyramids; their further course toward the cerebrum will be described farther on.

1 Also called "mesal lemnisci" in contradistinction to the "lateral lemnisci"—of different origin.
With the extension of the central gray to form the floor of the fourth ventricle, the caput cornu dorsale is displaced ectad so as to almost reach the surface, where it forms a projection, the funiculus lateralis (Rolandi), which enlarges caphalad into a distinct prominence, the tuberculum cinereum. At a higher level the caput is separated from the surface by the spinal root of the trigeminal nerve and by the ectal arcuate fibres (Fig. 575). The cervix of the cornu becomes broken up into a reticular formation by the decussating fibres. A portion of the base is placed ectad of the nucleus funiculi cuneati and is called the accessory cuneate nucleus, supposed to be a continuation of Clarke’s column.

The Formatio Reticularis (Fig. 575).—The formatio reticularis consists of diffusely scattered gray substance in a meshwork of white fibres. It is far more abundant in the pre- and postoblongata than in the cord. In trans-sections of the postoblongata it is seen to be divided by the hypoglossal nerve-root fascicles into a mesal and a lateral field. In the mesal field the gray substance is scanty and white fibres—principally longitudinal ones—preponderate; this is called the formatio reticularis alba in contradistinction to the lateral grayer reticulated field, the formatio reticularis grisea. Its numerous nerve-cells mostly possess short axones and for the most part exercise associative functions for the constantly active centres of respiration (nuclei of the vagus, phrenic, facial, etc.). Certain axones of longer course are collected into a small compact bundle just ventrad of the ventricular...

---

**Diagram 573.** Transverse section of the oblongata at the lower end of the olives. The roof of the fourth ventricle is not represented. (Testut, after Duval.)

**Diagram 574.** Transverse section of the oblongata at the middle of the olives. The roof of the fourth ventricle is not represented. (Testut, after Duval.)
floor and central canal (and aqueduct in the mid-brain), and known as the medial longitudinal fasciculus (*posterior longitudinal bundle*). This tract is in intimate association with the cranial nerve nuclei. The formatio alba is principally made up of this tract and the lemniscus (interolivary stratum).

The Raphé (Fig. 575).—The raphé is situated in the middle line of the oblongata above the decussation of the pyramids. It consists of nerve-fibres intermingled with nerve-cells. The fibres have different directions, which can only be seen in suitable microscopic sections, thus: (1) Some run dorso-ventrad; these are continuous with the superficial arciform fibres. (2) Some are longitudinal; these are derived from the arciform fibres, which on entering the raphé change their direction and become longitudinal. (3) Some are oblique; these are continuous with the deep arciform fibres which pass from the raphé.

The nerve-cells of the raphé are multipolar; some are connected with the dorsolateral fibres, others with the superficial arcuate fibres.

The Restis.—The restis succeeds the gracile and cuneate nuclei in the dorsolateral part of the oblongata. Its fibres converge from various sources and ultimately enter the cerebellum as its postpeduncle. For a description of these fibre systems see the section on the “peduncles of the cerebellum.”

The Nucleus of the Olive or Inferior Olivary Nucleus (*nucleus olivarius inferior*) is a corrugated lamina of gray substance whose extent nearly corresponds to that of the external elevation called the olive. It can be compared to a hollow oval sac or purse, slit on its mesal aspect and the edges of the slit everted. The opening is called the hilum. Numerous fibres stream into the interior through the hilum, while others cut through the lamina to join the fibre-arches of the reticular field and there passing toward the restis.

What are known as accessory olivary nuclei (*nucleii olivarii accessorii*) are smaller detached or semidetached portions of the olivary nucleus named, according to their position, the dorsal and medial accessory olivary nuclei (*nucleus olivarius accessorius dorsalis et medialis*). The root fascicles of the hypoglossal nerve pass between the medial accessory nucleus and the chief olivary nucleus.
The olivary nuclei play an important part as relay stations in cerebellar connections. A considerable mass of fibres, the olivo-cerebellar fibres (fibrae cerebello-olivares), originate in the olivary nucleus of one side to enter the cerebellum along the restis of the opposite side. A much lesser number of fibres, running contrariwise, reach the olivary nuclei from the opposite cerebellar hemispheres—the cerebello-olivary (vestibulo-olivary tract) fibres. The olivary nuclei are also the termini of two important tracts: (1) the spino-olivary tract or Helweg's bundle and (2) the thalamo-olivary tract.

The Arcuate Fibre Systems.—The arcuate fibre systems comprise two sets of fibres according as they course dorsad or ventrad of the olivary nuclei:

1. The Ental Arcuate Fibres comprise the olivo-cerebellar fibres, just described, and a number of commissural systems for the association of the segmental reticular gray ganglia and cranial-nerve nuclei. Others pass cerebralward, others to the cerebellum.

2. The Ectal Arcuate Fibres take origin (a) from the gracile and cuneate nuclei and enter the restis of the same side; (b) from the same-nuclei of the opposite side, decussating in the raphé and sweeping ventrad over the pyramid and olive, forming a thin layer over them and ultimately reaching the restis. Many of these fibres are interrupted, on each side, in the nucleus arcuatus, a thin, isolated lamina of gray matter lying on the ventral aspect of the pyramid.

The nucleus lateralis is seen in the lateral column, (lower part of oblongata) as a diffuse gray mass lying between the gliosa and the olive; it gradually disappears cephalad.

The nucleus intercalatus (of Staderini and Van Gehuchten) forms the elongated, wedge-shaped elevation in the medial triangle of the caudal portion of the ventricular floor called the area plumiformis (p. 880); the nucleus derives its name from its (intercalated) position between the hypoglossal and dorso-vagal nuclei. Its functional connections are not yet precisely known.

A nucleus postremus has been described (J. T. Wilson) as lying subjacent to the area postrema.

The nucleus funiculi teretis lies close to the median sulcus in the altitude of the acoustic stricte, and seems to bear an intimate relation to these.

Summary of the Gray Masses in the Postoblongata:

* Central tubular gray (in "closed" part).
* Gray floor of fourth ventricle (in "open" part).
* Gliosa (or gelatinosa Rolandi).
* Nucleus funiculi gracilis.
* Nucleus funiculi cuneatus.
* Nucleus funiculi cuneati accessorius.
* Nucleus lateralis.
* Nucleus olivaris inferior.
* Nucleus olivaris accessorius dorsalis.
* Nucleus olivaris accessorius medialis.
* Nucleus arcuatus.
  Nucleus nervi hypoglossi.
* Nucleus intercalatus.
* Nucleus postremus.
  Nucleus vagi (alæ cinereæ).
  Nucleus vestibularis (spinal division).
* Nucleus funiculi teretis.
  Nucleus ambiguus.
  Nucleus tractus solitarii.
  Nucleus tractus spinalis n. trigemini.
* Formatio reticularis.
In the foregoing enumeration of the gray masses of the postoblongata, those marked with an asterisk have been described above; the remaining structures relate to the deep connections of the cranial nerves and will be discussed in detail under that head.

**Internal Structure of the Pons and Pre-oblongata.**—Trans-sections of the pons also pass through the pre-oblongata (or tegmental part of the pons). To consider first the internal structure of the pons proper (or pars basilaris pontis): The pons is composed chiefly of (1) transverse fibres arranged in coarse bundles, (2) longitudinal fibres gathered in compact bundles, and (3) diffusely scattered masses of gray substance among the fibre bundles, the nuclei pontis.

The **Transverse Fibres.**—The transverse fibres, corresponding to the large size of the cerebellum, are more abundant in man, relatively, than in any other animal. They form a massive series of bundles coursing ventrad of the brain axis from one cerebellar hemisphere to the other. At the caudal border of the pons they embrace the pyramidal tracts as well, but farther cephalad the transverse pontile fibres are seen to intersect the pyramidal tracts, breaking these up into pyramidal fasciculi; still farther cephalad the pyramidal tracts are wholly embedded in the mass of transverse pontile fibres so that these in turn, with reference to the location of the pyramidal tracts, may be divided into a superficial and a deep set. Laterad they are gathered together to form the medipeduncles (described on p. 901).

The **Longitudinal Fibres.**—The longitudinal fibres consist chiefly of the pyramidal tracts, which are solid strands at their entrance to and exit from the pons, but are broken up into lesser bundles at its middle. A certain number of the pyramidal fibres, as well as other cerebro-pontile fibre-tracts, terminate in relation with the cells of the nuclei pontis, as well as certain of the efferent cranial-nerve nuclei. This fact accounts for the demonstrable diminution in bulk of the pyramidal tract in its course through the pons.

The **Nuclei Pontis.**—The nuclei pontis are small aggregations of gray substance (which in serial sections show them to be continuations of the arcuate nuclei) diffusely scattered among the fibre-systems of the pons proper. They are intercalated in the course (1) of tracts passing from one cerebellar hemisphere to the other and (2) of descending cerebro-pontile tracts. The cells of the pontile nuclei send their axones chiefly to the opposite cerebellar hemisphere and play an important part as links in the complex chain of the neurone systems which make the cerebellum such an important organ of senso-motor coordination.

In the contact-zone of pons proper and the pre-oblongata (or pontile tegmentum) lies a group of transversely decussating fibres with interspersed gray masses with large cells called the **trapezium.** This body will be more fully described in connection with the central auditory paths.

The **Pre-oblongata.**—The pre-oblongata (or tegmental part of the pons) is of much smaller bulk than the pons proper, as seen on trans-sections. On the dorsal surface is spread a layer of gray substance, covered by endyma, which forms the floor of the cephalic part of the fourth ventricle. Beneath this gray substance lies the **formatio reticularis** divided into symmetrical halves by the raphé—continued from the postoblongata. Embedded in the formatio reticularis are various isolated masses of gray substance and various more or less compact fibre-tracts. Among the gray masses are several of the cranial-nerve nuclei, to be described in a separate section, and the following:

The **Superior Olivary Nucleus** (**nucleus olivarius superior**) is a small gray mass or aggregation of several smaller masses situated laterad of the trapezium, intercalated in the path of the trapezial fibres and forming a link in the central acoustic chain (Fig. 579).
The **Nucleus Incertus** (Streeter) is an aggregation of gray substance in the floor of the fourth ventricle near the median sulcus and forming a slight, rounded elevation which extends to the aqueduct. Its functional relations are unknown.

**Fibre-tracts in the Pre-oblongata.**—Among the fibre-tracts in the pre-oblongata the chief ones are (1) the medially lemniscus, (2) the laterally lemniscus, (3) the medially longitudinal bundle, and (4) the prepeduncles of the cerebellum.

The **Medial Lemniscus.**—Each medial lemniscus, in its passage through the pre-oblongata, is gathered into a compact, ribbon-like bundle along the contact-zone of the tegmentum and pons proper, latero-ventrad of the trapezium, some fibres of which traverse it on their way toward the raphé. The medial lemniscus has been described in the postoblongata as occupying the field between raphé and inferior olivary nucleus (the interolivary stratum); in its ascent the medial lemniscus gradually trends laterad so that it almost reaches the surface (Figs. 571 and 573).

The **Lateral Lemniscus.**—The lateral lemniscus is a constituent of the central auditory path and will be described more fully in the sequel. In trans-sections above the level of the trigeminal nuclei the lateral lemniscus is seen as a flattened band spreading over the surface (externally the trigonum lemnisci) ectad of the prepeduncle. Its fibres are interrupted by an intercalated nucleus of the lateral lemniscus.

The **Medial Longitudinal Bundle** *(posterior longitudinal bundle).*—The medially longitudinal bundle maintains its position just ventrad of the central gray, close to the raphé.

The **Cerebellar Prepeduncle.**—The cerebellar prepeduncle, in trans-sections, is seen to be a very compact bundle of crescentic outline with the concavity turned toward the ventricular cavity. Its dorsi-mesal edge is joined to the valvula; its ventral border is sunk into the tegmentum and in its ascent it becomes submerged laterally beneath the lateral lemniscus, dorsally beneath the quadrigeminal plate of the mid-brain.

**Summary of the Gray Masses in the Pre-oblongata:**

Nucleus of Abducent Nerve.
Nucleus of Facial Nerve.
Afferent and Efferent Nucleus of Trigeminal Nerve.
Nucleus of Spinal Root of Trigeminal Nerve.

\[ \{ \text{Cochlear Division} \} \quad \{ \text{Dorsal Nucleus.} \]  
\[ \{ \text{Vestibular Division} \} \quad \{ \text{Ventral Nucleus.} \]  
\[ \{ \text{Medial Nucleus.} \]  
\[ \{ \text{Lateral Nucleus.} \]  
\[ \{ \text{Superior Nucleus.} \]

* Superior Olivary Nucleus.
* Nucleus of Trapezium.
* Reticular Ganglionic Formation.
* Nucleus Incertus.
* Nucleus of Lateral Lemniscus.

Those marked with an asterisk have already been described; the remaining structures relate to the deep connections of several cranial nerves to be described in the succeeding section.

**Central Connections of the Cranial Nerves attached to the Hind-brain.**—Eight of the twelve pairs of cranial nerves are attached to the hind-brain portion of the central axis. Their superficial or apparent origin and the cranial foramina of exit are enumerated in the table on page 889. In coordination with the internal descriptive anatomy of the hind-brain the central connections of these eight cranial nerves must now be considered. They comprise:
### CENTRAL CONNECTIONS OF THE CRANIAL NERVES

Another nerve which pursues a remarkably aberrant course, becoming associated with three of the above-mentioned cranial nerves, is the *nervus intermedius*, known peripherally as the *chorda tympani*. It is chiefly sensor (taste) in function, but also contains efferent fibres which are excito-glandular for the submaxillary and sublingual salivary glands.

In the hind-brain axis lie certain gray masses which are functionally homologous with the nuclear masses in the different parts of the spinal central gray. These defined nests of nerve-elements, from their relations to the cranial-nerve roots, are called the *cranial-nerve nuclei* or *nidi*. Their analogy to the origins of the spinal nerves extends to the shape and character of their cell-elements and their differentiation into (a) *nuclei of origin* and (b) *nuclei of termination* or *recipient nuclei*.

**The Nuclei of Origin.**—Nuclei of origin or motor nuclei are cell-clusters from which arise the axones of efferent nerves or the efferent components of the mixed nerves. Some of these nuclei are in line with the basal portion of the ventral gray horn in the cord below and are termed, owing to their situation near the mesal plane, the *medial nuclei of origin*. Other nuclei are isolated cell-columns in the line of the *caput cornu ventrale* detached by the decussation of the pyramids, termed, from their position in the tegmental substance, the *lateral nuclei of origin*.

The different nuclei of origin of the efferent cranial nerves are under the dominance of the cerebral cortex by way of the cortico-tegmental (or cortico-bulbar) path—usually included in the pyramidal tract.

**The Nuclei of Termination.**—The nuclei of termination or sensor cranial-nerve nidi are likewise repetitions in structure of the dorsal horn of the spinal gray, but with less regularity and definiteness of position. Thus, while the caput gliosum of the cord is continuous with the nucleus of the spinal root of the trigeminal nerve, other recipient or afferent nuclei are more or less isolated in the tegmental substance, while the two (lateral and ventral) nuclei of the cochlear nerve actually lie on the surface of the brain-stem.

The afferent impulses carried in by the sensor cranial nerves excite impulses in the neurones of the nuclei of termination; their axones enter the tegmental substance as arcuate fibres, cross the mesal plane to join the lemnisci to connect with the thalamus and postgeminum and *via* thalamus and postgeminum with the cerebral cortex.

The location of the various cranial nerve nuclei in the brain-stem may be understood by a reference to the diagrams in Figs. 567, 576, 577, and 578.

**Hypoglossal Nerve.**—The nucleus of origin of the hypoglossal nerve is a rod-like cell-column close to the mesal plane, extending for about 7 mm. in the caudal
portion of the fourth ventricle, while its extraventricular portion extends about 5 mm. caudad of the tip of the calamus. Its efferent axones course ventral between the formatio reticularis alba and grisen, thence between the olivary and medial accessory olivary nuclei, to emerge between pyramid and olive. None of the fibres decussate across the middle line, but the nuclei are coördinated by commissural fibres. Axones from cortical cells (ventral third of pre-central gyre) terminate in relation with the cells of the hypoglossal nucleus.

The hypoglossal nucleus permits of subdivision into groups: (a) a medial and (b) a lateral sub-group. The lateral group innervates the palatoglossus and pharyngoglossus, while the medial nuclear group innervates the remainder of the tongue muscles (lingualis transversus and inferior, genioglossus and hyoglossus).

**The Accessory Nerve.**—The accessory nerve is also a purely motor or efferent nerve whose axones arise from an attenuated nucleus, with large multipolar cells, in direct continuation with the nucleus ambiguus cephalad, and with the dorso-lateral cell-column of the ventral horn of the upper five or six segments of the cord. The oblongatal portion of the nucleus, giving rise to the encephalic root of the accessory nerve, may also be termed the nidus laryngei, for its axones join the vagus nerve to innervate the laryngeal muscles (in contradistinction to the nidus pharyngei or nucleus ambiguus, whose axones join the vagus and glosso-pharyngeal to be distributed to the pharynx). The axones from the spinal nucleus are distributed to the Trapezius and Sterno-mastoid muscles.

The nucleus of the accessory nerve is likewise under the dominion of the cerebral cortex by way of the pyramidal tract, and a reflex arc is completed by afferent axones from the dorsal roots of the spinal nerves.

The **Vagus and Glosso-pharyngeal Nuclei** are usually considered in their aggregate, justified not only by their similarity in origin and central connections, but also by the uncertainty which prevails regarding their peripheral interlacement and complex terminations. Both nerves are in greater part afferent, but also contain efferent axones.

1. **Afferent Portions.**—The afferent axones of the vagus arise from the cells in the jugular ganglion and ganglion nodosum (ganglion of the trunk); the afferent axones of the glossopharyngeal arise from the cells in its ganglion superius and ganglion...
petrosum. The root-fascicles of both nerves enter the oblongata along its dorso-lateral groove and the axones then undergo bifurcation into ascending and descending rami, similar to those of the dorsal roots of the spinal nerves. The ascending rami end in the nucleus alae cinereae (nucleus vagi et glossopharyngei); the descending rami collect to form a compact bundle called the tractus solitarius or trineural fasciculus, and terminating in a gray cell-column called the nucleus of the solitary tract—a caudal prolongation of the nucleus alae cinereae. Both tract and nucleus become attenuated caudal, to disappear in the fourth cervical segment (relation with phrenic nerve nucleus), while cephalad it has been traced as far as the region of the locus ceruleus (relation with trigeminal nerve nuclei?).

From the cells of the nucleus alae cinereae and nucleus tractus solitarii axones pass across the raphé to the contralateral interolivary stratum to join the medial lemniscus, establishing connections with the thalamus and cortex; other axones join the tractus nucleo-cerebellaris.

2. Efferent Portions.—The efferent components of the vagus and glosso-pharyngeal nerves come from two sources: (a) the dorsal efferent (vagal) nucleus and (b) the nucleus ambiguus.

The dorsal efferent nucleus lies ventro-mesad of the principal nucleus alæ cinereae and laterad of the hypoglossal nucleus. The axones from its cells pass obliquely ventro-laterad to enter the root-fascicles of the vagus and to become distributed to

---

1 There are other "solitary" fasciculi in the nervous system, and the name "trineural fasciculus" aptly characterizes a tract which has for its object that mutual interchange of functions among the central nuclei of the accessory, vagus, and glosso-pharyngeal nerves.

2 The nucleus of the solitary tract lies to the mesal side of the tract. Another nucleus has been described by Mellus, lying laterad of the tract.
the oesophagus, stomach, trachea, and bronchi. Whether the gloso-pharyngeal nerve receives efferent axones or not is still in debate.

The nucleus ambiguus (nidus pharyngei) is a rod-like mass of large, multipolar cells seen, in trans-sections, lying in the gray, reticular formation midway between olive and trineural fasciculus. The axones arising from its cells run dorsi-mesad at first, then turn abruptly ectad to join the vagus (and gloso-pharyngeal?) nerve-root fascicles, becoming distributed to the pharyngeal muscles, oesophagus, crico-thyroid and laryngeal muscles.

The Acoustic Nerve.—The acoustic nerve consists of a cochlear and a vestibular division; the former is concerned with the sense of hearing, the latter with the sense of equilibrium.

1. The Cochlear or true auditory nerve arises in the bipolar cells of the cochlear spiral ganglion; its axones terminate in (a) the dorsal nucleus (tuberculum acusticum), a pyriform mass on the dorso-lateral aspect of the restis, and (b) the ventral nucleus, somewhat detached from the former.

From the dorsal nucleus cells arise the axones which compose the striae acusticae, myelinic fibre-bundles traversing the ventricular surface to near the median sulcus, dipping into the tegmental substance, crossing to the opposite side in the raphé, and eventually joining the lateral lemniscus to end in the postgeminum and postgeniculum.

From the ventral nucleus cells arise the axones which course transversely to form the trapezium at the contact-zone of the pons proper and tegmentum. Additional axones from cells in the superior olives of both sides and in the trapezium itself increase the bulk of this tract; some of the primary axones end in relation with

---

**Fig. 578.**—Primary terminal nuclei of the afferent (sensor) cranial nerves schematically represented in a supposedly transparent brain-stem, lateral view. The optic and olfactory centres are omitted.
These axone-groups form the contralateral lemniscus lateralis, which contains the intercalated nucleus of the lateral lemniscus as a relay station, to be continued to the postgeminum and postgeniculum and thence to the cortical auditory “centre” in the supertemporal gyr.

2. The Vestibular Nerve axones arise in the bipolar vestibular ganglion cells (G. of Scarpa), enter the brain-stem, and bifurcate into ascending and descending rami, which terminate as follows: The ascending rami end in the medial nucleus (Schwalbe’s); the descending rami end in the spinal vestibular nucleus, which extends down to the gracile and cuneate nuclear level; another group of axones ends in the lateral nucleus (nucleus magnocellularis) (Deiters’); while a fourth and last group ends in the superior nucleus (Bechterew’s). From the cells of all these nuclei of termination axones proceed toward the cortex, dentatum, and fastigatum of the cerebellum, as part of the nucleo-cerebellar tract, to the nuclei of the abducent, trochlear, trigeminal, and oculomotor nerves by collaterals from axones in the medial longitudinal bundle, to the thalamus, and to the ventral-horn nuclei of the spinal cord along the tractus vestibulospinalis. The far-reaching and complex connections of the vestibular nerve with the cerebellum and the centres for eye-muscles and the spinal centres for bodily movements make this cranial nerve a most interesting subject for the active research now going on.

The Facial Nerve.—The facial nerve proper is to be distinguished from its so-called sensor root, or pars intermedia, or nervus intermedius.

The axones of the efferent facial nerve arise from cells forming the facial nucleus in the ventro-lateral region of the reticular formation, in line with the nucleus ambiguus or nidus pharyngei, a little over 4 mm. from the ventricular floor. These axones converge toward the ventricular floor to form a compact bundle which curves over the abducent nucleus from behind (caudad), overlying it like a horse-shoe over a ball (genu facialis internum); not as a straight but as a bent horseshoe, bent so that its cephalic branch is directed more laterad than its caudal branch.

---

**Fig. 579.—Diagram of the central auditory tract (system of the second order).**

---

---

---
After having encircled the abducens nucleus, the facial root passes ventro-laterad, passing its own nucleus ectad, and emerging in the postoblongatal groove (recessus facialis).

Pyramidal fibres from the precentral cortex place this nucleus under the influence of the will; it also receives fibres from the trigeminal and acoustic central systems.

The *nervus intermedius* is a mixed nerve, containing afferent (taste) fibres and efferent (excito-glandular or secretory) fibres. With respect to its afferent component it may be regarded as an aberrant portion of the glossopharyngeal nerve.

1. **Afferent Portion.**—These axones arise, from the cells of the *geniculate ganglion*, implanted upon the genu facialis externum, and terminate in a nuclear extension cephalad of the *nucleus tractus solitarii*. They probably convey gustatory sense impulses from the tip of the tongue and the pillars of the soft palate.

2. **Efferent Portion.**—A nucleus of origin for the excito-glandular elements has been described as a group of cells extending beneath the ventricular floor from the level of the facial nucleus to that of the motor trigeminal nerve, close to the raphé and called the *nucleus salivatorius*.

Peripherally we shall study this nerve as the *chorda tympani*. The mixed nature of the nervus intermedius and of the geniculate ganglion makes it probable that they combine the elements of a sympathetic and a spinal ganglion; the nerve, at least, contains both vegetative and sensorial elements.

The *Abducent Nerve.*—The abducent nerve is a small motor nerve supplying the External Rectus muscle of the eyeball. Its nucleus of origin, with large, multipolar cells, lies close to the median plane beneath the eminentia abducentis. The axones from these cells pass ventrad through the tegmentum and trapezium, and laterad of the pyramidal tract, to emerge in the postoblongatal groove. The nuclei are brought under the dominion of the cerebral cortex by pyramidal fibres of the opposite side. They are likewise brought into intimate relation with the trigeminal, acoustic, and opposite oculomotor nerve nuclei.

The *Trigeminal Nerve.*—The trigeminal is relatively enormous and has correspondingly extensive central connections, including nuclei in the mid-brain, pre- and post-oblongata, and spinal cord. It is a mixed senso-motor nerve and the afferent and efferent divisions must be considered separately.

1. **Afferent Portion.**—The axones of the afferent or sensor root arise in the cells of the large semilunar (Gasserian) ganglion. As in the dorsal roots of the spinal nerves, these axones bifurcate, on entering the brain-axis, into ascending and descending rami. These terminate in a cephalic nuclear extension of the caput glossum of the cord; the ascending rami terminate in the so-called sensor nucleus of the trigeminus, the descending rami in the nucleus of the spinal tract of the trigeminus, which extends as far as the second cervical segment of the cord. The sensor nucleus, at the level of the entrance of the nerve, is quite massive, becoming attenuated cephalad. The spinal tract, in its descent, likewise decreases rapidly as it gives off its terminal axones to the nucleus of the tract. The cells of these terminal nuclei send out axones which cross the median plane, giving off collaterals to the facial nucleus, to join the medial lemniscus to reach the thalamus, and, via thalamus, the somesthetic cerebral cortex. Other axones are distributed (a) to the motor or efferent nucleus of the trigeminus and (b) to the motor or efferent cranial-nerve nuclei.

2. **Efferent Portion.**—The efferent or motor component of the trigeminal nerve consists of axones arising from cells in two nidi: (a) the principal nucleus in the dorso-lateral part of the pre-oblongatal tegmentum, dorso-mesad of the sensor nucleus; (b) a small, slender, so-called mesencephalic root-nucleus (*nucleus radicis descendentis nervi trigemini*) extending cephalad of the region of the locus ceruleus to lie along the aqueduct in the mid-brain. The fibres from the principal
nucleus supply the muscles of mastication. The distribution of the fibres from the mesencephalic root is not precisely known. Kölliker suggests that they may supply the Tensor veli palatini, Tensor tympani, Mylo-hyoid and anterior belly of the Digastric.

Like other motor nuclei, these efferent divisions of the trigeminal are under the dominion of the cerebral cortex via pyramidal fibres.

The Cerebellum.—The cerebellum occupies the greater part of the posterior or cerebellar part of the skull and is the largest portion of the hind-brain. It is overlapped by the occipital lobes of the cerebrum, being separated from these by the tentorium. It lies dorsal of the pons-oblongata and partly embraces this portion of the brain-stem. It is composed of a white central core with scattered gray masses, and a surface layer of gray substance that is of darker hue than the cerebral cortex.

The cerebellum is convoluted on a plan entirely different from that of the cerebrum. Each primary fold is folded by secondary and these in turn by tertiary folds, so that on sagittal section a cypress-leaf appearance is noted, the arbor vitae cerebelli. The interior or medullary white substance follows all these branchings and sub-branchings, forming a skeleton of the minute folds which are called folia. These folia are demarcated on the surface by numerous curved and more or less parallel fissures of various depths.

![The Cerebellum](image)

Fig. 580.—Upper surface of the cerebellum. (Schäfer.)

The cerebellum is connected to the brain-stem by three pairs of peduncles and by vestigial portions of the primitive dorsal wall of the brain-tube. Among the latter the medullary vela or laminae are most important; they are the valvula (superior medullary velum) and the velum (inferior medullary velum), which enter into the formation of the “roof” of the fourth ventricle.

The rounded margin of the cerebellum demarcates two surfaces looking respectively “upward” and “downward,” or cephalic and caudal surfaces. Both are convex, the inferior or caudal surface more so than the upper or cephalic. The inferior surface shows a deep median depression, the vallecula, into which the oblongata is sunk. The ventral margin is widely notched to partly embrace the brain-stem (pre-oblongata and quadrigemina); a dorsal notch (incisura cerebelli posterior), which is smaller and narrower and lodges the falcula, separates the hemispheres as these project beyond the postvermis.

The cerebellum is arbitrarily sub-divided into a medial segment, the vermis or worm, from its annulated appearance, and two lateral portions, commonly called...
the cerebellar "hemispheres" or pileums. The vermis may, according to the aspect in which it is viewed, be divided into the prevermis on the upper or cephalic surface, and the postvermis on the inferior or caudal aspect. The prevermis is hardly distinguished from the adjacent sloping surfaces of the hemispheres; occasionally a slight furrow exists on either side. Ordinarily the term is to be restricted to the high median elevation usually called the monticulus cerebelli. The postvermis is more distinctly bounded by a deep fissure, the sulcus valleculae, on each side, separating it from the corresponding lateral hemisphere.

Among the many fissures which traverse the surface of the cerebellum, one is particularly conspicuous as a deep elef which may be traced along the dorso-lateral margin from the dorsal notch to the point of entrance of the cerebellar peduncles. This is the peduncular sulcus or great horizontal sulcus (sulcus horizontalis cerebelli), and it divides the cerebellum into a cephalic and caudal or upper and lower part. The sulcus is usually quite deep in the hemispheral portion, but it frequently fails to traverse the vermis. Other deep fissures demarcate the lobes or major sub-divisions of the intricately convoluted surface of the cerebellum.

Conventionally the lobes and fissures or sulci are described upon the "upper and "lower" surfaces respectively, and this mode of description is briefly adhered to here. A better idea of the topographical relations of the lobes and sulci in the vermis and the hemispheres may be gained from a study of the divisions of the cerebellum as it extended in one plane as well as on sagittal sections through the mesal and lateral planes.

**Lobes and Fissures of the Cerebellum.**—The surface of the cerebellum is traversed by eight more or less curved and deep fissures demarcating nine lobar sub-divisions. Distinctive names are given to the portions of each lobe in the hemispheres as contrasted with that in the vermis, although often without warrant, as the two are quite continuous and merit no such distinction. This burdensome nomenclature seems so firmly rooted in descriptive anatomy that the various terms must be repeated here. The arrangement of the fissures and lobes will be understood by reference to the following schema, in which the structures are named from "before backward," or cephalo-caudad:
The **Lingula** (lingula cerebelli) is a tongue-shaped process of the vermis lying in the ventral cerebellar notch, ventrad of the central lobe, and is partially or completely concealed by it. It consists of 5, 6, or 7 lamellae lying upon and connected with the dorsum of the valvula. At either side the lingula gradually shades off, being prolonged only for a short distance toward the region of the peduncles as the vincula lingulae.

The **Central Lobe** (lobulus centralis) is a small median mass situated in the ventral notch, dorsad of and overlapping the lingula. Its lateral, wing-like prolongation is called the **ala lobuli centralis**.

The **Culminal Lobe** (lobulus monticuli) is much larger than the two lobes just described and constitutes, with the succeeding lobe (the clival lobe), the bulk of the prevermis and "upper" surface of the cerebellum. It partly overlaps the central lobe. Its lateral extensions are also termed the **anterior crescentic lobes**.

1 The anterior and posterior crescentic lobes are often called the pars anterior and pars posterior respectively of the "lobulus quadrangularis."

---

- **Am**, amygdala
- **Bivent.**, biventral lobe

---

57
The Clival Lobe is of considerable size, separated from the culminal lobe by the preclival fissure and from the cacuminal lobe by the postclival fissure. Its lateral extensions are also termed the posterior crescentic lobes.

The anterior and posterior crescentic lobes of either side have been described by some writers as the pars anterior and pars posterior of the quadrate lobe or lobulus quadrangularis.

The Cacuminal Lobe (folium vermis; superior semilunar lobe) is a short, narrow band at the dorsal margin of the vermis, which expands in either hemisphere into a lobe of considerable size, of semilunar shape, and bounded caudad by the peduncular fissure.

The Tuberal Lobe is of small size in the region of the postvermis, but laterally spreads out into the large inferior semilunar (lobulus semilunaris inferior) and gracile lobes demarcated by the intervening postgracile fissure. These lobes comprise at least two-thirds of the “inferior” surface of the cerebellar hemispheres.

The Gracile Lobe is often divided by an intragracile fissure into pre- and postgracile lobes.

The Pyramidal Lobe is a conical projection, forming the largest prominence of the postvermis. It is continued laterad into the hemisphere as the biventral lobe (lobulus biventer); the demarcation between the latter and the pyramis proper is accentuated by the deep sulcus valleculae.

The Uvular Lobe (uvula vermis) occupies a considerable portion of the postvermis as the uvula, while its lateral extension in either hemisphere, the tonsilla or amygdala (tonsilla cerebelli), is a rounded mass lying in a deep fossa between the uvula and biventral lobe. (This fossa was termed, by the older anatomists, the nidus avis or “bird’s nest” [Reil and Vieq d’Azyr].) The junction of uvula and tonsilla is an attenuated isthmus marked by a few shallow furrows and termed the furrowed band.

The Nodular Lobe comprises the nodulus (nodulus vermis) (in the postvermis) and the flocculus (floeculi secondarii) of each side, connected by a delicate lamina of white matter, the velum. Each flocculus lies adjacent to the ventro-lateral surface of the peduncular mass, extending into the ventral extremity of the pedun-
cular fissure. The flocculi of the two sides are connected with each other by a band of white matter, termed the velum (posterior medullary velum) in its medial portion, while its lateral expansions toward the flocculi are termed the peduncles of the flocculi.

**The Internal Structure of the Cerebellum.**—In any section of the cerebellum we may recognize the interior white substance, corpus medullare (medullary body), and the peripheral gray cortex. The white substance in each lateral hemisphere is more bulky than in the median vermis, while the cortex is of more uniform thickness throughout. In a sagittal section in the mesal plane the central white core is seen to divide into two main branches, preramus and postramus; these main branches divide and subdivide into a series of medullary laminae surmounted by the foliated cortex, and presenting the characteristic appearance known as the arbor vitae cerebelli.

**Isolated Gray Masses or Nuclei of the Cerebellum.**—Embedded in the white matter of the cerebellum are several gray masses. They are four in number on each side:

1. **Dentatum or dentate nucleus.**
2. **Embolus or nucleus emboliformis.**
3. **Globulus or nucleus globosus.**
4. **Fastigatum or nucleus fastigii.**
The dentatum is the largest and best studied of the cerebellar nuclei. It is located in the mesal part of the corresponding cerebellar hemisphere, in the direct prolongation of the prepedunculus, which appears to enter it. It consists of a folded lamina of gray matter convoluted like the similar nucleus of the olive, and opens cephalo-mesad where its hilum (hilus nuclei dentati) permits of the entrance and exit of fibres from various sources.

The embolus is a small mass of gray substance, elongated cephalo-caudad, and placed entad of the dentatum, partly covering its hilum.

The globulus consists of several small round or oval masses connected with each other and lying entad of the preceding.

The fastigatum (nucleus of the "roof") is second in size to the dentatum, situated close to the mesal plane directly dorsad of the fourth ventricle, or in the fastigium of the cerebellum, and within the postvermis. The nuclei of opposite sides approach each other so nearly as almost to fuse.

The Cerebellar Peduncles.—Three pairs of peduncles constitute the chief avenues for the entrance and emergence of the fibres composing the white substance of the cerebellum and connecting adjacent parts of the brain-stem therewith. The peduncles are, on each side, the prepeduncle, medipeduncle, and postpeduncle.

The Postpeduncle (corpus restiforme) is the continuation of the restis of the oblongata. It contains both afferent and efferent fibres, connecting the cerebellar cortex with structures situated caudad: (1) The dorsal or direct spino-cerebellar tract, composed of axones arising in Clarke's column (spinal cord) and terminating in the cortex of the prevermis on both sides of the median line, but chiefly on the opposite side. (2) The olivo-cerebellar tract, composed of axones arising in the (inferior) olivary nuclei—principally from the contralateral or opposite olive, and terminating in the cortex of the prevermis and adjacent hemispheral portions, as well as in the dentatum. (3) External arcuate fibres from the homo-lateral and contralateral nuclei of the gracile and cuneate funiculi. (4) The nucleo-cerebellar
tract, composed of axones from the recipient nuclei of certain cranial nerves (vestibular, trigeminal). (5) The cerebello-spinal (descending) tract, terminating in relation with the ventral-horn cells at various levels of the spinal cord.

The Medipeduncles (brachia pontis) are the largest of the three pairs. They consist of a mass of curved fibres comprising the pons and entering either cerebellar hemisphere between the parted lips of the ventral end of the peduncular fissure, just ectad of the postpeduncle. Each peduncle contains axones coursing in opposite directions and in large part may be considered as purely commissural fibres. Some of the axones terminate, however, in the nuclei pontis to convey impulses so the cells therein; these in turn send their axones (tractus pontocerebellares) into the opposite medipeduncle, and therefore constitute interrupted commissural systems. A few fibre-systems in the medipeduncles establish relations with certain other structures in the brain-stem, notably the nuclei of the oculomotor, trochlear, and abducent cranial nerves.

The Prepeduncles (brachia conjunctiva) emerge cephalad from the cerebellum entad of the medipeduncles. As they extend cephalad they converge to form the lateral boundaries of the fourth ventricle and partly roofing it in. On trans-section they appear of oval outline, somewhat concave toward the cavity of the ventricle. The valvula, a thin lamina of white substance, spans the interval between the converging prepeduncles, and thus completes the roofing-in of the cephalic portion of the fourth ventricle.

The prepeduncles consist almost wholly of axones arising from the cells of the dentatum, the ectal part of the fastigium of the same side, and mesal part of the fastigium of the opposite side. In their course, converging cephalad, these bundles pass into the tegmentum of the mid-brain ventrad of the quadrigemina, and decussate almost wholly. The fibres of each peduncle terminate in the rubrum (red nucleus) of the opposite side, although a few continue to enter the thalamus.

This system of fibres is also called the tractus cerebello-tegmentalis, and axones of inverse functional direction have been included therein.

The Ventral spino-cerebellar tract (Gowers' tract) is in relation with the prepeduncle and valvula. Unlike the dorsal or direct spino-cerebellar tract, it does not enter the cerebellum along the postpeduncle. Its fibres pass farther cephalad, through the reticular formation of the pre- and post-oblongata, to become reflected dorso-caudad at the level of the isthmus of the hind-brain, and entering the valvula, proceed with the prepeduncle into the cerebellum.

The Medullary Vela.—These are two thin, relatively undeveloped laminae of white substance, representatives of the mid-dorsal wall of the brain-tube adjacent to the cerebellar proton, and in the adult brain appear as prolongations of the white central core of the cerebellum. They are the valvula (anterior or superior medullary velum; valve of Vieussens) and the velum (posterior or inferior medullary velum).

The Valvula is a thin lamina of white substance spanning the interval between the converging prepeduncles, and with these assisting in the formation of the "roof" of the fourth ventricle. Caudad it is continuous with the white substance of the cerebellum, while on its dorsal surface lie the five to seven folia of the lingula.
Cephalad it narrows as the quadrigemina are approached, and a slight median ridge, the frenulum, descends upon the dorsal surface of its apical portion from between the postgemina; on either side of the frenulum may be seen the superficial root of the trochlear nerve. The majority of the fibres in the valvula are longitudinal; as already described (p. 901), the ventral spino-cerebellar tract reaches the cerebellum along the valvula.

The Velum is a still thinner lamina of white substance which bears the same relations to the nodulus that the valvula presents to the lingula. Laterad it extends to the flocculus of either side. The velum ends in a free crescentic edge and its endynal and pial coverings continue as a fused, delicate membrane, the metatela.

The valvula and velum enter the cerebellum at an acute angle, forming the peaked roof (fastigium), while the tent-like recess is called the recessus tecti.

The Fibres Proper of the Cerebellum.—The fibre proprius of the cerebellum are of two kinds: (1) commissural fibres, which cross the middle line to connect the opposite halves of the cerebellum, some at the anterior part and others at the posterior part of the vermis; (2) association fibres, which are homo-lateral fibres connecting adjacent laminae with each other.

Microscopic Appearance of the Cerebellar Cortex.—The cerebellar cortex, on section, presents two marked layers: an outer, of a pale-gray color, the molecular layer, and an inner, of a rusty-brown tint, the granular layer. At the contact line of these two layers, but more within the molecular than the granular, are found the characteristic nerve-elements of the cerebellum, the flask-shaped Purkinje nerve-cells.

The Molecular or Ectal Layer consists of cells and delicate fibrillae embedded in a neuroglial network. The cells are small and are characterized by the course of their branching axones which run parallel with the surface of the folium, give off numerous collaterals which pass in a vertical direction toward the cell-bodies of the Purkinjean elements and embrace these in a basket-like network. Hence these cells are called basket-cells (Fig. 587).

The Purkinjean Cells are flask-shaped, and form a stratum at the junction of the molecular and granular layers, their bases directed toward the latter. Each cell gives off an axone entad, while ectad it gives off numerous dichotomously branching dendrites covering a very large field of the molecular layer. The axone, after giving off several collaterals which pass toward different parts of the granular layer, becomes myelinic not far from the cell-body and passes into the white substance to establish connections with other folia within the cerebellum or with more distant brain-structures.

The Granular or Ental Layer is characterized by containing numerous small nerve-cells or granules of a reddish-brown color, together with many nerve-fibrils. Most of the cells are nearly spherical and provided with short dendrites, which spread out in a spider-like manner in the granular layer. Their axones pass outward into the molecular layer, and, bifurcating at right angles, run horizontally for some distance. In the outer part of the granular layer are also to be observed some larger cells, of the type termed Golgi cells (Fig. 587). Their axones undergo frequent division as soon as they leave the nerve-cells, and pass into the granular layer, while their dendrites ramify chiefly in the molecular layer.

Finally, in the gray substance of the cerebellar cortex fibres are to be seen which come from the white centre and penetrate the cortex. The cell origin of these fibres is unknown, though it is believed that it is probably in the gray substance of the spinal cord. Some of these fibres end in the granular layer, by dividing into numerous branches, on which are to be seen peculiar moss-like appendages; hence they have been termed by Ramón y Cajal the moss-fibres (Fig. 587); they form an arborescence around the cells of the granular layer. Other fibres derived from the medullary centre can be traced into the molecular layer, where their
branches cling around the dendrites of Purkinje’s cells, and hence they have been named the clinging or tendril fibres (Fig. 587).

The cerebellum is an important senso-motor organ, transmuting sensor impressions into motor impulses under the dominance of the cerebral centres. Its connections with other brain portions and the spinal cord are established by the peduncular fibres. It is essentially an apparatus for the coördination of movements and the orientation of the body and its parts in space. These functions depend principally upon the reception of sensor impulses from (1) the vestibular nerve and (2) the spino-cerebellar (ascending) tracts. Motor impulses pass along (1) the cerebello-spinal (descending) tracts to the ventral-horn nuclei of the cervical cord; (2) the tractus rubro-spinalis, which arises in the rubrum (red nucleus)—an intercalated ganglionic mass connected with the cerebellar cortex by the prepeduncles, or tractus cerebello-tegmentales. The tractus rubro-spinalis is a tract for voluntary motor impulses next in importance to the pyramidal tract.

Weight of the Cerebellum.—Its average weight in the male is 165 grams and 155 grams in the female. It attains its maximum between the twenty-fifth and
nine-ty-fifth years, its increase in weight after the fourteenth year being relatively greater in the female than in the male. The proportion between the cerebellum and the cerebrum is as 1 to 7.5; among eminent men it is 1 to 8.5. In the newborn the ratio is as 1 to 20.

The Mid-brain (Mesencephalon).

The mid-brain is the short and constricted portion of the brain which lies in the opening of the tentorium cerebelli (incisura tentorii) and which connects the pons with the inter-brain and hemispheres, and hence it is frequently called the isthmus cerebri. It is developed from the second brain-vesicle, the cavity of which becomes the aqueduct. It comprises the crura cerebri, the quadrigemina, the geniculate bodies, and the aqueduct. Its two surfaces are ventral and dorsal. They are free, but concealed: the ventral surface by the apices of the temporal lobes which overlap it; the dorsal, by the overhanging cerebral hemispheres. The ventral surface, when exposed by drawing aside the temporal lobes, is seen to consist of two cylindrical bundles of white substance, which emerge from the pons and diverge as they pass forward and outward to enter the inner and under part of either hemisphere. They are the crura cerebri, and between them is a triangular area, the intercru-ral space; near the point of divergence of the crura the roots of the third nerve are seen to emerge in several bundles from a groove, the sulcus oculomotorius (sulcus nervi oculomotorii) (Fig. 551). The dorsal surface is not visible until a considerable portion of the cerebral hemispheres and other overlying structures have been removed. It then presents four rounded eminences placed in pairs, two cephalad and two caudad, and separated from one another by a crucial

![Diagram of the brainstem](image-url)
THE MID-BRAIN

905
depression. These are termed the quadrigemina (tubercula quadrigemina) (Fig. 588). The ventral and dorsal surfaces meet on the side of the mid-brain, and are separated from each other by a furrow, the lateral groove (sulcus lateralis mesencephali), which runs caudo-cephalad (Fig. 588).

External Morphology.—Dorsal Surface.—The quadrigemina are four rounded eminences placed in pairs separated by a flat median groove and a more sharply cut transverse furrow. The cephalic pair, the pregemina (superior colliculi; the nates of older authors), are the larger and the epiphysis rests in the flattened depression between them. The pregemina are oval, their long diameter being directed cephalo-lateral, and are of a yellowish-gray color. The postgemina (colliculi inferiores; the testes of older authors) are hemispherical in form, and lighter in color than the preceding. The lamina quadrigemina, comprising the whole of the dorsal wall of the mid-brain, extends from the root-region (postcomissure) of the epiphysis to the cephalic end of the valvula.

Each pre- and postgeminum is continued latero-ventrad in prominent white bands, the brachia. The band from the pregeminum is termed the prebrachium; that from the postgeminum is called the postbrachium.

The Prebrachium (brachium quadrigeminum superius) proceeds cephalo-ventrad between the overhanging pulvinar and a light-gray eminence, the postgeniculum. In reality it is a continuation of a part of the optic tract. The Postbrachium (brachium quadrigeminum inferior) proceeds in a similar direction to disappear beneath the postgeniculum.

Of the two geniculate bodies, on either side, the pregeniculum belongs rather to the thalamus, while the postgeniculum may properly be considered here among the structures of the mid-brain.

The Postgeniculum (corpus geniculatum mediale s. internale) is a small oval eminence on the lateral surface of the mid-brain in which the mesal root of the optic tract appears to terminate. The postbrachium likewise appears to run into this body; as a matter of fact, so far as is known, the postgeniculum is (1) a way-station for auditory impulses in their course toward the cerebrum; (2) the origin and terminus for the arched comissure of Gudden (infracommissure; commissura inferior [Gudeni]), by means of which circuitous path, through the chiasm, and along the mesal root of optic tract, the postgenicula of the two sides are connected.

The quadrigeminal lamina is continuous caudal with the cerebellar prepeduncles and the intervening valvula. A slight, median, ridge-like projection, the frenulum valvule, descends from between the postgemina onto the valvula; on either side of the frenulum emerge the slender trochlear nerves.

The Crura constitute the bulk of this portion of the brain-stem. Upon the ventral aspect of the brain they appear as two large, white, rope-like strands emerging from the pons and diverging to either cerebral hemisphere, becoming embraced by the optic tracts. Each crus is composed of a dorsal tegmental part—a continuation of the tegmentum of the hind-brain—and a ventral crusta or pes. These parts are demarcated from each other on the external surface by the oculomotor sulcus ventrad (which looks into the intercerebral space) and the sulcus lateralis mesencephali on the lateral aspect. The lateral surface shows dorsally the cerebellar prepeduncle dipping into the substance of the mid-brain, while between it and the crista is a small triangular field of oblique fibre-strands, not always well defined, called the trigonum lemnisci because the lateral lemniscus tends to reach the surface of the brain-stem at this situation (Fig. 588).

The surface of the crura shows a rope-like twist in the course of its fibre-bundles. Oblique or transverse fasciculi are sometimes seen upon the surface, two of which are fairly constant. They are (1) the taenia pontis, and (2) Gudden's tractus peduncularis transversas (cimbia).
The Taenia Pontis, as Horsley has shown, takes origin contralaterally in the gray substance continuous with the "interpeduncular ganglion," but ventral to it. The tenia then passes over the lateral lemniscus and cerebellar prepeduncle to the dentatum and fastigatum.

The Cimbia¹ or Tractus Peduncularis Transversus may he traced from the pregeminum and postgeminulum over the surface of the crus to near the ventro-meson, disappearing from view in the oculomotor sulcus.

**Internal Structures of the Mid-brain.**—If a cross-section be made through the mesencephalon it will be seen that each lateral half is divided into two unequal portions by a lamina of deeply pigmented gray substance, named the substantia nigra (intercalatum; ganglion of Soemmering). The postero-superior portion of the crus is named the tegmentum, and the antero-inferior the crusta or pes. The substantia nigra is curved on section with its concavity upward, and extends from the lateral groove externally to the oculomotor sulcus internally. The two crusts are in contact in front of the pons, from which point they diverge from each other, but the two halves of the tegmentum are joined to each other in the mesal

¹ In architecture—a band or fillet about a column. Also called fasciculus arciformis pedis.
plane by a forward prolongation of the raphé or median septum of the pons. Laterally the tegmenta are free, but dorsally they blend with the quadrigemina.

Traversing the mid-brain in the median plane and nearer the dorsal surface is the aqueduct, surrounded by the central tubular gray, which in this brain-segment has retained the comparatively primitive arrangement of the embryonic brain-tube.

The Aqueduct (Mesocele) and Central Gray Aqueduct.—The aqueduct is a narrow canal connecting the third with the fourth ventricle, and demarcating the lamina quadrigemina dorsal from the tegmental zone. Its shape on trans-section varies at different levels, being T-shaped caudal, oval or quadrangular along its middle, and triangular cephalad. It is lined by the endyma (columnar ciliated epithelium) and surrounded by the central aqueduct gray. The central gray is separated dorsally from the quadrigemina by the stratum lemnisci; ventrad near the median plane lie the medial longitudinal bundles. Within the gray substance lie certain well-defined cell-clusters, the nuclei of origin of the oculomotor and trochlear nerves and the mesencephalic root of the trigeminal nerve. These will be described in detail later.

The Substantia Nigra or Intercalatum.—The substantia nigra is a crescentic layer of deeply pigmented gray substance interpolated between the crus and the tegmentum. Mesad it nearly touches its fellow of the opposite side, being separated by the rudimentary ganglionic gray (the postperforatum) in the intercrural space. Its ventral face sends numerous ramifying prolongations among the fasciculi of the crus. It extends from the cephalic border of the pons to the subthalamic region, while its lateral edge reaches the surface along the lateral sulcus. Its cells are medium-sized, multipolar, their bodies approaching the fusiform, or angular in outline. The cells are characterized by a pigment (marked only in man) which varies from a pale brown in the young to an absolute blackness in the very aged. The axones arising from the cells proceed in various directions toward the tegmentum and crus, but their exact course is not known. Experimental excitation of this ganglionic mass elicits movements of deglutition accompanied by respiratory changes. Mellus has found in the monkey that a portion of the pyramidal tracts is interrupted in the substantia nigra.

The Quadrigemina.—The quadrigemina are largely composed of gray substance, but the pre- and postgemina differ distinctly in structure.

The Pregeminum presents a true cortical type, which is more evident in the optic lobes of lower vertebrates. In man the thin, outermost white layer—the stratum zonale—is an expansion of the optic tract. Beneath this lies a gray nucleus, with numerous small cells—the stratum cinereum—a cup-like layer of crescentic outline on trans-section. The succeeding ental layer is a white stratum, also derived from the optic tract—the stratum opticum. Between this and the underlying stratum lemnisci is a second gray layer, less defined because of the diffuse interlacing of white fibres.

Each pregemum is one of a series of primary centres of vision related more to eye-muscle reflexes resulting from optic and auditory stimuli than to actual light and color perception. Fibres from the retina, for the most part, form the stratum zonale and end in the ganglionic gray; others enter into the formation of the stratum opticum. Return fibres from the occipital cortex also enter the stratum opticum. The retinal and occipital fibres determine the formation of the prebrachium. Other fibres reach the pregemum through the lateral and modal lemnisci—from both sides—to end in relation with the deeper cells of the stratum cinereum. The connections of the pregemum with the cochlear centres afforded by the lateral lemniscus establishes the so-called optic-acoustic reflex path.

The Postgemina are more homogeneous in texture, comprising a pair of compact ganglia which on trans-section have the shape of biconvex lenses, encapsulated by white substance. The cells are small, multipolar, and very numerous, embedded
in a fine molecular groundwork. The white stratum zonale is principally derived from the fibres of the lateral lemniscus, which terminate in the central gray of the postgenminum as well as in the postgeniculium. The axones of the cells in the postgeninum course cephalad in the postbrachium, dip beneath the postgeninum into the tegmentum and proceed to the thalamus. The postgeminina are important links in the chain of the auditory neurone system, and are special localities for the reflexion of auditory impulses.

The Tegmentum.—The tegmentum of the mid-brain is continuous with the like formations in the hind-brain stem and consists of longitudinal fibre-bundles intersected by transverse arched fibre-systems with great substance irregularly scattered in the interstices, composing the formatio reticularis. In its ventral portion, on either side, and at the level of the pregeninum, lies a gray ganglionic mass, the rubrum or red nucleus. (nucleus tegmenti; nucleus ruber).

The Rubrum or Red Nucleus, so termed from its reddish tinge in the fresh brain, which it owes to the pigmentation of its cells as well as to its great vascularity, is found subjacent to the pregeninina in those section-levels where the substantia nigra has its greatest expansion. In trans-sections its outline is irregularly circular; in sagittal sections an elongated oval. The rubrum is the end-station for the majority of the decussated cerebellar prepeduncule fibres, for fibres from the cerebral cortex, and from the stratum. These fibre-bundles form for the nucleus a' capsule which is thicker on its ectal surface. From the cells of each rubrum arise axones which pass (1) to thalamus and cerebral cortex (links in the cerebello-cortical neurone-chain), and (2) axones which descend into the spinal cord to form the tractus rubrospinalis (Monakow's)—a continuation of an indirect motor path from the cerebral cortex to peripheral motor nerve. The tracts arising from the red nuclei of the two sides decussate with each other and descend in the tegmentum.

In the intercruical space lies a primitive gray ganglionic mass, the postperforatim. Cephalad of the pons, in the median line, lies a cluster of cells, the interpeduncular ganglion (Gudden). The fasciculus retroflexus (Meynert), whose fibres arise in the habenal ganglion, descends to end in the interpeduncular ganglion.

The principal longitudinal fibre-tracts in the tegmentum of the mid-brain are (1) the medial longitudinal fasciculus, (2) lateral lemniscus, (3) medial lemniscus, (4) the decussating cerebellar prepeduncules, (5) the decussating rubro-spinal tracts, and (6) the central segmental tracts.

The Medial Longitudinal Bundle lies on each side of the median plane, lying ventrad of the central aqueduct gray in the mid-brain and continuous throughout the brain-stem in its formatio reticularis. It is the continuation and the equivalent, but in a more differentiated form, of the ventral basis bundle of the spinal cord. It is formed by association neurones and acts as an associating agent with regard to many cranial and spinal-nerve centres for the performance of certain definite functions. Its neurones receive impulses from afferent elements and transmit them to motor or efferent elements. It particularly brings into relation the sensor cranial-nerve nuclei and the quadrigemina with the motor nerves of the eye (III, IV, and VI), of the face (VII), and of the trunk. A special nucleus for the bundle is described as being situated in the gray floor of the third ventricle, at its junction with the aqueduct. The axones from the cells of this nucleus cross to the opposite side through the postcommissure (Fig. 591).

The Lateral Lemniscus, we have learned, is a continuation of the auditory path in its course to the cerebral cortex. Its formation is described on p. 888. In the mid-brain the fibres of the lateral lemniscus course through the lateral part of the tegmentum, near the surface, and most of them end in the postgeninmal gray nucleus and in the postgeniculium. A few fibres are carried into the pregeninum.

The Medial Lemniscus, or principal conduction path for sensor impulses from the trunk and extremities, and already discussed in the preceding (p. 888), ascends
in the tegmentum of the mid-brain in the contact-zone with the crusta. In its ascent it is deflected slightly dorso-laterad by the red nucleus. The lateral border of the ribbon-like bundle is in contact with the lateral lemniscus, and forms an angle with it, as seen on trans-sections (Figs. 589 and 590).

Many of the fibres of the medial lemniscus terminate in the pregemum; the remainder proceed to the thalamus.

The Prepeduncles of the Cerebellum sink into the mid-brain tegmentum in a cephalo-ventral direction, the two prepeduncles converging and their fibres undergoing a complete decussation (Werneck's commissure) subjacent to the post-gemina. The crossed fibres end, for the most part, in the rubrum of each side; others circumvent the nucleus, forming a white capsule for it which is thicker on its ental surface, and proceed to the thalamus.

The Tractus Rubrospinalis (Monakow's) is composed of axones arising in the red nucleus, decussating with those of the opposite tract, and descending in
the tegmentum to the lateral intermedial fasciculus of the cord, to terminate in relation with ventral-horn cells.

The Central Tegmental Tract (olivary fasciculus) probably arises in the inferior olivary nucleus and ascends in the tegmentum. In the pre-oblongata it is best seen in trans-sections as a compact longitudinal bundle along the dorsi-mesal aspect of the superior olive. Cephalad it is said to end in the lenticula.

Fountain Decussation. — A dense decussation may be found in the space between the two red nuclei. The fibres composing the decussating bundles arise from cells in the pregramina and central aqueduct gray. After having crossed the middle line they descend, join the medial longitudinal fasciculus, and give off collaterals to, or terminate in the nuclei of the eye-muscle nerves.

The Crusta or Pes.—The crusta or pes is somewhat crescentic in outline on section and is composed of longitudinal fibre-bundles—the continuation of the internal capsule—divisible into three sectors. The middle sector comprises three-fifths of the cross-section area of the crusta, and comprises the pyramidal tract on its way from the cerebral cortex (motor area) to cranial and spinal centres below. The ectal sector, or lateral one-fifth, comprises the temporo-pontile tract; its axones arise from cortical cells in the temporal lobe and end in fine terminal arborizations in relation with cells of the nuclei pontis. The ental sector, or mesal one-fifth of the crusta, comprises the fronto-pontile tract; its axones arise from cells in the cortex of the frontal lobe and terminate in the nuclei pontis.

The Pyramidal Tract is a direct “voluntary” motor tract; the two cortico-pontile tracts enumerated above are links in a chain of neurones which constitute an indirect motor tract. The series may be shown in the following order: Cortico-pontile tract; nuclei pontis; cerebello-cortex; dentatum; prepeduncle; rubrum; tractus rubrospinalis; spinal gray; spinal nerve; muscle.

Summary of the Gray Masses in the Mid-brain.

* Central aqueduct gray
  (a) Oculomotor n. nucleus
  (b) Trochlear n. nucleus
  Nucleus radicis descendentis nervi trigemini
  * Nucleus of medial longitudinal bundle and postcommissure
  * Formatio reticularis
  * Substantia nigra (intercalatum)
  * Rubrum (red nucleus)
  * Stratum cinereum pregemini
  * Nucleus postgemini
  * “Interpeduncular” ganglion.

Structures marked with an asterisk have been considered in the preceding description. The central connections of the oculomotor, trochlear, and trigeminal nerves may now be described.

Deep Origin of Cranial Nerves Arising in the Mid-brain.—The mesencephalic root of the trigeminal nerve has been described on p. 894.

The Trochlear-nerve Nucleus.—The trochlear-nerve nucleus is situated in the level of the cephalic half of the postgeminum. It is a small oval mass of gray substance in the ventral part of the central aqueduct gray. The cells are large, sometimes stellate in appearance. The root fibres pursue a peculiar course; they accumulate in the latero-ventral angle of the aqueduct gray, run caudad, gradually rising dorsal, and suddenly turn mesad to undergo a complete decus-

---

1 Decussatio fontinalis, so called because of the resemblance of the scattering strands to the jets of a fountain.
2 Türck's bundle; not to be confused with Türck's column in the cord.
ation with the root of the opposite side in the valula, emerging laterad of the frenulum, or at the inner border of the prepuduncle.

The nucleus is placed under the dominion of the cerebral cortex by pyramidal fibres, and it is associated with other nuclei in the brain-stem by the medial longitudinal bundle.

The Oculomotor-nerve Nucleus.—The oculomotor-nerve nucleus is a group of cell-clusters in the ventral portion of the aqueduct gray, subjacent to the pregeminum, and extending cephalad to become lost in the gray wall of the third ventricle at the slope formed by the opening out of the aqueduct. Its nerve-elements are arranged in definite groups. The most cephalic of these is composed of smaller elements, closely crowded and embedded in deeply staining molecular ground-substance. In a flat-wise section of the brain-stem the outline of this nucleus resembles an inverted L or the tip of a boat-hook; the axones from the cells of this nucleus (of Edinger and Westphal) supply the ciliary muscle and sphincter iridis (pupillary motion). The main nucleus, composed of several sub-groups, lies caudo-laterad of the preceding, and is composed of larger cell-elements.

The root-fibre bundles from this nuclear group pass ventrad, breaking through the medial longitudinal fasciculus, separating like the strands of a horse's tail by the interference of the red nucleus, to become gathered into more compact bundles between the mesal edge of the substantia nigra and intercruhal region, and emerging by eight to twelve fascicules which compose the trunk of the oculomotor nerve.

The origin of each nerve is not limited to the nuclei of its side; a part is decussated and the decussated origin is related to the innervation of the Internal Rectus. By means of association neurones in the medial longitudinal fasciculus the oculomotor and abducent nuclei of one side are brought into relation, affording an organic basis for the synergism existing between the Internal and External Recti muscles in the conjugated lateral eye-movements.

The paradox of the facial nerve supplying muscles under the reflex dominion of the retina (orbicularis oculi) instead of the oculomotor may be explained by the assumed existence of fibres emerging from the oculomotor nucleus, entering the medial longitudinal fasciculus and joining the root of the facial.

Parts Derived from the Fore-brain.

The Fore-brain or Prosencephalon includes those portions of the brain which are derived from the cephalic one of the three primary brain-vesicles. It includes, according to prevailing schemas, a thalamic portion (the thalamencephalon or diencephalon) and the telencephalon. The two divisions constitute a structural continuity and exhibit a mutual dependency so close that the arbitrary distinction now in vogue tends to mislead. The relations of "diencephalon" and "telencephalon" are further complicated by the intimate fusion of the sides of the former (thalami) with the floors of the latter (caudata); this caudatothalamic fusion, in the adult brain, gives rise to some difficulty in distinguishing the two segments. The internal capsule which intervenes between thalamus and lenticula also intervenes between lenticula and caudatum, both telencephalic parts.

External Morphology.—The diencephalon or thalamencephalon comprises the thalami, the epiphysis and habenae, the pregeniculums, and the pars mammillaris hypothalami. (Other classifications include also the pars optica, with tuber, chiasm, and hypophysis. It is also defined as so much of the fore-brain as does not enter into the formation of the cerebral hemispheres.) Caudal it is continuous with the mid-brain, cephalad with the cerebral hemispheres. Its primitive cavity becomes metamorphosed in the adult into the third ventricle or diaelese as the lateral walls hypertrophy to form the thalami. Its ventral surface is the relatively
insignificant gray lamina in the intercrural space. Its dorsal surface is concealed from view by the massive hemispheres and their great commissure, the callosum, and by the fornix. Its actual roof, separating it from the overlapping cerebral parts, is a delicate membranous fold, the diatela or velum interpositum.

The Thalami.†—The thalami constitute the bulk of this portion of the brain. They are large ovoid masses of gray substance so named by the ancients after their resemblance to a pair of couches. Each thalamus is smaller frontad than caudad and the caudal ends are more widely separated from each other. The mesal or ventricular surface is largely free, except for an area, of variable size, by which the two thalami are fused in 90 per cent. of brains. This thalamic fusion is also called the medicomissure. This surface is covered by endyma and of smooth contour. Its dorsal limit is marked by an endymal ridge, usually torn through in dissection, the ripa² or tænia thalami, fortified by a subjacent narrow band of fibres called the stria medullaris, which may be traced to the habenal nucleus and habenal commissure (or “stalk” of the epiphysis). Caudad lies a depressed triangular area—the trigonum habenae, situated cephalad of the preglomerinum.

The dorsal surface is usually described as being free, but only a narrow ectal portion can be so described, the endyma of the lateral ventricle being slightly reflected upon it (the lamina affixa) before entering into the formation of the paraplexus. The rest of the dorsal surface is not lined by endyma, but is in contact with the pial fold called the velum interpositum. This surface is of a whitish color owing to a thin layer of white fibres, the stratum zonale. A faint oblique groove crosses this surface in a caudo-lateral direction, corresponding to the ectal

† Thalamos, bed or couch; bed-chamber.
² The name ripa was proposed by Wilder for the line formed by the rupture of the endyma along the lines of its reflection from entocelian (ventricular) surfaces.
edge of the fornix. Laterad it is demarcated from the caudatum by a groove which is occupied by a slender band of fibres and the striatal vein, called the *tania semicircularis* or *stria terminalis*. The surface is not of even contour throughout, usually showing three eminences (in addition to the pulvinar) corresponding to the main nuclear aggregations within the thalamus, viz.:

- Tuberculum anterius.
- Tuberculum medialis.
- Tuberculum lateralis.

---

**The Tuberculum Anterius.**—The tuberculum anterius forms a marked bulging frontal extremity, which helps to form the boundary of the *porta* (*foramen of Monro*) or aperture of communication between lateral and third ventricles.

The caudal extremity of the thalamus is a prominent, bolster-like projection which overhangs the brachia of the quadrigemina and is called the *pulvinar*. A smaller oval prominence, situated ventro-laterad of the pulvinar, is termed the *pregeniculum* (*corpus geniculatum externum*)—a partial end-station for the optic tract.
The lateral surface of the thalamus is in contact with the internal capsule—that
great concentration of fibre-tracts coursing to and from cerebral centres and
forming the crusca below. To this white stratum the thalamus itself contributes
fibres destined to reach the cortex, and in turn it receives fibres from the cortex.
These thalamo-cortical and cortico-thalamic sets of fibres constitute the thalamic
radiation, forming a more or less distinct reticulated capsular zone (external
medullary lamina; stratum reticulatum) for the thalamus.

The ventral surface is in contact with the sub-thalamic tegmental substance
and continuous with the central gray of the third ventricle lining its sides and floor.

Internal Structure of the Thalamus and its Connections.—The thalamus is composed
of gray substance, with large multipolar cells, which is sub-divided into a
number of distinct nuclei; twenty such have been described; three are universally
recognized. They are separated from each other by a white layer (lamina medul-
laris interna) which runs parallel to the wall of the third ventricle for its greater
length; caudally it runs mesad, overlapped by the eetal nucleus, and numerous
sub-laminae run into it. Frontad the internal medullary lamina sub-divides into
two branches, thus permitting the intrusion of the nucleus anterius between the
two main nuclei (medial and lateral).

The nucleus anterior lies fronto-dorsad; in it terminate the axones of the fasciculus
thalamomammillaris (fasciculus albicantothalami—bundle of Vicq d’Azyr). The nucleus medialis is lined mesad by the central gray of the third ventricle and is
usually fused with its fellow of the opposite side (medicomissure). A special
spheroidal cell-cluster in this nucleus is called the centrum medianum (Luys).
The nucleus lateralis is the largest of the three, extending the entire length of
the thalamus and including the pulvinar. A special semilunar cluster of cells in the
ventral portion of this nucleus is called the nucleus semilunaris (Flechsig).

The Connections of the Thalamus.—The thalamus is a ganglion interposed
between the sensor tracts in the tegmentum and the cerebral cortex, as well as
an important link in the optic path. It also gives rise to motor tracts con-
cerned with instinctive movements of an emotional nature. It is a relay station
for the various tracts which convey sensations of touch, temperature, and pain
from the body, extremities, head, and neck, of muscle-sense, and of the special
senses. It transmits these impulses to, and, reciprocally, receives impulses from
the cerebral cortex. As an “emotional” centre it is also under the inhibitory
influence of the cerebral cortex, which, if the emotion be not too strong, prevents
its external manifestation.

The thalamo-cortical and cortico-thalamic fibres, with the internal capsule, enter
into the corona radiata or fan-like formation of the white substance of the cerebral
hemisphere. Although there is no anatomic sub-division into distinct groups of
these fibres as they stream to and from the thalamus, it is customary to distinguish
a frontal, a parietal, an occipital, and a ventral stalk. The frontal and parietal
stalks, as their names indicate, pass between thalamus and fronto-parietal cortex,
as well as to the lenticular and caudatum. The occipital stalk is composed of
fibres passing in both directions between the pulvinar and occipital cortex, con-
stituting the so-called optic radiation. The ventral stalk comprises the ansa
lenticularis (thalamolenticular) and the ansa peduncularis (thalamotemporal and
thalamoinsular). They will be described in detail farther on.

The Fregeniculum is an intercalar ganglion proper to the optic nerve, derived
from the thalamus. On section it is seen to be characterized by the regular
alternation of deeply gray and white lamine. The latter are thicker and com-
poosed of fibres which enter the pregeniculum from the optic tract and optic radia-
tion. The nerve-cells in the gray substance are large, multipolar, and pigmented.

[Note.—The pregeniculum and the more isolated postgeniculum are gener-
ally included under the head of metathalamus.]
The *Hypothalamic Tegmental Substance*, continuous with the mid-brain tegmentum, is interpolated between the ventral face of the thalamus, the red nucleus, and a continuation of the substantia nigra known as the *corpus hypothalamicus* or *body of Luys*. Through the hypothalamic tegmentum stream the fibres of the *medial lemniscus*, of the *cerebellar prepdenduncle*, and from the red nucleus, to end in relation with thalamic cells. The corpus hypothalamicus is a grayish-brown, lentiform mass which lies in the ideal continuation frontad of the lateral part of the substantia nigra, and, like it, situated between pes and tegmentum. It is made up of fine myelinated fibres crowded in great profusion and confusion, with numerous delicate, coiled capillaries and sparse, multipolar, more or less pigmented, nerve elements of moderate size. The outline of the body is defined by a white capsule, some of the fibres of which are seen to decussate in the floor of the third ventricle, with those of the opposite side dorso-caudal of the albeantia.

The *Epiphysis* (*corpus pineale*) (Figs. 592, 593).—The epiphysis (*pineal body*, from its shape resembling a fir-cone—*pinus*) is a small, reddish-gray body placed between the caudal ends of the thalami and occupying the depression between the two pregressina. It is covered by the velum interpositum, which intervenes between it and the splenium of the callosum. It is an outgrowth which is not regarded as an important neural ingredient of the human brain and is generally believed to be a rudimentary relic, representing a cyclopean eye\(^1\) of some extinct ancestral vertebrate, homologous with the parietal organ, resembling a mollusean eye of a living species of lizard (the *Hatteria* of Australia). Its attached base is a hollow peduncle divisible into a dorsal and ventral part by the intrusion of the *epiphealseal recess* (*recessus pinealis*) of the third ventricle. The *dorsal stalk* continues on either side and upon each thalamus as the stria medullaris; it is reinforced by commissural fibres joining the habenae of the two sides; hence another name for the dorsal stalk is the *habenal commissure* (*supracommissure* of Osborn). The *ventral stalk* is folded over another commissural band—the *postcommissure*.

Structure.—The epiphysis, or pineal gland, consists of a number of follicles, lined by epithelium, and connected together by ingrowths of connective tissue. The follicles contain a transparent, viscid fluid, and a quantity of sabulous matter named *brain sand* (*acerbus cerebrii*), composed of phosphate and carbonate of lime, phosphate of magnesia and ammonia, with a little animal matter. These concretions are almost constant in their existence, and are present at all periods of life.

In the interval between the epiphysis and the caudal end of the thalamus lies a small triangular depression (sometimes an elevation) known as the *trigonum habenae*, marking the position of the *nidus* or *ganglion habenae*, a group of small angular cells. The axones from these cells are collected ventrad into the *fasciculus retroflexus* (Meynert), which courses through the tegmentum mesad of the red nucleus to end in the *interpeduncular ganglion* (Gudden) in the postperforatum. In addition to this fasciculus, the habenae is the reunion point for two other sets of fibres: (1) the *stria medullaris* and (2) the *habena proper* or *habenal commissure*. The stria medullaris (p. 912) is made up of axones arising from two sources: (1) cells in the hippocampus (*via fornix*) and (2) cells in the ganglion opticum basale. These join near the fornix column (anterior pillar of fornix) and run caudad on the mesal thalamic surface, to end in the habenal ganglion of the same side and, by crossing in the dorsal stalk of the epiphysis form the habenal commissure, ending in the corresponding nidus habenae of the opposite side.

Postcommissure.—The postcommissure is a round band of white fibres crossing from side to side in the ventral stalk of the epiphysis bridging the aqueduct at

\(^1\) Although most vertebrates show a single epiphysis or parietal organ, it is double in the lamprey and certain reptiles; the two epiphyses lie one in front of the other—not side by side (although probably paired organs originally). The frontal organ sends its fibres into the habenal nucleus; the caudal organ to the region of the postcommissure (tectum opticum).
its continuation into the third ventricle. The postcommis sure shares relation with both fore- and mid-brain structures and is formed of decussating fibres which may be enumerated in the following systems: (a) fibres arising in the special nucleus (described on p. 908) for the medial longitudinal bundle; (b) fibres connecting the two thalami; (c) fibres connecting the habenal nidi; (d) fibres connecting the pregmina.

[Note.—The habenae, epiphysis, and postcommis sure are generally included under the head of epithalamus.]

The Postperforatum (locus perforatus posticus).—The postperforatum has been described on p. 861. It marks the situation of the “interpeduncular ganglion,” small in man, but very large in rodent brains. From the cells in this primitive gray lamina arise the fibre-tracts already described as the tænia pontis (p. 906), and often visible at the point of emergence from the gray substance of the intercrural space.

The Albicantia (Fig. 592).—The albicantia or mammillaria are two symmetrical, small, round, white protuberances situated side by side in the intercrural space cephalad of the postperforatum, at a point where the floor of the third ventricle rapidly decreases in thickness to form the tuber. The color of each albian is white, owing to a superficial stratum of fibres derived from the fornix. Within lie three nuclear masses; two medial, constituting the main mass, and a smaller lateral nucleus applied against the former, so as to represent a crescent on cross-section.

The fibres of the fornix terminate in the albi cans. From its cells arise two fasciculi which have a common neurone origin. Cajal discovered, and Kölliker confirmed the fact, that the axones from the medial nucleus cells bifurcate; one set of limbs passes fronto-dorsad to form the fasciculus thalamomamillaris (bundle of Vteq d’Azyr), which ends in the nucleus anterius of the thalamus, while the other set of limbs of the primary axones passes caudal to form the fasciculus pedunculomamillaris in the mid-brain tegmentum; its destination is doubtful. The axones from the lateral nucleus join the latter bundle.

[Note.—The postperforatum and the albicantia are generally included under the head of the Pars Mammillaris Hypothalami.]

Third Ventricle (ventriculus tertius) (Fig. 592).—The third ventricle is the adult representative of the cavity of the primary fore-brain vesicle, but only so much of it as is not carried laterad, on either side, in the rapidly growing, eventually huge cerebral hemisphere buds to form the lateral ventricles. It is a narrow, cleft-like interval between the two thalami and hypothalamic gray, limited frontad by the terma, continuous caudad with the aqueduct and laterad, through the porta, with the lateral ventricles. Its roof is destitute of nerve tissue and is formed by a delicate, fused endymal and pial layer, invaginated on either side of the median plane by paraplexuses. The pial layer is one of the constituents of the fold known as the velum. The floor of the ventricle is formed by structures already described on the basal aspect in the intercrural space, viz., the tuber, albicantia, and postperforatum, as well as the chiasm and a portion of the tegmentum of the crura. Much of the floor, it may be noted, is formed by the primitive, undifferentiated central gray; and although the optic vesicle developed from its ventro-cephalic portion, the caudal shifting of central optic connections to thalamus and mid-brain has made this portion of the neural tube wall comparatively insignificant. The lateral walls are formed, in part by the thalami, in part by the hypothalamic gray ventral extension. The fornix may be seen, shining through a thin lamina of gray substance and the endyma, coursing caudo-ventrad to the albicans. A slight furrow, the aulix or sulcus of Monro, may sometimes be traced from the aqueduct to the porta, curving ventrad of a bridge-like fusion of the two thalami—the medicommission. (The latter term is inappropriate, as no
commissural fibres appear to pass from one thalamus to the other in this "thalamic fusion;" it is absent in about 10 per cent. of brains examined.)

The cephalic wall is formed by the terma, the rudimentary median-cephalic wall of the neural tube. The terma is attached to the dorsum of the chiasm; dorsally it is reënforced by the precommissure.

As seen in mesial section or as shown by a cast of the ventricle (Fig. 592) it is seen to be of irregular outline. Frontal is the optic recess, dorsad of the chiasm; caudad thereof is the infundibular recess in the tuber. The epiphyseal recess is seen between the habenal commissure and the postcommissure. Dorsad of the epiphysis is a diverticular recess of variable extent (recessus suprapinealis).

If the segmentation of the fore-brain into two divisions be adopted ultimately, it will be necessary to allot one portion of the third ventricle (between the thalami) to the diencephalon (hence diac(e)le), and the rest to the telencephalon (the medial cavity of which is termed the aula by Wilder).

In anticipation of the description of the cerebral hemispheres we may consider here the remaining structures in the floor of the third ventricle, usually included under the head of the pars optica hypothalami of the telencephalon, in order to lead up to a description of the cerebral connections of the optic tract.

External Morphology of the Optic Portion of the Hypothalamus.—This includes the tuber and hypophysis, the terma, the chiasm, and the optic tracts.

The Tuber (tuber cinereum) (Fig. 592).—The tuber is a thin-walled conical projection in the interceral space cephalad of the albicantia. Its apical portion is attenuated to form the stalk of the hypophysis; this is generally termed the infundibulum, while the cavity of the funnel-shaped diverticulum is called the infundibular recess of the third ventricle. The gray lamina composing the tuber is continuous with the central ventricular gray, and therefore with the terma.

The Hypophysis.—The hypophysis is a structure of two-fold origin, giving rise to a division into a prehypophysis and a posthypophysis. The posthypophysis alone is of neural origin, developing as a ventral diverticulum from the primitive neural tube. The prehypophysis develops from the stomodeum, or primitive buccal cavity, as a tubular diverticulum (Rathke's), which eventually loses its connection with the oral tissues to become included within the cranial cavity and intimately attached to the neural bud. Both pre- and posthypophysis are therefore of ectodermal origin and have developed from a conjunction of surface tissues which have migrated from opposed (ventral and dorsal) parts through the head! The prehypophysis is much the larger and somewhat embraces the posthypophysis; the two are inseparable, however, and together occupy the fossa hypophyseos of the sphenoid.

The two parts of the hypophysis are as distinct in structure as they are in embryonic origin. The posthypophysis consists of a mass of neuroglia, connective tissue, and bloodvessels; the structure of the prehypophysis is distinctly glandular, resembling that of the parathyroid bodies. It is surmised that the latter is the functional part of the hypophysis—concerned with the internal secretions, and usually involved in the pathological form of giantism called acromegaly.

The Terma (lamina terminalis s. cinerea) (Fig. 592).—The terma is a thin, easily torn lamina between the chiasm and the precommissure, limited laterally by the closely approximated hemicerebra, and constituting the primitive, undifferentiated cephalic boundary of the original neural tube.

The Optic Tract and its Central Connections.—In the section on the development of the brain it was learned that the optic nerve is not a peripheral nerve; it is rather a central brain tract extruded from the neural tube. Evidence is at hand that in ancestral vertebrates the general cutaneous sensor system was also capable

---

1 Occasionally the channel persists as the cranio-pharyngeal canal.
of light perception. With the recession of the neural tube from the surface and in company with the morphological differentiation of the head-end, a light-perceiving pair of organs arose as a special development. The distal end of the optic brain-vesicle becomes the retina, in structure like the brain-wall, whose cell-axones carry afferent impulses to the brain. Although the optic fibres enter the ventral wall of the brain, the retina is originally derived from the dorso-lateral (sensor) wall of the second neuromere (Fig. 558). The parietal organs, also light-perceiving, likewise developed as paired dorsal buds farther caudad, eventually to atrophy, as the more frontal optic organs better subserved the purposes of the organism.

The remarkable and as yet unexplained fact regarding the optic apparatus is that the afferent fibres from the retinal cells pass into the ventral wall to cross to the opposite side, forming a decussation which is total, or nearly so, in vertebrates below the mammals; the more laterally placed the eyes are the more nearly total is the decussation.1

Although the optic vesicle is a diverticulum of the fore-brain in its cephalic portion, the optic tract in its central connections becomes intimately related with the pregeniculum and pulvinar, with the pregeminum of the mid-brain, and with the occipital cortex of the cerebrum. Some of these central structures are way-stations in reflex-paths; the occipital cortex alone is the actual visual centre, though visual perceptions are here brought into association with tactile, auditory, and other impulses.

1 Possibly the reflex contraction of the muscles on one side of the body in the ancestral vertebrate followed the perception of a menacing object by the eye of the opposite side; hence the advantage of a decussation.
Chiasm.—From the retina of each eye the so-called optic nerves converge to partially decussate at the base of the brain to form the chiasm, a white quadrangular plate which presses in the primitive central gray floor of the third ventricle, as previously described. Approximately one-third of the fibres of each optic nerve do not cross to the opposite side. The chiasm is further reinforced by the infracommissure (of Gudden) and other lesser fibre-tracts (commissura superior [Meynert] and commissura ansata [Kölliker]). The fibres in the chiasm are so complexly interwoven that only through exhaustive experimental, developmental, and pathologic studies has it been possible to understand its structure. Broadly stated, the fibres from the medial (or nasal) halves of the retina decussate in toto, while those from the lateral (or temporal) halves do not cross. Leaving the chiasm, the crossed medial and uncrossed lateral fibres form the slightly flattened optic tracts coursing caudo-lateral, embracing the crura cerebri and dividing in the neighborhood of the pregeniculum into two "roots," a mesal and a lateral root. The mesal root is in reality not a part of the true optic path; it is a separate fascicular representation of the infracommissure of Gudden, composed of fibres forming a reciprocal bond of union (commissural) between the postgeniculums of the two sides and coursing through the chiasm (Fig. 594). The lateral root of the optic tract is the true visual path, composed of (a) the uncrossed fibres from the lateral half of the retina of the same side and (b) the crossed fibres from the mesal half of the retina of the opposite side. The fibres of the lateral root are distributed to the primary or lower optic centres as follows: (1) Most fibres end in the pregeniculum; (2) a lesser number end in the pulvinar; (3) the remainder end in the nucleus of the pregeniculum.

The pregeniculum and pulvinar are ganglionic way-stations or internodes in which visual impulses are reflected, in large part, to the visual cortex in the occipital lobe; the pregenium, on the other hand, plays no part in the conduction of impulses perceived as light or color; it presides rather over the eye-muscle reflexes to visual stimuli, and in its turn is under the dominion of the higher cortical centre. Reflex impulses are sent to oblongatal and spinal centres along axones entering into the formation of the medial longitudinal bundle. The axones of corticifugal neurones proceed to the nucleus of the pregeneculum along the optic radiation.

The connections of the pregeniculum and pulvinar with the higher cortical centre of vision are established by neurones, the cells of which lie in the two ganglia just mentioned, and whose axones stream in an arched, more or less compact bundle in the white matter of the hemiserebra toward the occipital cortex. Another system of neurones, whose cells lie in the cortex, sends its axones in the reverse direction (corticifugal) to the two lower centres. The cerebral tract thus formed between primary and secondary (cortical) centres is called the optic radiation, to be studied more fully in the sequel. The components of the optic path are delineated schematically in Fig. 594.

The Cerebral Hemispheres.

External Morphology.—Of all the component parts of the brain, the cerebral hemispheres form the largest part, and their preponderance and remarkable specialization underlie the extraordinary manifestations of the intellect so highly amplified in man.

The term cerebrum, often employed loosely as embracing several brain-parts,
is here intended to include the brain-mantle and the olfactory lobe—equivalent to the telencephalon of His, with the exception of the pars optica hypothalami. As already indicated in the section on brain-development, there has occurred, in the evolutionary history of man's vertebrate ancestry, a progressive increase of the secondary fore-brain, with concomitant reduction of the rhinencephalon, or smell-brain—the most archaic portion because of the important relations of the smell-sense to the life history of the earliest vertebrates.\(^1\)

In a mesal view of a hemisected brain (Fig. 595) may be seen the various parts of the brain-stem and the cerebellum overlapped by the preponderantly greater cerebrum. Among the many notable features exposed to view in this brain-section are certain fibre-masses, commissures, extending across the meson, and therefore divided by the knife in this preparation. Of the commissures pertaining to the cerebrum one is conspicuous for its size and firm consistency. This great fore-brain commissure is the callosum already mentioned as being demonstrable in the depths of the intercerebral cleft on divaricating the lips of this fissure. The callosum constitutes a massive system of association fibres for the bilateral coordination of corresponding cortical parts. It is thickened caudally, forming the splenium of the callosum; frontad it bends on itself ventro-caudad to form the genu ("knee"), including an interval, between the two limbs, which is flanked on both sides by a thin lamina (hemiseptum) and bounded ventrad by the fornix, constituting a closed cavity, the pseudocele (or "fifth ventricle"). The recurved ventral part of the genu tapers into a thinner, beak-shaped part, the rostrum. The rostrum is joined to the terma, frontad of the precommissure, by a thin lamina, the copula (lamina rostralis; lamina baseos alba).

\(^1\) For a more thorough discussion on the natural subdivision of the fore-brain, based upon comparative morphology, see the paper by G. Elliott Smith, *Journal of Anatomy and Physiology*, 1901.
An arched structure composed of longitudinal fibre-bundles comes to view ventrad of the junction of the splenium with the body of the callosum, proceeds fronto-ventrad with its convexity frontad, to sink from view in the substance of the hypothalamic gray at a point just caudal of the precommissure. This white arched bundle is the fornix. Between it and the callosum, rostrum, and copula stretches a thin, translucent lamina of nerve-tissue—the hemiseptum. The hemisepta of the two sides together have usually been termed the septum pellucidum, while the enclosed narrow cavity is called the pseudocele or fifth ventricle. The subjacent parts revealed in this section have already been described; the morphology and internal relations of the callosum, fornix, and hemiseptum will be described at a later stage.

The cerebral hemispheres together, as viewed from above or dorsally, appear as two symmetrical masses in close apposition, conforming in outline to that of the cranial cavity, which they so nearly fill. The frontal extremities or poles are massive and rounded, preponderatingly so in comparison with the brains of any related primate species. The occipital poles are each more pointed, but expand frontad into the widest part of the cerebrum—the parietal lobes. The cerebral hemispheres or, briefly, the hemicerebra are partially separated from each other by the intercerebral cleft or fissure (fissura longitudinalis cerebri), into which fits
a fold of the dura—the **falk**. By means of a large commissural band of white fibres—the **callosum**—the cerebral halves are joined together in the depths of the intercerebral cleft. All adjacent parts of the brain are overlapped by the ponderous cerebrum so as to entirely conceal the thalamic portion and the mid-brain, while the occipital lobes overlap the cerebellum with the intervening tentorium—another fold of the dura. Further description will be restricted to each hemicerebrum.

**Configuration of Each Hemicerebrum.**—Each hemicerebrum presents an *outer convex surface* (*facies convessa cerebri*), applied to the corresponding half of the cranial vault; a *mesal flattened surface* (*facies medialis cerebri*), which lies in a sagittal plane, applied to the corresponding surface of the opposite hemicerebrum, with the intercerebral cleft intervening, and for the most part in contact with the falk; and a *basal or ventral surface*, of irregular form, resting frontad upon the floors of the anterior and middle cranial fossae, and caudad upon the tentorium.

Prominent in the lateral and ventral views is the blunt projection of the temporal pole, while at the ventro-lateral border, nearer the occipital pole, is a slightly marked indentation usually called the **pre-occipital notch**. The deep vallecular depression between the orbital surface and the temporal pole accommodates the great wing of the sphenoid.

More or less distinct borders demarcate the surfaces. The arched **dorsi-mesal border** intervenes between the mesal and the convex surfaces; a straight **mesorbital border** intervenes between the orbital and mesal surfaces of the frontal lobe; a **ventro-lateral border** separates the tentorial surface from the lateral, convex surface of the occipital and temporal lobes; while an obtuse border—the **mesoventral or internal occipital border** separates the tentorial from the mesal surfaces.

**Cerebral Fissures and Gyres.**—The surface of each hemicerebrum presents alternating depressions or **fissures** which demarcate gyral elevations—the **convolutions** or **gyres**.¹ The fissures vary in depth from that of a mere shallow groove to as much as 30 mm., and may attain a length of 15 cm. They are more or less

¹ Consistent with the use of the English *lobe* and *lobes* (for *lobus* and *lobi*), the English *gyrus* and *gyres* are preferable to *gyrus* and *gyri*. The term *fissure* is here uniformly employed for all anfractuosities of the surface, though *sulcus* (pl. *sulci*) is quite as generally used; sometimes both terms are indiscriminately mixed.
THE CEREBRAL HEMISPHERES

sinuous and ramified. They mark the surface with fairly approximate uniformity, that is, one rarely finds an un fissured surface more than 15 to 20 mm. in width. Numerous functional and mechanical influences must be credited with bringing about the complex foldings of the cerebral surface, principally (a) resistance of the cranium to the expanding brain or "mechanical packing;" (b) differences of growth-rate in different parts of the cortical surface; (c) differences of growth-rate of different fibre-bundles retarding cortical expansion along the fissure-lines and elongating to help in the formation of the gyres. The obvious result, whatever the influences may be, is an expansion of the cerebral cortex to an enormous degree, so that, instead of having a surface-area of only 60,000 sq. mm. (if unconvoluted), the average adult cerebrum has a cortical area of 200,000 sq. mm. or more. Furthermore, the vascular pia, closely investing the surface and dipping into every fissure, is expanded in a like manner, affording an ample and uniform supply of blood for the entire cerebral cortex.

The cerebral vesicle of the foetal brain presents a smooth surface during the first half of intrauterine life, except for the depressed sylvian fossa at the site of the future insula—destined to become buried in the depths of the sylvian elefant formed by the apposition of the more energetically growing contiguous parts of the cerebral mantle. Some of the cerebral fissures develop early as infoldings of the comparatively thin wall of the vesicle, and hence produce corresponding projections into the cerebral cavity; these are termed the total or complete fissures. The remaining fissures are only linear depressions of the surface not involving the entire thickness of the wall—the partial or incomplete fissures. The complete fissures and their correlative projections into the cerebral cavity (lateral ventricle) are:

Among the remaining cerebral fissures, of which over fifty have been recognized and named, some are constant in representation in all normal brains, while others are of variable occurrence in different individual specimens. The constant fissures are those which regularly exist as interlobar and intergyral boundary lines forming a common pattern for all normal brains, but these, like all cerebral fissures, are subject to many individual variations as to course, depth, length, mode of branching, and Anastomosis with neighboring fissures or manner of interruption by gyral isthmuses. The range of individual variations is so great that no two brains can be said to be exactly alike; in fact, one may find numberless stages of complexity in the cerebral surface configuration from the simply fissured brains of mentally inferior individuals and races to the complexly fissured and more highly organized brains of vigorous thinkers and talented geniuses among the highly intellectual races of man.

Cerebral Lobes and Fissures.—The cerebral surface is divided into five principal areas called lobes, demarcated by certain constant fissures which are more or less conspicuous, and were therefore selected by the older anatomists as arbitrary boundary lines; these are termed the interlobar fissures.

The lobes are: (1) the frontal; (2) the parietal; (3) the temporal; (4) the occipital; (5) the insula. The inter-lobar fissures are: (1) the sylvian; (2) the central; (3) the occipital; (4) the calcarine; (5) the circuminsular. A series of fissures demarcating

---

1 The so-called transitory fissures of older descriptions may be neglected, since the researches of Retzius, Hochstetter, and Mall have shown these to be in reality artifacts due to postmortem swelling.
the rhinencephalon from the pallium or cerebral mantle proper will be considered at a later stage.

The Interlobar Fissures. The Sylvian Fissure and its Rami (fissura cerebri lateralis [Sylvii]).—This fissure is a well-marked cleft on the base and side of the hemicerebrum. Traced laterad from the region of the preperforatum, it begins as a deep depression between the orbital surface of the frontal lobe and the temporal pole, corresponding to the bony ridge formed by the lesser wing of the sphenoid and extending to the convex surface. This portion of the fissure is termed the basisylvian fissure or vallecula sylvii, as far as the sylvian point. The sylvian point marks the conjunction of the main portion of the sylvian fissure with its basisylvian part as well as one or two rami. These rami are: (1) the presylvian ramus; (2) the subsylvian ramus.

Fig. 598.—Cerebral fissures and gyres viewed dorsally.

The Presylvian Ramus usually proceeds dorsad, slightly inclined frontad, for a distance of 2 to 3 cm. into the subfrontal gyre.

The Subsylvian Ramus (anterior horizontal limb) extends frontad for a distance of 1.5 to 2. cm., parallel to the orbito-frontal (superciliary) margin.

These two rami often spring as shorter branches from a common stem and both may be replaced by a single unbranched limb.

The sylvian fissure proper is the most conspicuous part. It extends from the sylvian point in a caudal direction, inclined slightly dorsad, on the lateral surface of the cerebrum for a distance averaging 6 cm. It separates the temporal lobe
wholly from the frontal and partly from the parietal lobe. It usually ends in an upturned manner, in the parietal lobe, the change of direction being often more abrupt than gradual; this terminal piece receives the name of epiylvian ramus. Occasionally a short ramus is sent ventrad into the supertemporal gyre and is called the hypo.sylvian ramus.

The sylvian fissure ranges in depth from 15 mm. or less at the presylvian point to 25 or 30 mm. at the postsylvian point, correlative with the contour of the insula, which lies in its depths. If the lips of the sylvian fissure be divaricated the insula is revealed as a cortical district, of tetrahedral form, which is normally completely concealed by overlapping portions of the hemicerebrum called the opercula. These are four in number: (1) the operculum proper, (2) the preoperculum, (3) the suboperculum, and (4) the postoperculum.

The operculum (frontoparietal operculum) is composed of the adjacent portions of the ventral border of the frontal and parietal lobes, the sylvian fissure intervening between it and the postoperculum, which is the overlapping part of the temporal lobe. The pre-operculum is a small triangular portion embraced by the presylvian and subsylvian rami, and is also called the pars triangularis or Broca's cap. The suboperculum (orbital operculum) is small, demarcated by the subsylvian ramus, and for the most part on the orbital face of the frontal lobe, projecting slightly over the frontal part of the insula, with its margin separated from the temporal pole by the basylvian cleft.

The overlapping opercula are demarcated from the insula by the circumsylvian fissure (sulcus circularis Reilii).

Development of the Insula and the Sylvian Cleft.—The insular cortical district is topographically correlative with the great gray ganglia of the cerebral hemisphere, particularly the lenticular, from whose ectal surface the insular cortex is but little removed. As will be learned at a later stage, few if any projection fibres pass to and from the insula; its function is almost wholly associative for adjacent parts of the cerebral mantle. The insula therefore becomes buried beneath the more energetically growing and bulging parts immediately around it. There is at first a slight fossa (observable in the tenth to twelfth week) which, as development proceeds, and as the overhanging operculum encroach upon the insula, becomes more deeply situated as a cleft-like depression until at birth the fossa has become a fissure, with the insula perhaps slightly exposed near its cephalic extremity, where the incomplete apposition of the opercula leaves a triangular space. This

---

Fig. 599.—Central fissure fully opened up, so as to exhibit the interlocking gyres.
space is usually obliterated in childhood, but is commonly met with in certain races (negro, Australian) and in brains showing developmental defects or arrest. The mechanics of the formation of the surface outline of the sylvian fissure by the apposition of the growing and plastic opercula may be understood by a reference to Fig. 604.  

The Central Fissure (fissura of Rolando [sulcus centralis]).—The central fissure is situated at about the middle of the convex surface, and, coursing obliquely latero-frontad, divides this surface into approximately equal parts, intervening between the frontal and parietal lobes. It may be traced from a point at or near the dorsi-mesal border, about 1 cm. caudad of the mid-point of the occipito-frontal arc. It then runs sinuously latero-frontad to within a short distance of the sylvian fissure, about 2 cm. caudad of the sylvian point; its line of general direction makes an angle of about 70 degrees with the median line (Rolandic angle). If measured along its sinuosities, its length averages 10.5 cm. Its curved course may be analyzed into five alternate curves (sometimes more or less), of which three are convex frontad and two caudad. It is rarely very much branched and does not often anastomose with neighboring fissures. Its dorsal end bears a constant relation to the caudal limb of the para-central, frontad of which it can be found as a hook-like curve. If the lips of the central fissure be divaricated, interdigitating sub-gyres are commonly seen in its depths. These interlocking gyres are often fused to a greater or lesser degree, and a total interruption of the fissure has, in rare instances, been observed. The central fissure develops at about the end of the fifth month of intrauterine life, not as a single integer, but as the result of the union of two segments: a short dorsal and a longer ventral segment. As development proceeds these segments eventually unite end to end, and at the site of this union a vadum (or shallow uprising of the floor of the fissure) or even a complete isthmus may be demonstrated in the adult brain. Only three cases of bilateral interruption are on record.  

The Occipital Fissure (fissura occipitalis).—The occipital fissure is a deep cleft across the dorsi-mesal border trans-secting the occipito-frontal arc at about 5 cm. from the occipital pole, and extending upon both the mesal and the convex surfaces. On the meson it attains a length of 3 to 3.5 cm. (to its junction with the calcarine fissure) while its lateral extent is shorter (2 to 2.5 cm.). It is quite deep throughout and usually shows a number of interdigitating sub-gyres.  

The Calcarine Fissure (fissura calcarina).—The calcarine fissure is a slightly arched fissure which is usually joined with the occipital fissure at the apex of the cuneus and extends caudal to the occipital pole, ending in a bifurcation. The fissure is composed of two integers which may be partially or completely separated (by a vadum or an isthmus); the caudal segment may then be distinguished as the post-calcarine fissure.  

The occipital and calcarine fissures join to form a Y-shaped junction; the two limbs of the Y embrace the cuneus, while the stem is continued as the occipito-calcarine stem for a distance of about 3 cm. This fissural stem is allotted to the occipital fissure by some and to the calcarine fissure by other authors. As there is no greater frequency of confluence with one as against the other, so far as present statistics go, it is preferable to assign no special relationship for this stem to one or the other principal fissure.  

I. Frontal Lobe. Fissures of the Frontal Lobe. 1. Lateral Surface.—The lateral surface is bounded by the dorsi-mesal arched border, by the fronto-orbital (or superciliary) border, by the sylvian fissure (in part), and by the central fissure. The principal fissures making this surface demarcate four gyres: (1) the precentral, (2) superfrontal, (3) medifrontal, and (4) subfrontal gyres. The fissures are: (1) the precentral, (2) superfrontal, and (3) subfrontal fissures. In addition must be described certain fissures which are intragryral and of more or less constant occurrence.
The Precentral Fissural Complex (sulcus precentralis).—Two fissural integers which are sometimes joined extend more or less parallel with the central fissure. The mesally situated piece is usually of zygal (yoke-shaped) shape or triradiate, and usually anastomoses with the superfrontal fissure. From its position it is termed the supercentral or superior precentral fissure (sulcus precentralis superior). The laterally situated piece is of longer extent, sometimes straight or slightly sinuous, sometimes arched like an inverted L, or T-shaped. It usually anastomoses with the subfrontal fissure. The two precentral segments demarcate the precentral gyre from the remaining three gyres of the lateral surface of the frontal lobe.

The Superfrontal Fissure (sulcus frontalis superior) usually springs from the supercentral and pursues a sinuous course frontad, to become lost, as a rule, in the zigzag or transverse ramifications of the prefrontal region. It is usually quite ramified and often anastomoses with other fissures. It demarcates the superfrontal from the medifrontal gyre.

The Subfrontal Fissure (sulcus frontalis inferior) is most often confluent with the precentral, less often with the supercentral fissure. It proceeds frontad in an arched course, to end either in a bifurcation or by anastomosing with other fissures (radiate fissures, orbito-frontal fissures, or medifrontal fissures). The subfrontal fissure demarcates the medifrontal from the subfrontal gyre.

Both the superfrontal and medifrontal gyres are characterized by a more or less pronounced longitudinal subdivision by less constant fissural segments. They are: (1) the paramesal fissure (sulcus paramedialis) occupying an intermediate position between the superfrontal fissure and the dorsi-mesal border, in the superfrontal gyre, more often composed of a series of short segments which become lost in the more complex configuration of the prefrontal region; (2) the medifrontal fissure (sulcus frontalis medius) situated in the prefrontal part of the medifrontal gyre, rarely extending throughout, and usually ending cephalad in a widely spread bifurcation which constitutes the orbito-frontal fissure when independent. The medifrontal fissure is usually very much ramified and frequently anastomoses with neighboring fissures. The fissure is a characteristic of human and anthropoid brains only.

![Diagram of the cerebral hemispheres](image-url)
By the occurrence of either or both paramesal and medifrontal fissures, the ordinary three-tier type of frontal lobe is converted into a four-tier and five-tier type; the latter more often in the brains of the more highly intellectual—a feature which is concomitant with the comparatively late phyletic and embryonic development of the two secondary fissures described.

Other, less important, fissures are: (1) the inflected fissure (fissura inflecta), incising the dorsi-mesal border between the central fissure and the cephalic limb of the paracentral; (2) the radiate fissure, near the lateral orbito-frontal border; (3) the trans-precentral, a short oblique piece ventrad of the central and usually dipping into the sylvian cleft, and (4) the diagonal fissure between the presylvian ramus and the ventral end of the central, and often confluent with the precentral (Fig. 600)

2. MESAL SURFACE.—The mesal surface of the frontal surface lobe is bounded by the dorsi-mesal border, the mesorbital border, and the callosal fissure. An arcuate fissure or system of fissures intermediate between the dorsi-mesal margin and the callosal fissure divides this surface into the superfrontal gyre, mesal aspect, and the callosal gyre. The name "calloso-marginal" was usually applied to this fissure, but an examination of many brains reveals a certain integrality of fissural parts which are not always connected. One constant segment from its relations with the central fissure is called the paracentral fissure, composed of a main stem with a cephalic and a caudal limb, embracing the paracentral gyre. Frontad thereof extends the supercallosal fissure, often in two segments, running a concentric course between the arched dorsi-mesal border and the genu of the callosum. The supercallosal may be confluent with the paracentral. The supercallosal is, as a rule, quite ramified, its branches transcribing the superfrotal gyre. In the prefrontal region and ventrad of the genu of the callosum lie one or two fissures, more or less parallel to the mesorbital border, and called, respectively, the rostral and subrostral fissures (sulci rostrales) .

3. ORBITAL SURFACE.—The orbital surface of the frontal lobe is constantly marked by a straight fissure, the olfactory fissure (sulci olfactorius), which runs parallel to the mesorbital border and is occupied by the olfactory bulb and tract. It is about 5 cm. in length and demarcates the mesorbital gyre from the remaining orbital gyres. This orbital surface is marked by a fissural system (sulci orbitales)
that is usually of zygal type, H-shaped or K-shaped, quadriradiate, or, rarely, triradiate. When the transverse element is sufficiently pronounced it merits the name of transorbital fissure, demarcating the preorbital from the postorbital gyral field.

Gyres of the Frontal Lobe (lobus frontalis). 1. Lateral Surface.—The precentral gyre (gyrus centralis anterior), one of the chief motor areas of the cerebral cortex, is a moderately sinuous gyre extending from the dorsi-mesal border to the sylvian fissure and demarcated by the central and the precentral fissures (supercentral + precentral).

The superfrontal gyre is limited laterally by the superfrontal fissure, while it is continuous over the dorsi-mesal border with its mesal surface. It merges insensibly with the medifrontal gyre in the prefrontal region, while it may be partially subdivided by the paramesal fissure.

The medifrontal gyre (gyrus frontalis medius) is broader than the preceding, demarcated by the superfrontal and subfrontal fissures, and often marked by the medifrontal fissure in its prefrontal portion.

The subfrontal gyre (gyrus frontalis inferior) is limited by the subfrontal fissure and the basisylvian + sylvian proper. It is traversed by the presylvian and subsylvian rami, embracing the pre-operculum or pars triangularis. The gyre is of historic importance since Broca, in 1861, declared it to be the seat of speech control. (See Cerebral Localization.)

There being no fissure at this border, it is improper to give the mesal surface of this gyre a different name (i.e., "marginal gyrus" of the authors).

Fig. 602.—Fissures and gyres of the basal surface of the cerebrum.

The cerebral hemispheres.
2. Mesal Surface.—On the mesal surface of the frontal lobe and embracing the dorsal end of the central fissure lies an oval lobule or gyre called the paracentral gyre (lobulus paracentralis), limited by the paracentral fissure with its caudal and cephalic limbs. Frontal thereof extends the large arched mesal surface of the superfrontal gyre ( gyrus frontalis superior), limited by the supercallosal fissure. Between the latter fissure and the callosal fissure, concentrically situated with respect to the superfrontal, lies the callosal gyre (the “ gyrus formicatus” of the authors).

Frontal these two gyres arch around the genu of the callosum, to become merged through the disappearance of the intervening supercallosal fissure, and the rostral fissures alone mark this surface.

3. Orbital Surface.—The olfactory fissure and the mesorbital border bound the mesorbital gyre ( gyrus rectus). The remaining orbital surface is not regularly divisible on account of the great variability of the orbital fissures; when the transorbital fissure is pronounced, a pre- and postorbital gyre may be distinguished.

The postorbital limbus is a formation occasionally met with on the orbital surface. It consists of a curved, welt-shaped eminence demarcated by an incisure created by the lesser wing of the sphenoid, and due, apparently, to the intrusion of the postorbital portion into the middle fossa.

II. Parietal Lobe ( lopus parietalis). Fissures of the Parietal Lobe. 1. Lateral Surface.—The lateral surface is bounded by the dorsi-mesial border, by the central fissure, and by a part of the sylvian fissure; it is only partially demarcated from the occipital lobe by the occipital fissure, and merges gradually into the temporal lobe.

The principal fissures marking its surface consist of a group of integral segments showing various degrees of confluence in different individuals and formerly known in the aggregate as the intraparietal sulcus of Turner (sulcus intraparietalis). Two of the fissural segments present much the same parallelism to the central fissure which was noted for the precentral group, and hence these are termed the postcentral fissural complex.

The postcentral fissural complex ( sulcus postcentralis) comprises a longer mesal and a shorter lateral (and ventral) segment, which are confluent in about 75 per cent. of brains and then very much resemble in length, continuity, and course the central fissure. This appearance has given rise to reports of alleged duplication of the central; an analysis of the relations of the dorsal ends of the fissures in question with the caudal limb of the paracentral removes all doubt.

The postcentral fissure (proper) is the longer mesal (and dorsal) segment. Its dorsal end is frequently bifurcated and sometimes embraces the dorsal extension of the caudal limb of the paracentral. The subcentral fissure constitutes the shorter latero-ventral segment.

The parietal fissure is usually a slightly arched fissure inclining meso-caudal, sometimes independent but more often confluent, with one or both of the postcentral segments just described. It demarcates the parietal gyre from the subparietal district.

The paroccipital fissure, in whole or in part, probably represents a part of the simian exoccipital or “ Affenspalte,” isolated by the upgrowth of gyral protos which are totally submerged in the ape brain, but rose to the surface concomitantly with the rise in functional dignity of cortical areas so important in the human brain. The fissure is almost invariably of zygal shape, its stem directed sagittally, its ends bifurcated. Its confluence with the parietal fissure seems to be subject to some morphologic law; continuity is the rule on the left side (77 per cent.), and occurs less often on the right. The combination of continuity on the right and separation on the left is a rare one (6 per cent.).
Less constant fissures are the transparietal, in the parietal lobe and the inter-
medial (Fig. 600). In the subparietal district terminate the upturned ends of
the sylvian (i. e., episylvian ramus) of the supertemporal and the meditempo-
rall fissures.

2. Mesal Surface.—The mesal surface of the parietal lobe is equivalent to
the quadrangular precuneus, limited by the paracentral and occipital fissures,
while ventrad it is imperfectly separated from the callosal gyre by the precuneal
fissure (postlimbic sulcus), usually of zygal or triradiate form and occasionally
confuent with the paracentral.

Gyres of the Parietal Lobe. 1. Lateral Surface.—The postcentral gyre (gyrus
centralis posterior) is one of the chief somesthetic areas of the cortex. It is a long,
more or less sinuous convolution extending obliquely from the dorsi-mesal border
to the sylvian fissure and demarcated by the central and the postcentral + sub-
central fissures.

The parietal gyre (gyrus parietalis) lies between the dorsi-mesal border and the
parietal fissure, bounded cephalad by the postcentral, caudad partly by the
occipital fissure, the transition to occipital lobe being maintained by the arched
par occipital gyre.

The subparietal district or lobule (lobulus parietalis inferior) is divided into
three convolutions which arch around the upturned ends of the sylvian, super-
temporal, and meditemporal, and merge insensibly with the adjacent temporo-
occipital gyres. The marginal (supramarginal) gyre arches over the extremity
of the episylvian ramus and is connected frontad with the postcentral gyre, ventrad
with the supertemporal gyre. The angular gyre (gyrus angularis) arches over the
upturned extremity of the supertemporal fissure, and its limbs fuse with the super-
temporal and meditemporal gyres. The postparietal gyre is not always clearly
defined; it arches around the upturned end of the meditemporal or its representa-
tive segment; mesally it is bounded by the par occipital fissure. Variable inter-
medial fissures sometimes help to define the angular gyre from its two neighbors.

2. Mesal Surface.—The mesal surface of the parietal lobe has already
been described as equivalent to the precuneus, from its position in “front” of the
cuneus or quadrate lobe from its general shape. It is sometimes marked by a
mesal extension of the transparietal fissure or by intraprecuneal fissures.

III. Occipital Lobe (lobus occipitalis). Fissures of the Occipital Lobe. 1. Lat-
eral Surface.—The lateral surface of the occipital lobe is imperfectly demarcated
from the adjacent parietal and temporal lobes in most brains. The sharply defined
exoccipital fissure or “Affenspalte” of other primates has, in the ancestry of man,
been reduced to a series of fissural segments by the upgrowth of submerged cortical
parts. The par occipital fissure, we have already learned, probably represents
one of the gaps in the series; another may be the sulcus lunatus (Elliott Smith),
usually termed the lateral occipital by the authors; lastly, a fissure sometimes called
the inferior occipital (suboccipital), and usually embraced, on the occipital pole,
by the bifurcate limbs of the postcalcarine, may complete the series. Further
researches are necessary to elucidate the morphology of this region.

2. Mesal Surface.—The mesal surface is equivalent to the wedge-shaped
region embraced by the occipital and calcarine fissures, and called the cuneus.
A fairly constant cuneal fissure traverses its surface parallel to the calcarine.

If it is ever determined that the morphological boundary of the occipital lobe is
as outlined above, the lobe is practically excluded from the basal surface of the
hemicerebrum.

IV. Temporal Lobe (lobus temporalis). Fissures of the Temporal Lobe. 1. Lat-
eral Surface.—The lateral surface of the temporal lobe is bounded by the
basisylvian and sylvian fissures and by the ventro-lateral border; caudally it
merges into the adjacent parietal and occipital lobes.
The supertemporal fissure (sulcus temporalis superior) is a deep, long (10 to 12 cm.), and usually continuous fissure which begins near the temporal pole, proceeds ventrad of but parallel with the sylvian, to become upturned in the parietal lobe and embraced by the arched angular gyre.

The meditemporal fissure (sulcus temporalis medius) is rarely continuous; more often it is represented by a series of segments, two, three, or four in number, the caudal segment running more vertically into the parietal lobe to be embraced by the postparietal gyre. The meditemporal fissural segments run nearly parallel with the supertemporal and demarcate the meditemporal from the subtemporal gyre.

2. Tentorial or Ventral Surface.—Close to the ventro-lateral margin and more or less parallel with it runs the subtemporal fissure (sulcus temporalis inferior), extending from near the temporal to near the occipital pole. It is rarely continuous, being usually broken up into two or more segments. It demarcates the subtemporal from the subcollateral gyre.

The collateral fissure (fissura collateralis) is a well-marked long (8 to 12 cm.) and deep fissure extending from near the occipital to near the temporal pole. Caudally it demarcates the subcalcarine gyre from the subcollateral; frontad it intervenes between the latter gyre and the hippocampal gyre. Its middle part is correlative with the collateral eminence. On the ventro-mesal aspect of the temporal lobe and near its pole, cephalad of the uncus is a moderately marked fissure or groove called, because of its topographic relation to the amygdala—a gray, ganglionic mass—the amygdaline fissure (fissura ectorkinalis s. posthinalis) or incisura temporalis.

3. Dorsal or Opercular Surface.—The dorsal or opercular surface of the temporal lobe enters into the formation of the sylvian cleft. It is but slightly marked by a few oblique or transverse furrows (trans temporal fissures) demarcating slightly elevated transtemporal gyres.

Gyres of the Temporal Lobe.—The five principal fissures named subdivide the lobe into five gyres. On the lateral surface lie the supertemporal, meditemporal, and subtemporal gyres (gg. temporalis superior, medius et inferior); on the tentorial surface are the subcalcarine (gyrus lingualis), subcollateral (gyrus fusiformis; g. occipitotemporalis) and part of the subtemporal.

The hippocampal gyre (gyrus hippocampi), formerly included in the "limbic lobe," but morphologically belonging to the neopallium, occupies the dorsi-mesal part of the ventral surface of the temporal lobe. The longer or shorter extension of the occipito-calcarine stem partially (forming the isthmus gyri hippocampi) interrupts its continuity with the callosal gyre. It is demarcated by the collateral fissure (in part) and the hippocampal fissure, broadens out toward the temporal pole, and appears to become bent upon itself dorsally to form the uncinate gyre (uncus). As will be learned in the sequel, the hippocampal gyre is demarcated.
from the uncus proper by the intervention of the frenulum Giacomini—an extension of the narrow, gray, dentate gyre.

Near the temporal pole it is demarcated from the subcollateral gyre by the fissura rhinica, or postrhinal fissure; this fissure is not infrequently confluent with the collateral.

The surface of the hippocampal gyre, particularly in the zone along the hippocampal fissure, is of a more whitish color than is characteristic of other cerebral gyres; this is due to a white reticular stratum of fibres, the substantia reticularis alba (Arnold). The convex, broader part of the gyre is marked by numerous small, wart-like eminences, resembling the skin of an amphibian, and called by Retzius the verrucae gyri hippocampi. Just ventrad of the uncinate portion, or the terminus of the hippocampal fissure, lies a groove marking the impression of the free edge of the tentorium.

---

**The Insula (Central Lobe or Island of Reil)** (Figs. 603, 604, 605).—The insula lies deeply in the sylvian cleft and can only be seen when the lips of that cleft are widely separated, since it is overlapped by the opercula already described. With the opercula removed, the insula presents a tetrahedral shape with its apex or pole directed ventro-cephalad. Its borders are sharply outlined by the circum-insular fissure except in the depths of the basisylvian cleft, where the insular cortex is continuous with the gray substance of the preperforatum—the threshold or limen insulae (belonging to the rhinencephalon). An oblique transinsular or central insular fissure divides this district into a larger preinsula and a smaller postinsula. The postinsula is usually a single long gyre (gyrus longus insulae), while the preinsula is subdivided by shallow fissures into three, four, or five shorter preinsular gyres built upon a radiate plan, converging in the region of the insular pole. As already hinted, the insula represents an area of the brain-mantle whose growth did not

---

1 Called by Wilder, on account of its correlation with the amygdala, the amygdaline fissure. Schwalbe calls it (in part) the incisura temporais.
keep pace with that of the surrounding parts; hence its submergence by them. The close apposition of the insular region to the subjacent basal ganglia, and the failure of development of great masses of projection fibres so prominent elsewhere, were doubtless factors therein. The insular cortex is uninterruptedly continuous with the rest of the cortex, but it has become specialized into the purest association centre in the cerebrum, and we shall learn of its intimate relations to the faculty of speech at a later stage.

The Rhinencephalon or Olfactory Lobe (lobus olfactorius) (Figs. 606, 607, 609).—The grouping of the parts constituting the central olfactory structures under the term “rhinencephalon” as distinguished from the rest of the forebrain (pallium) was first clearly made by Turner and proved by His to be embryologically well founded and by Edinger to agree with phylogenetic development. More light has been thrown upon the subject recently by Retzius and Elliott Smith. The sense of smell, while highly useful in the quest for food in earlier and lower forms of vertebrates, is relatively little used in the mental life of man. The enormous preponderance of the cerebral mantle and the concomitant atrophy of the rhinencephalon in the human brain afford one of the most striking contrasts in brain morphology. This relatively feeble development in bulk of the olfactory apparatus in the human brain by no means renders its description simple. In fact, not until its development in lower macrosmatic animals was studied could anatomists form even an approximately clear conception of the seemingly disjointed remnants in the human brain of an olfactory apparatus so relatively huge in lower animals. The great expansion of the cerebral hemispheres and of the great commissure which connects them (the callosum) has been an important factor in widely displacing primitively connected parts. The developmental history must be sought for in the writings of Edinger, Retzius, and Elliott Smith.

The Rhinencephalon comprises:
1. Peripheral parts
2. Central or Cortical parts.

A comprehensive term for the peripheral part is lobus olfactorius, divisible into pre- and postolfactory parts.

Preolfactory lobe
1. Bulbus olfactorius.
2. Tractus olfactorius.
3. Tuberculum olfactorium and trigonum.
4. Area parolfactoria (Broca).
5. Stria (gyrus) olfactorius medialis.
6. Stria (gyrus) olfactorius intermedialis.
7. Stria (gyrus) olfactorius lateralis.
9. Gyrus subcallosus and Broca’s diagonal band.

Postolfactory lobe

The Preolfactory Division.—The olfactory bulb and tract form a long and slender band with a bulbous extremity situated on the basal aspect of the frontal lobe and constituting a rudimentary remnant of a relatively large diverticulum, developed from the sensor ectoderm close to the border of the neural plate before it becomes converted into the neural tube and situated on either side of the neuropore at the extreme frontal end. Although hollow at first, the cavity (rhinocoele) soon becomes obliterated.

The olfactory bulb (bulbus olfactorius) is an oval mass of reddish-gray color, which rests on the cribiform plate of the ethmoid and is received in the olfactory fissure on the orbital surface of the frontal lobe. It receives the numerous olfactory nerves (fila olfactoria) from the nasal mucous membrane. The olfactory
tract (tractus olfactorius) is a band of white substance, of prismatic outline on section, its apical ridge fitting into the olfactory fissure. Toward its root-region it is somewhat narrowed.

The medial and lateral olfactory gyres are also termed the medial and lateral roots of the tract, and diverge in the region of the trigonum. The olfactory tubercle (tuberculum olfactorium) is best seen if the bulb and tract be lifted away from the olfactory fissure; the tubercle appears as a small pyramidal elevation, its apex buried in the olfactory fissure, its irregularly triangular base forming the trigonum olfactorium, a small gray area frontad of the preperforatum. This area is marked by ridge-like elevations which appear like radiating roots of the tract, and named, according to their position, the medial, intermediate, and lateral roots, striae or gyres. The lateral olfactory stria or gyre is continuous with the limen insulae in the depths of the basisylvian cleft, and thence passes to the uncus to end in the gyrus ambiens and gyrus semilunaris. The sharp turn made at the limen insulae is called the angulus lateralis. The medial olfactory stria or gyre, a narrow gyral band, proceeds mesad and merges with the adjacent cerebral surface; its extension on the mesal surface is known as the parolfactory area (Broca) limited frontad by the anterior parolfactory sulcus (sulcus parolfactorius anterior) and separated from the subcallosal gyre by the posterior parolfactory sulcus (sulcus parolfactorius posterior).

The intermediate stria is not always very distinct; when present it may be traced from the proximal end of the olfactory tract for a short distance over the gray field of the trigonum, to plunge into the gray of the preperforatum.

Postolfactory Division.—The preperforatum (anterior perforated substance) occupies an irregular quadrate field between the olfactory trigone and the optic chiasm and tract. A more or less marked groove (sulcus parolfactorius posterior), which is identical with the fissura prima (His) of the embryo, separates the trigonum from the preperforatum. Its frontal part, much perforated, is of a darker

4. Fasciola.
5. Indusium, medial and lateral longitudinal striae upon the callosum.
7. Gyri subcallosi.
8. Fornix and fimbria.

Central

10. Part of precommissure.
11. Part of hemiseptums.

Central or Cortical Parts of the Rhinencephalon.—Following the suggestion made by Broca in 1878, it has been customary to designate these various parts by the comprehensive term: limbic lobe. Broca’s notion of the limbic lobe in man was founded upon attempts to homologize the human cerebral configurations with those found in lower animals. More recent researches have proved that Broca’s “limbic lobe” included parts belonging to the neopallium and not to the rhinencephalon. The term is therefore inappropriate in a morphologic sense.

The hippocampus is the submerged, peculiarly folded margin of the cerebral

¹ Not to be confounded with the hippocampal gyr of the pallium.
hemisphere produced by the hippocampal fissure. Its architecture can best be understood by referring to a frontal section (Fig. 608). It is seen that the whole cerebral marginal wall is pushed into the ventricular cavity (medicornu) as a fold caused by the intrusion of the hippocampal fissure. A secondary fold—not produced by a fissure, however—constitutes the gyrus dentatus. Superimposed lies a prominent white band—the fimbria—composed of axones from the hippocampal cells, assisting in the formation of a white lamina, subjacent to the endyma of the ventricle, and called the alveus. The whole formation is characteristic of this region and from its fancied resemblance to a ram’s horn—a symbol used on the temple of Jupiter Ammon—the name of cornu ammonis has been given; the name hippocampus was applied because of a fancied resemblance to the marine animal of the same name. The ventricular relations and internal structure of the hippocampus will be given farther on (p. 947).

The uncus, with the atrophied lateral olfactory stria, is all that remains in the human brain of the relatively large pyriform lobe of lower forms. It appears to be a hook-like retroflexion of the hippocampal gyre which is partially encircled by the gyrus dentatus. Morphologically speaking, it is only the apical portion, or that which lies caudad of the dentate gyre which is the true uncus (the gyrus intralimbicus of Retzius); the remainder is neopallial and a part of the hippocampal gyre. The uncinate or intralimbic gyre may be traced caudad in the depths of the fimbrio-dentate fissure, along the dentate gyre, the dentato-fascicular

\[\text{Fig. 608. — Trans-section of the hippocampal gyrus. (Edinger.)}\]

1 Frequently, but incorrectly, given as Ammon’s Horn.
groove intervening, to be continued as the fasciola (gyrus fasciolaris of Retzius) over the splenium of the callosum.

If the hippocampal gyre be depressed for the purpose of examining the depths of the hippocampal fissure, there is revealed a narrow, gray band whose surface is scored by numerous incisures and whose edge is notched at frequent intervals. This corrugated band is the dentate gyre or fascia dentata. Partly overlapping it, but farther laterad, lies a white band—the fimbria—extending caudad from the uncus to become continued as the fornix.

The dentate gyre is demarcated from the hippocampal gyre by the hippocampal fissure, from the fimbria by the fimbriodentate fissure, in whose depths lies the narrow continuation of the uncus or gyrus intralimbicus—the fasciola. Extending caudad, and for the most part parallel with the fimbria, it loses its corrugated appearance on approaching the splenium, then fuses with the fasciola, parting company with the fimbria (which now becomes fornix), to be continued upon the callosum as a thin, broad plate of gray matter—the indusium or gyrus epicallosus. At the uncus the dentate gyre makes an abrupt turn to appear upon the mesal surface, out of the depths of the hippocampal fissure, and encircles the neck of the uncus, forming the frenulum Giacomini. Beyond this point it can be traced, in rare instances, to the gyrus semilunaris.

The gyri Andreae Retzii are rudimentary gyral formations consisting of small, rounded, oval or spirally corrugated eminences situated ventral of the splenium in the angular interval between the dentate and the hippocampal gyres. Structurally they have been shown to belong to the hippocampal formation.

The indusium (gyrus epicallosus s. supracallosus), considered to be a vestige of the hippocampus, is a thin strip of gray substance superimposed upon the callosum and raised into two paired ridges by longitudinal fibre-bundles which constitute the mesal and lateral longitudinal striae. The indusium and its striae are continued cephalad into the gyrus subcallosus; perhaps, also, into the parolfactory area (Fig. 607).

The central connections of the rhinencephalon will be considered in the description of the internal configuration of the hemisphere. (See Fornix, Precommissure, etc.)

Internal Configuration.—Each hemicerebrum contains a cavity, the lateral ventricle or paracelle, an extension of the primitive neural cavity carried outward, its contours modified by the developmental changes in the growth-history of the secondary fore-brain vesicle. This central cavity is surrounded by the thick, convoluted walls of nerve-tissue which make up the bulky cerebral hemispheres. The cerebral tissue, as elsewhere in the central axis, is made up of gray and white substance. Two well-marked types of gray substance are recognizable: (a) the cortical, so named because its situation upon an interior white centre, invites comparison with the rind (cortex) of a fruit; (b) the massive ganglionic or nugget-like masses not dissimilar from the thalamus already described, comprising, in this division of the brain, the caudatum, lenticula, and amygdala. The white substance fills out the entire space intervening between the cortex, the cavity of the lateral ventricle and the great basal ganglia, and is composed of myelinic axones which connect the elements of the cortex with other parts of the nerve system, or with other regions of the cortex of the same or the opposite hemicerebrum.

If a brain, resting upon its basal surface, be sliced by successive horizontal sections from above, the peripheral gray and internal white are brought into view. The more superficial sections reveal relatively more gray than white substance; deeper sections show a reverse condition and a section immediately dorsad of the

---

1 The mesal striae are also called Striae Lancii; the lateral stria, Tenia tecti.
callosum reveals, in each hemicerebrum, a very extensive semioval field of white substance, the centrum semiovale, surrounded on all sides by a narrow, convoluted margin of gray substance, the cortex. A close examination of the cut surface, in a fresh and normal brain, shows it to be studded with numerous minute red dots (punta vasculosa) produced by the escape of blood from divided blood-vessels.

The Cortex.—The cortex, as revealed in such a section, is not of uniform thickness throughout; different regions show different cortical thicknesses. In general, the cortex is somewhat thicker at the summit of a gyre than in the depths of an adjoining fissure, and it is thicker upon the convex than upon the mesal or basal surfaces. The maximum thickness is observed in the cortex of the central gyres and the insula; the minimum at the frontal and occipital poles, notably the latter. Not only is the cortex not of uniform thickness, but it is not of homogeneous structure as seen with the naked eye. An alternation of gray and white stripes is discernible, particularly in the occipital cortex, where a white band runs parallel with the cortical surface between two gray strata; this white stripe, first described by Gennari and usually bearing his name, is also called the band of Vicq d’Azyr.

![Diagram of the brain](image)

Fig. 609.—Mesial view of a partly dissected hemicerebrum, to show the relations of fimbria, fasciola, dentate gyre, and uncus.

The preponderance of white substance over gray substance in the cerebrum is a human characteristic concomitant with the relative increase of the association cortex, in turn demanding a more intricate interconnection of the many nerve-cells by a multitude of association neurones. These coördinating fibre-systems are as truly representative of the complexity of man’s thought apparatus as the number of interconnecting wires within a telephone “central” station is indicative of the amplitude of connections possible in that system. The proportions of gray and white substance are expressed in the following tabulation:

The removal, by successive slices, of the dorsal parts of the cerebrum soon brings into view the large expanse of transverse myelinic fibres, the callosum, which connects the two hemispheres.

The Callosum (corpus callosum; trabes cerebri; commissura maxima).—The callosum is a thick stratum of transversely directed nerve-fibres, by which
almost every part of one hemicerebrum is connected with the corresponding part of the other hemicerebrum (Figs. 610 and 611). The axones composing it arise from the small pyramidal or the polymorphous cells of the cerebral cortex, or they may be collaterals from the long association or even the projection neurones. They pass in both directions and within the centrum semiovale radiate in various directions (radiatio callosi) between the fibres of the corona radiata to terminate in the layer of small pyramidal cells of the cortex, thus forming a great transverse commissural system, and at the same time roofing in the greater part of the lateral ventricle in each half. A portion of the dorsal surface is free for a width of about 1 cm. on either side of the mesal plane, partly covered by the indusium and overlapped by the callosal gyres of the two sides, a fold of pia intervening.

The radiating mass of fibres may, for convenience of description, be subdivided into a pars frontalis, a pars parietalis, and a pars occipitotemporalis. The frontal and occipito-temporal portions are compressed or thickened mesally because the fibres cannot pass directly across, but curve, respectively, frontad and caudad in each hemicerebrum to form two tong-like bundles, the preforceps (forceps anterior s. minor) and postforceps (forceps posterior s. major). The pars parietalis constitutes the greater part of the "body" of the callosum. The fibres traversing the body (truncus corporis callosi) and the adjacent part of the splenium curve round the postcornu and trigonum ventriculi of the lateral ventricle, to form a thin but definite white stratum, the tapetum, in the roof and ecal wall of these parts of the cavity.

The transverse direction of the fibres is rendered apparent in a dorsal view of the exposed callosum in the form of the stria transverse. These are but little obscured by a thin, gray lamina—the indusium—which is thickened longitudinally by two symmetrically situated fibre-strands, the mesal (striae lancisii) and lateral longitudinal striae (teniae tectae), already mentioned as rudiments of the rhinencephalon.

The best conception of the size and form of the callosum is obtained from a view of a mesal section. It is then seen to be a long, thick, somewhat flattened arch which bends sharply upon itself frontad to form the genu (genu corporis callosi) while its caudal end is rounded and somewhat folded closely upon itself to form the splenium. The callosum ranges in length from 7 to 10 cm., its cross-section area from 5 to 10 sq. cm., being longer and larger in heavier brains and in those of the highly intellectual as compared with smaller and less highly efficient brains. It extends to within 4 cm. of the frontal pole and to within 6 cm. of the occipital pole. The thickness of the "body" averages 5 mm., of the splenium

---

Fig. 610.—Diagram of coronal section of cerebrum to show course of fibres of callosum. (Testut.)
Fig. 611.—Diagram of horizontal section of cerebrum to show course of fibres of callosum. (Testut.)
9 mm. or more, while the maximum thickness of the genu is about 13 to 15 mm. The reflected portion or rostrum (rostrum corporis callosi) gradually tapers into a very thin lamina, the copula (lamina basoea alba), which in turn joins the terma frontad of the precommissure.

The splenium (spleenium corporis callosi) projects as a rounded welt over the mid-brain, but is separated from it by a pial fold—the velum interpositum. Further frontad the fornix becomes fused to the ventral surface of the callosum for a short distance, to again leave in its more arched course toward the albicans. Two thin laminae, one on either side of the median plane, but closely applied to each other and frequently partially fused, occupy the interval between callosum and the fornix of each side. The laminae together are termed the septum lucidum of the authors, each one being called a hemiseptum; the enclosed cavity is called the pseudocele or fifth ventricle, though not derived from the original neural cavity.

**Development.**—The callosum develops as a mass of commissural fibres which grow from side to side in the terma (lamina terminalis). The terma serves as a matrix for several commissural systems, viz., the hippocampal or fornicommissure and the precommissure, in addition to the callosum. The last develops rapidly in higher mammalian brains, thrusts aside the hippocampal margin of the pallium so that it atrophies in large part, and stretches out within its sharply bent arch a portion of the precommissural wall of each cerebral vesicle. It thus withdraws a part of the intercerebral cleft, eventually enclosing it entirely as the pseudocele. The stages of development are shown schematically in Fig. 612 and its development in the human embryo is shown in Fig. 613. The callosum is most fully developed in man and does not appear below the marsupials. Its growth kept pace with the preponderatingly greater development of the neopallium in higher forms, and it may be looked upon as an index of the elaboration of at least one division of the association systems—those concerned with bilateral coördinations.

**The Lateral Ventrices.**—An incision through the callosum, on either side of the median plane, will expose two large, irregular, symmetrically situated cavities, the lateral ventricles (paracæles), extending through a great part of each hemi-cerebrum. Each lateral ventricle communicates with the third ventricle through a small opening, the pora or foramen of Monro, situated between the fornico-lum (anterior pillar of fornix) and frontal end of thalamus. The cavity is lined throughout by endyma; it is narrow in some and wide in other localities, and contains cerebro-spinal fluid.

The shape of the ventricle is best understood by reference to a cast of its interior and its location within the cerebrum may be appreciated by a study of Figs. 614 and 615. Conventionally the paracæle or lateral ventricle is described as being composed of a body or cella and three horn-like extensions or cornua. Viewed laterally its contour corresponds to that of the cerebral hemisphere and its cornua project toward the three poles, viz., frontal, occipital, and temporal.
Fig. 613.—Brains of human embryos; mesal aspects of median sagittal section show the development of the callosum: A, fourth month; B, fifth month; C, sixth month; D, seventh month.
The body \((pars\ centralis\ ventriculi\ lateralis)\) or cella of the lateral ventricle is defined as that portion whichextends from the porta to the region of the splenium. Itsfrontal prolongation is called the precornu. Near the splenium thecavity may be traced ventro-laterad into a capacious part \((trigonum\ ventriculi)\), fromwhich the postcornu and medicornu are prolonged, respectively, toward theoccipital and temporal poles.

The Precornu \((cornu\ anterius)\) passes frontad, inclined slightly ventro-laterad. Its floor is the head \((caput)\) of the caudatum, forming a rounded incline slopingmesad toward a trench-like recess floored by the rostrum of the callosum. Its roof is the preforceps of the callosum. Its mesal wall is formed by a portion of the hemiseptum. Laterally it is limited by the apposition, at an acute angle, of callosum and caudatum. Its apex reaches the ventricular surface of the genu of the callosum. The general outline of the ventricle, in a frontal section, is triangular (Fig. 625).

![Diagram](https://example.com/diagram.png)

**Fig. 614.**—Showing the ventricular system of the brain as a solid cast as if seen through a transparent brain.

The body of the cavity is curved with its convexity dorsad; its outline in transsections varies from the triangular to a mere slit which slopes slightly meso-ventrad. It is wholly roofed in by the callosum \((pars\ frontoparietalis)\). Its floor is formed by the following structures named in order from its ectal toward its ental limit: (1) caudatum; (2) a groove which marks the line of coalescence of caudatum and thalamus and lodges the tectual vein and a narrow fibre-strand—the taenia semicircularis, beneath the endyma; (3) a reflexion of the endyma onto a narrow area of the thalamus; (4) the paraplexus or choroid plexus of the lateral ventricle; (5) the thin, sharp (fimbriated) edge of the fornix. The caudatum narrows rapidly as it passes caudad. The taenia semicircularis, lying along the ental border of the ventricular surface of the caudatum, is a small band of white fibres arching from the amygdala (near the temporal pole to the preperforatum. The entrance of a part of the thalamus into the formation of the floor of the paracelle is apparent enough, but morphologically it should be strictly excluded there-
from. The thalamus is in no way formed from the parietes of the secondary fore-brain vesicle (telencephalon), for it is, in fact, excluded by a layer of endyma (lamina affixa) reflected onto, and often separable from, the surface of the thalamus, so that it appears as a constituent of the floor because of the transparency of the endymal sheet. The paraplexus is a richly vascular invagination over which the endyma is continuous to again become reflected onto the fornix along its

sharp edge. A reference to Fig. 608, showing the topographical relations of these structures in a frontal section, may be of assistance.

The cavity is thence continued ventro-lateral in a bold sweep to become expanded as an obliquely pyramidal space of a somewhat triangular outline on section, and placed subjacent to the parietal lobe—the trigonum ventriculi. A conspicuous feature in its floor is the collateral eminence, correlated with the
collateral fissure. From the trigonum, the most capacious part of the paracelc, the cavity is prolonged in opposite directions as the medicornu and postcornu.

The Medicornu (cornu inferius) is a prolongation of the ventricular cavity, from its trigone toward the temporal pole, which pursues a curved course with its convexity directed ventro-laterad (Figs. 614 and 615), corresponding to the curved contour of the temporal lobe, and situated at a depth of about 3 cm. from its lateral surface as well as from the temporal pole. The roof is formed by (a) the tapetum of the callosum; (b) the cauda (tail) of the caudatum; (c) the tænia semi-circularis. The medial wall is principally composed of the hippocampus, a prominent welt-like eminence bulging into the cavity, largely filling it, and produced by the hippocampal fissure. The hippocampus nearly conceals from view the actual floor, which is of variable extent in different brains and usually marked by an extension of the collateral eminence previously described. Surmounting the corrugated hippocampal formation and projecting slightly into the cavity, is the fimbria, and from its sharp edge the ventricular endyma is reflected upon the invaginated paraplexus. The paraplexus of the medicornu is more voluminous than that of the body of the ventricle, and must be lifted in order to expose the whole of the ventricular aspect of the hippocampus.

At the apex of the medicornu the roof presents a more or less pronounced bulging, the amygdaloid tubercle, due to the presence of the amygdala, a small mass of ganglionic gray from which the tænia semicircularis arises and in which the caudatum apparently ends.

The Postcornu is a shorter diverticulum which passes toward the occipital pole in a gently curved course, with its convexity directed laterad. It is not very capacious, usually slit-like on section, and tapers to a point within 2 or 3 cm. of the occipital pole. Its roof, slanting latero-ventrad, is formed by the tapetum of the
callosum. On the inner or mesal wall two elongated bulgings may be observed. The upper or dorsal elevation, called the occipital bulb or bulb of the cornu (bulbus cornu posterioris; callosal eminence [Wilder]), is formed by the compact arched postforceps of the callosum as it curves around the very deep occipital fissure. The occipital bulb is not always well marked. Ventral of it lies a more constant limbus or welt-like elevation, the calcar (calcar avis; hippocampus minor), a projection produced by the infolding of the cerebral wall along the calcarine fissure. The paraplexus does not enter the postcornu.

The Choroid Fissure or Rima (rima transversa cerebri magna; fissure of Bichat) is not a true fissure, and only becomes one when the (paraplexus) choroid plexus of the lateral ventricle is torn from its connections. The rima is nevertheless a gap between the diencephalic part and the overlapping and recurved telencephalon produced by the extension of the secondary fore-brain vesicle in an arcuate manner which Hill described by the phrase "rotation of the great fore-brain." It is along this arcuate and fissure-like gap that the richly vascular (pial) paraplexus invaginates the atrophied parietae of the secondary fore-brain to form the paraplexus which is everywhere covered by endyma. The rima extends from the porta to near the tip of the mediocornu in an arcuate course and endymal reflections everywhere close in this gap except at the porta (Fig. 617). The manner in which this is accomplished may best be understood by a study of trans-section showing the endymal reflections from the ventricular wall onto the invaginated paraplexus. The caudato-thalamic fusion and the intrusion of the great fibre-masses constituting the cerebral crura play their parts in complicating the relations in brains of higher type.

The Paraplexus and Velum.—The paraplexus is a highly vascular, fringe-like structure composed of pia which is invaginated into the paracele along the rima, or gap between hemicerebrum and diencephalon. The portion of the paraplexus protruding into the "body" of the paracele is the fringed vascular border—a triangular fold of pia—the velum interpositum (tela chorioidea superior), which, as its name implies, is interposed between the relatively small primary fore-brain and the enormous overlapping secondary fore-brain, and is produced by the overgrowth of the latter onto the former. Inasmuch as the nerve-tissue in the roof of the third ventricle atrophies totally, the ventral fold of the pia comes into contact with the endyma of that ventricle and here permits a similar vascular invagination in the form of two parallel fringes hanging into the cavity (diaplexus
or choroid plexuses of the third ventricle). The dorsal leaf of the pial fold is in contact with the ventral face of the body of the fornix. Frontad, the velum tapers toward the region of the two portae, where the paraplexuses of the two sides are continuous with each other. The ventricular surface of the choroid plexuses is everywhere covered by endyma which is reflected from it to the fimbriated edge of the fornix on the one hand and to the line of the tenia semicircularis (over the thalamus by the lamina affixa) on the other. Its vascular components, in addition to undefined lymphatic channels, are: the prechoroid (anterior choroid) artery, a branch of the internal carotid, entering the paraplexus of the medicornu; the postchoroid (posterior choroid) artery from the postcerebral artery reaching the paraplexus in the neighborhood of the splenium. The venules of the plexus join to form a tortuous medicornual vein which terminates frontad by joining one of the velar veins.

The velar veins (veins of Galen), one on each side close to the median line, running in the fold of the velum, are formed by the union of the tænial, striatal, and medicornual veins. The two velar veins unite to form a common trunk which empties into the straight sinus.

The Hippocampus and Fornix.—The hippocampus and the fornix merit special description. The hippocampus, as seen in the medicornu, is a white eminence about 5 cm. in length, of a curved elongated form, enlarging cephalad and tapering caudad as the hippocampal fissure decreases in depth. The enlarged extremity is marked by alternate elevations and depressions, usually three in number, the hippocampal digitations; because of its resemblance to a lion's paw it is sometimes called the pes leonis or pes hippocampi. The white appearance of the ventricular aspect of the hippocampus is due to a stratum of white substance, the alveus, made up of myelinic axones from hippocampal cells and continued into the fimbria. The fimbria is folded so that its sharp margin is directed toward the cavity of the medicornu; eventually its fibres will be seen to enter into the formation of the fornix. The formation of the hippocampus is best observed in a coronal section (Fig. 608). In this view it is seen to be a peculiarly folded margin of the cerebral cortex, corrugated by the intrusion of the hippocampal and fimbriodentate
fissures. Morphologically it is a vestigial submerged portion of the rhinencephalon, as a part of which it has already been described.

Fig. 619.—The fornix, velum, and medicornu of the lateral ventricle.

Fig. 620.—Transverse section of the middle horn of the lateral ventricle.
The fornix (Figs. 615, 621, 622) is really a paired structure consisting of bilaterally symmetrical halves composed of longitudinally directed fibres which arch on each side from the region of the uncus to the albicans. The two lateral parts join each other in the mesal plane along the summit of the arch to form the body of the fornix (corpus fornicis). Frontad they diverge slightly as they proceed toward the albicantia; caudad they diverge more widely. The paired diverging portions are called
respectively the anterior and posterior pillars of the fornix. The fibres of each half-
fornix arise from the pyramidal cells in the hippocampus and their course will
be traced from this source to the ending in the albicans. Beginning at first as a
stratum of white substance (alveus) constituting the ectlal surface of the ventricular
bulge of the hippocampus, the fibres become collected along its medial border
in a narrow but distinct folded band, the fimbria. This increases in calibre
as increments are added to it along its course, until, at the apical region of the trigonum ventriculi, it leaves the dwindling hippocampus to ascend in a curved course (dorsi-mesad) toward the subsplenial callosal surface as a thick, flattened band. Once free from the hippocampus on each side, the two converging bands of opposite sides are called the posterior pillars or crura fornixis. The majority of the fibres continue frontad in each half-fornix, but a number course transversely to enter the crus fornixis of the opposite side to end in the hippocampal formation. These fibres, of transverse course, form a thin lamina filling in the small triangular space in the subsplenial region between the converging erum fornixis and constituting the fornicomissure (lyra; psalterium; hippocampal commissure). Occasionally a small recess called Verga’s ventricle is formed between callosum and fornicomissure.

The two half-fornices now become joined in the mesal plane and, leaving the subsplenic surface of the callosum, dip fronto-ventrad in an arch—the body of the fornix. Its caudal part is broad and each half is of triangular outline (on section) with a sharp edge directed laterad. Where it is not in contact with the callosum it affords attachment, on each side of the mesal plane, to the hemiseptum. Laterad of these lines of attachment the dorsal surface of each fornix enters into the formation of the floor of the lateral ventricle and is covered by endyma (Fig. 615). The ventral surface rests upon the velum, which separates it from the third ventricle and the dorsal surface of the thalamus.

Near the region of the precommissure the fornix again divides into its constituent lateral halves, separating as rounded strands called the fornicolumns or anterior pillars. These curve ventrad to form the frontal boundary of the porta and thence plunge into the hypothalamic gray, inclined slightly caudad, to end in the albicans. The terminals of the fornix fibres come into relation with the cells of the nucleus of the albicans, which in turn give off the bifurcating Y-shaped axone-bundles already described (p. 920).

In rare instances each fornicolumn has been seen to divide on approaching the precommissure, a part passing frontad thereof as an anomalous precommissural

---

**Fig. 625.—A frontal section of the brain in the plane of the precommissure.**
fornicolumn. The fornix, in its course from hippocampus to albidans, gives off, in addition to those described as hippocampal commissural fibres, axones (a) to the opposite half-fornix, decussating in the fused portion (body), (b) to the hemiseptum, and (c) to the gray tissues of the preperforatum (Fig. 607). It constitutes an inner olfactory arc as distinguished from the epicallosal or outer arc, represented by the atrophied indusium and its longitudinal strie.

The Septum Lucidum (septum pellucidum).—The so-called septum lucidum really consists of two vertically placed lamina or hemisepa. Between them lies a narrow, enclosed space, the pseudocele or fifth ventricle (cavum septi pellucida), roofed in by the callosum, while the floor consists of the fused fornices and the rostrom. Each hemiseptum bounds a part of the precornu and body of the paracele in its mesal wall and in a lateral view is of triangular outline. The hemisepa represent the thin, undeveloped parts of the mesal walls of the cerebral vesicles, which were enclosed within the rapidly developing arch of the callosum. The pseudocele is therefore a closed-off part of the original intercerebral cleft and not a part of the neural cavity as its older name “fifth ventricle” seems to imply.

The Precommissure.—The precommissure is a bundle of white fibres, of oval outline in a sagittal section, which crosses the mid-line as a localized reinforcement of the terma, slightly bulging into the frontal part (aula) of the third ventricle and clothed by its endyma. It is a comparatively insignificant intercerebral commissure in the human brain, having become diminished as the callosum increased in mammalian development. It courses from side to side frontal of the fornicolumns, ventrad of the head of the caudatum, and passes, in part, through the frontal end of the lenticula. Its fibres radiate chiefly to the cortex of the temporal lobe and to certain parts of the rhinencephalon.

The bundle is slightly twisted in each lateral, buried part. Two divisions are distinguishable: 1. The pars anterior or frontal part (in the median plane) contains two groups of fibres belonging to the olfactory apparatus: (a) fibres arising from the mitral cells in the olfactory bulb of one side to the same layer in the opposite bulb; (b) fibres which associate the uncus of one side with that of the other. 2. The pars posterior contains the fibres passing between the cortices of the two temporal lobes.

Gray Masses in the Hemicerebrum.—Aside from the cortex, the hemicerebrum contains certain gray ganglionic masses in its interior, more or less embedded in the white centrum and called, because of their proximity to the base of the cerebrum, the basal ganglia. These comprise the caudatum, the lenticula, and the amygdala. It is usual to include the claustrum among the basal ganglia, but morphologically this structure belongs rather to the insular cortex.

Conventionally the caudatum and lenticula together are described as the striatum (corpus striatum)—a ganglionic mass which in earlier vertebrate brains bore intimate relations with the olfactory apparatus, but later, with the rise in functional dignity and growth of the neopallium, underwent specialization and differentiation concomitant with the reduction of the rhinencephalon. The intrusion of great projection fibre-masses, thrusting the cortical gray outward, has not been everywhere uniform, and we still find, in the human brain, a common ground in which the neopallial cortical gray, the striatum, rhinencephalon, and amygdala meet—the site of fusion being in the gray substance of the preperforatum. To the cortical mantle they are regarded as bearing the relation of subordinate (subcortical) centres. In the human brain the striatum—so-called because of its striated appearance in sections—is composed of two masses, the caudatum and lenticula, directly continuous with each other at their frontal ends (Fig. 627). The connecting gray bridge becomes broken up into numerous small bands of gray substance as the fibre-masses of the internal capsule insinuate themselves between the two nuclei (Fig. 624).
The Caudatum (nucleus caudatus) (Figs. 623, 626, 627) presents a ventricular and a capsular surface; the ventricular surface, covered by endyma, forms part of the floor of the body and precornu, while in the medicornu it is a constituent of its roof, owing to its arched contour in correspondence with the sweeping curve of the ventricle itself. It is of a pyriform shape with a very much attenuated tail. The large, thick head projects into the precornu whilst its thinner tail is prolonged caudo-laterad, separated from the thalamus by the narrow tenia semicircularis. Following the curved contour of the ventricle it is prolonged as a narrow gray band in the roof of the medicornu, where it joins the amygdala. The non-ventricular or capsular surface is embedded in the white substance of the hemi-cerebrum, and is chiefly related to the internal capsule.

The ventricular surface shows, in microscopic sections, a dense endymal lining. The capsular face is not sharply outlined, numerous strands of fibres, to and from the internal capsule, entering it obliquely so as to appear as streaks.

Fig. 626.—The basal ganglia and thalamus schematically represented in a supposedly transparent brain (right side); on the left is shown the outline of the paracele (lateral ventricle).
which extend to about the middle of the ganglion, there separating into finer and finer strands which become lost to the naked eye.

The Lenticula (Figs. 624, 626, 628) is wholly embedded in the white substance and must be studied in sections. In its shape it resembles an irregular triangular pyramid with its convex base directed laterad and parallel with and near to the cortical expanse of the insula and of about the same extent. Its ental, apical portion is directed toward the interval between caudatum (head) and thalamus. The contour and slope of the surfaces of the ental pyramidal face may be judged from the model pictured in Fig. 627. Its outline, as revealed in sections passing in different planes, is shown in Figs. 625 and 628.

Sections of the lenticula show it to be composed of three\(^1\) concentric segments separated by two white medullary laminae. The segments are known as articuli; the ental one is designated the putamen; the two ental zones constitute the pallidum (globus pallidus). The putamen is the larger and of a deeper reddish-gray tint; the two mesal divisions are lighter in color owing to a greater proportion of radiating streaks of white fibres passing to and from the internal capsule. The ental outline of the putamen is sharply defined against a white lamina, the external capsule.

The Amygdala is usually regarded as an hypertrophied aggregation of the temporal cortex which has become nearly isolated from its cortical connection by intruding white substance. It is a rounded, gray, striated mass situated in the forepart of the temporal lobe in the roof of the medicornu at its apex, where it produces the bulging called the amygdaloïd tubercle. Caudad it is joined by the tail of the caudatum; frontad it is continuous with the putamen. Except for the marked streaking shown in sections, its structure is like that of the cortex. Its cells apparently give rise to the narrow band of fibres—the tænia semicircularis— which courses along the mesal margin of the ventricular surface of the caudatum throughout its arched course and ends in the preperforatal gray so that it nearly completes a circle.

The Clastrum is a thin plate of gray substance embedded in the white substance which intervenes between the putamen and the insular cortex, and corresponding in extent to these. Its dorsal edge is very much attenuated; traced ventrad it thickens considerably and becomes continuous with the surface gray at the preperforatum. Its ental surface presents alternate ridges and depressions which correspond to the corrugations of the insular cortex. The “external capsule” intervenes between its ental face and the putamen of the lenticula. From the insular cortex proper it is separated by a white lamina which may be termed the periclastral lamina or capsula extrema. Apparently the claustrum is the thickened and isolated spindle-cell stratum of the insular cortex, a feature which

---

\(^1\) Four and even five have been observed.
may be of significance in relation to the preponderatingly associative function of the insular region.

**Internal Capsule** (Fig. 628).—Between the lenticula on the one hand and the caudatum and thalamus on the other lies the internal capsule, a broad band of white fibres which, as seen on horizontal section, appears bent, very much as a leg is bent on the thigh, with the knee (genu) directed mesad. The frontal or caudato-lenticular division or limb is confined between the opposed faces of the caudatum and lenticula. The genu receives the mesal apex of the lenticula in its hollow, while

![Fig. 628.—Horizontal section through the cerebrum. The various structures are shown in their natural appearance on the right side and are named on the left side.](image)

the caudal or thalamo-lenticular limb lies between the opposed faces of lenticula and thalamus. The frontal limb constitutes about one-third, the caudal limb two-thirds of the internal capsule mass.

The term "internal capsule" is often loosely employed and is variously stated to include fibre-tracts which do not course between the cerebral cortex and the "lower" brain centres. In a strict sense it is a mass of fibres which converge, like the sticks of a fan, toward the cerebral base and into the crusta. Dorsad of the basal ganglia the fibres radiate in various directions, streaming among the radiating callosal fibres and forming the so-called corona radiata. Yet other
fibre-tracts leave and enter the great ganglia at various altitudes along the internal capsule, and we must therefore distinguish the following cerebral fibre-systems.

**Projecting systems**, ascending and descending (in the functional sense), of longer and shorter course, connecting the cerebral cortex with (a) spinal gray centres; (b) mid-brain and pontile nuclei; (c) basal ganglia and thalamus. The last-mentioned system traverses the internal capsule to a greater or lesser extent, but does not continue into the crista. These various systems are summarized on page 963. It may here be mentioned that the internal capsule, topograpically, exhibits a functional dissociation in that its frontal or lenticulo-caudal limb is composed of preponderantly corticipetal fibres, while corticifugal fibres form the major portion of the thalamolenticular limb (Fig. 629). In the frontal limb are the thalamo-frontal and thalamo-striate fibres; the former ending in the cortex of the frontal lobe, the latter in the caudatum and lenticula. The chief corticifugal components are the fronto-pontile tract, and fewer fronto-thalamic and striato-thalamic fibres. The fronto-pontile tract arises in the cortex of the prefrontal region, traverses the frontal limb of the internal capsule, forms the ental sector (one-fifth) of the crista, and ends in the nuclei pontis.

In the genu and the thalamolenticular limb of the internal capsule course several important fibre-tracts which are chiefly corticifugal.

The **Pyramidal (Motor) Tract**, in its course from the precentral cortex to the lower motor centres occupies the frontal half of this limb. The portion in the genu, often designated the **geniculate tract**, comprises the pyramidal fibres which are destined to go to the facial and hypoglossal nerve nuclei; further caudad lie, in succession, the fibres going to the motor centres for the upper and the lower extremity. The most caudal segment (also called the **retrolenticular part**) of the internal capsule contains (a) the **optic radiation**, composed of fibres coursing in both directions between the occipital cortex and the pulvinar, pregeniculum and pregenminum; (b) the **auditory radiation**, composed of fibres passing in both directions between the cortex of the temporal lobe (auditory centre) and the postgenminum and postgeniculum; (c) the **occipito-
pontile and temporo-pontile tracts from the occipital and part of the temporal cortex, coursing through the caudal segment of the internal capsule, constituting the ectal (one-fifth) sector of the crista and ending in the nuclei pontis. In addition there are scattered fibre-bundles which arise from the ventral portion of

the thalamus, enter the internal capsule to pass toward the cortex, in part through the lenticula, in part in the sublenticular zone, to form the \textit{ansa lenticularis}. The reinforcement of this sublenticular white-fibre tract by cortico-thalamic fibres from the temporal lobe to thalamus forms the \textit{ansa peduncularis}. The topographic relations of the various tract-masses as seen in a flat-wise section is schematically

![Diagram of motor path from right brain.](image)
shown in Fig. 630; on the whole they correspond to the cortical areas with which they are connected.

The External Capsule (Fig. 628).—The external capsule is a thin lamina of white substance interposed between the ectal face of the lenticula and the claustrum. Dorsally, frontad and caudad, at the corresponding borders of the lenticula, it joins the internal capsule mass, while ventrally it is continuous with the white centrum of the temporal lobe. Its comparatively few projection fibres course to and from the ventral parts of the thalamus; its chief constituents are association axones for the circuminsular cortical areas.

Intimate Structure of the Cerebral Cortex and its Special Types in Different Regions (Fig. 631).—A section of the cerebral cortex reveals a tendency on the part of its constituent cells to arrange themselves in layers which alternate with zones less rich in cellular elements. Among the cells course the axones arising from them or terminating in their neighborhood. The axones are chiefly amylene, though some are myelinic for a part of their intracortical course. The cells, of various sizes and shapes, together with their dendrites and axones are embedded in a matrix of neuroglia.

The nerve-cells in a typical section of the cortex are arranged in five tangential layers, as follows: (1) the molecular layer; (2) the ectal polymorphous cell layer; (3) the layer of small pyramidal cells; (4) the layer of large pyramidal cells; (5) the ental polymorphous cell layer.

The molecular layer (neuroglia layer) lies immediately subjacent to the pia and is chiefly made up of glia cells and fibres amongst which the dendrites of the subjacent layer of cells intrude.

The ectal polymorphous layer cells are polygonal, triangular and fusiform in shape and tend to gather in groups in certain cortical regions. The fusiform cells are placed with their long axes parallel (i.e., tangential) to the gyrall surface and are presumably associative in function.

The Layer of Small and the Layer of Large Pyramidal Cells.—The cells in the second and third layers may be studied together, since, with the exception of the difference in size and the more superficial position of the smaller cells, they resemble each other. The body of each cell is pyramidal in shape, its base being directed to the deeper parts and its apex toward the surface. It contains granular pigment, and stains deeply with ordinary reagents. The nucleus is nucleolated, of large size, and round or oval in shape. The base of the cell gives off the axone, and this passes into the central white substance,
giving off collaterals in its course to be distributed as a projection, commissural, or association fibres. Both the apical and basal parts of the cell give off dendrites. The apical dendrite is directed toward the surface, and ends in the molecular layer by dividing into numerous branches, all of which may be seen to be studded with projecting bristle-like processes when prepared by the silver or methylene-blue method. The larger pyramidal cells, especially in the precentral gyr, may exceed 50 µ in length and 40 µ in breadth, and are termed giant cells. The chief function of the small pyramidal cells is commissural and associative. The chief function of the large pyramids is motor, but they have also commissural and associative functions.

Layer of Ental Polymorphous Cells.—The cells in this layer, as their name implies, vary greatly in contour, the commonest varieties being of a spindle, star, oval, or triangular shape. Their dendrites are directed outward, toward, but do not reach, the molecular layer; their axones pass into the subjacent white substance. From this layer come commissural fibres, long association fibres, and some projection fibres.

There are two other kinds of cells in the cerebral cortex, but their axones pass in a direction opposite to that of the pyramidal and polymorphous cells, among which they lie. They are: (a) the cells of Golgi, the axones of which do not become myelinated, but divide immediately after their origin into a large number of branches, which are directed toward the surface of the cortex; (b) the cells of Martinotti, which are chiefly found in the polymorphous layer. Their dendrites are short, and may have an ascending or descending course, while their axones pass out into the molecular layer and form an extensive horizontal arborization.

Nerve-fibres in the Cortex.—These fill up a large part of the intervals between the cells. Some of these fibres form fasciculi; some are isolated, and others are arranged in plexuses. They may be myelinic or amyelinic, the latter comprising the axones of the smallest pyramidal cells and the cells of Golgi. In their direction the fibres may be either transverse, the transverse tangential or horizontal fibres, or vertical, the vertical or radial fibres. The transverse fibres run parallel to the surface of the hemisphere, intersecting the vertical fibres at a right angle. They consist of several strata, of which the following are the most important: (1) a stratum of white fibres covering the superficial aspect of the molecular layer; (2) the band of Bechterew, found in certain parts of the superficial portion of the layer of the smaller pyramidal cells; (3) the external or outer band of Baillarger or the band of Gennari, which runs through the layer of large pyramidal cells; (4) the internal band of Baillarger, which intervenes between the layer of large pyramidal cells and the polymorphous layer. According to Cajal, the transverse fibres consist of (a) the collaterals of the pyramidal and polymorphous cells and of the cells of Martinotti; (b) the arborizations of the axones of Golgi's cells; (c) the collaterals and terminal arborizations of the projection, commissural, or association fibres. The vertical fibres: Some of these, viz., the axones of the pyramidal and polymorphous cells, are directed toward the central white substance, while others, the terminations of the commissural, projection, or association fibres, pass outward to end in the cortex. The axones of the cells of Martinotti are also ascending fibres.

In certain parts of the cortex this typical structure is departed from. The chief of these regions are: (1) the occipital lobe, (2) the transtemporal gyres, (3) the hippocampus, (4) the dentate, and (5) the olfactory bulb.

Special Types of Gray Substance. 1. The Occipital Lobe.—In the cuneus and the calcarine fissure of the occipital lobe, Cajal has recently described as many as nine layers. Here the inner band of Baillarger is absent; the outer band of Baillarger or band of Gennari is, on the other hand, of considerable thickness. If a section be examined microscopically, an additional layer is seen to be interpolated.
between the molecular layer and the layer of small pyramidal cells. This extra layer consists of two or three strata of fusiform cells, the long axes of which are at right angles to the surface. Each cell gives off two dendrites, external and internal, from the latter of which the axone arises and passes into the white central substance. In the layer of small pyramidal cells, fusiform cells, identical with the above, are seen, as well as ovoid or star-like elements with ascending axones, the cells of Martinotti. This area of the cortex forms the visual centre, and it has been shown by Dr. J. S. Bolton⁷ that in old-standing cases of optic atrophy the thickness of Gennari's band is reduced by nearly 50 per cent.

2. The Transtemporal Gyres.—The transtemporal gyres are distinguished by a reduction of thickness of the pyramidal cell layer with closer approximation of the giant-cells to each other, while the fusiform cell layer is more deeply situated than elsewhere. This cortical formation is the end-station for cochlear nerve projections.

3. The Hippocampus.—In the hippocampus the molecular layer is very thick and contains a large number of Golgi cells. It has been divided into three strata: (a) S. convolutum or S. granulosum, containing many tangential fibres; (b) S. lacunosum, presenting numerous lymphatic or vascular spaces; (c) S. radiatum, exhibiting a rich plexus of fibrils. The two layers of pyramidal cells are condensed into one, and these are mostly of large size. The axones of the cells in the polymorphous layer may run in an ascending, descending, or horizontal direction. Between the polymorphous layer and the ventricular ependyma is the white substance of the alveus (Fig. 608).

4. The Dentate Gyre.—In the rudimentary dentate convolution the molecular layer contains some pyramidal cells, while the pyramidal layer is almost entirely represented by small ovoid elements.

5. The Olfactory Bulb.—In many of the lower animals this contains a cavity which communicates through the hollow olfactory stalk with the cavity of the lateral ventricle. In man the original cavity is filled by neuroglia and its wall becomes thickened, but much more so on its ventral than on its dorsal aspect. Its dorsal part contains a small amount of gray and white substance, but this is scanty and ill defined. A section through the ventral part shows it to consist of the following layers from without inward. (1) A layer of olfactory-nerve fibres, which are the myelinated axones prolonged from the olfactory cells of the nose, and which reach the bulb by passing through the cribriform plate of the ethmoid bone. At first they cover the bulb, and then penetrate it to end by forming synapses with the dendrites of the mitral cells, presently to be described. (2) Glomerular layer (stratum glomerulosum): This contains numerous spheroidal reticulated enlargements, termed glomeruli, which are produced by the branching and arborization of the processes of the olfactory nerve-fibres with the descending dendrites of the mitral cells. (3) Molecular layer: This layer is formed of a matrix of neuroglia, embedded in which are the mitral cells. These cells are pyramidal in shape, and the basal part of each gives off a thick dendrite which descends into the glomerular layer, where it arborizes as above, or, on the other hand, interfaces with similar dendrites of neighboring mitral cells. The axones pass through the next layer into the white substance of the bulb, from which, after becoming bent on themselves at a right angle, they are continued into the olfactory tract. (4) Nerve-fibre layer: This lies next the central core of neuroglia, and its fibres consist of the axones or afferent processes of the mitral cells which are passing on their way to the brain; some efferent fibres are, however, also present, and terminate in the molecular layer and presumably come via the precommisssure from the mitral cells of the opposite bulb.

The **claustrum**, although usually enumerated among the basal ganglia, is probably the thickened and isolated deepest layer of fusiform cells belonging to the cortex of the insula. The white lamina\(^1\) intervening between it and the cortex proper consists of association axones of longer and shorter course.

**Summary of the Cerebral Fibre Systems.**—The white substance of the cerebrum consists of myelinic fibres intricately interwoven but permitting of classification into three systems arranged according to the course they take. These systems comprise: (1) **association fibres**, which connect neighboring or distant parts within the same hemicerebrum; (2) **commissural fibres**, which unite allied parts in the two cerebral halves and come transversely across the mid-line to form the commissures; (3) **projection fibres**, which connect the cerebral cortex with lower centres in the brain and spinal cord, and, conversely, those fibres which connect lower centres with the cerebral cortex.

1. The **Association Fibres** (Fig. 632) connect different structures in the same hemispheres, and are in or near to the cortex. They take origin from the small pyramidal and polymorphous cells of the deep layer of the cortex. Their direction is parallel to the surface of the hemisphere, and in their course they cross the projection and commissural fibres. They are of two kinds: (1) those which unite adjacent convolutions, **short association fibres**; (2) those which pass between more distant parts in the same hemisphere, **long association fibres**.

The **short association fibres** are situated immediately beneath the gray cortex of the hemispheres, and connect together adjacent convolutions. They constitute subcortical tracts and are divided into **arcuate fibres** and **tangential fibres**. Some of these fibres connect the "visual sensor area with the visual memory area, and the auditory sensor with the auditory memory area."

The **long association fibres** associate cerebral centres which are far apart. They are gathered into bundles and dip down deep into the centrum ovale. They include the following: (a) the **uncinate fasciculus**; (b) the **superior longitudinal fasciculus**; (c) the **inferior longitudinal fasciculus** (doubtful); (d) the **cingulum**; and (e) the **fasciculus rectus**.

---

1. Previously described as the *pericalveal lamina or capsula extrema.*
(a) The **Uncinate Fasciculus** (*f. uncinatus*) passes between the uncinate gyre and the orbital portion of the frontal lobe; in its course it curves beneath the depths of the basisylvian fissure (Fig. 632).

(b) The **Superior Longitudinal Fasciculus** (*fasciculus longitudinalis superior*) (Fig. 632).—The superior longitudinal fasciculus is beneath the convex surface of the hemisphere. It joins the frontal cortex with the parietal and temporal cortex and brings into relation the motor speech centres and the centres of auditory and visual memories.

(c) The **Inferior Longitudinal Fasciculus** is usually described as a tract associating the centres of auditory and visual memory. Such association fibres undoubtedly exist, but it is doubtful whether they are collected into a distinct fasciculus. The bundle which is usually designated by this term has been proved to be in part the projection system between the occipital cortex and the thalamus and pregeniculm (E. Redlich) and in part also the fibres from the temporal cortex (medietemporal and subtentorial gyre) to the crusta.

(d) The **Cingulum**, also called the *fornix periphericus*, is a band of white fibres that course in the white substance of the callosal gyr and runs excentrically to the calosum. Its fibres may be traced frontad into the mesal olfactory stria and the preperforatum, while caudal they radiate into the hippocampus. It may be regarded as an association tract of the rhinencephalon akin to the fornix.

(e) The **Fasciculus Rectus** or **Perpendicular Fasciculus** runs dorsoventrad in the occipito-parietal transition and associates the subparietal gyres...
with the medi- and subtemporal gyres; a part of the fasciculus associates the dorsal occipital region with its ventral part and with the subcollateral gyre (Fig. 632).

The FORNIX, previously described, may be enumerated among the long association tracts; it belongs exclusively to the olfactory apparatus.

2. The **Commissural Fibres** are grouped under the following heads: (a) the callosum, described on p. 939; (b) the precommis sure, described on p. 952; and (c) the fornico commis sure, described on p. 951.

3. The **Projection Fibres** connect the cerebral cortex with lower brain centres (caudatum and lenticula, thalamus, hypothalamic region, quadrigemina, pons, oblongata), and with the spinal cord centres. They either project impulses from the cortex to the periphery or bring in impressions from without. Their radiations to and from the cortex, together with the radiations of the callosal fibres, give rise to the characteristic appearance of the corona radiata. We may distinguish the projection tracts of long course from those of short course and, in the functional sense, those that are centrifugal, descending or motor, from those that are centripetal, ascending, or sensor. The latter mode of classification is more desirable.

1. **Descending (corticifugal) Tracts** are composed of axones arising from the cortical pyramidal cells.

   (a) The **pyramidal or motor tract** from the "motor area," comprising the precentral gyre and paracentral gyre, courses through the genu and frontal two-thirds of the thalamo-lenticular limb of the internal capsule, forms the middle (three-fifths) sector of the crus ta, passes through the pons into the postoblongata and spinal cord. The tract may be subdivided into a cortico-bulbar and a cortico-sinal division.

   The cortico-bulbar division is the pyramidal tract to the efferent cranial-nerve nuclei. Only those fibres which are destined to go to the facial and hypoglossal can be traced throughout. They originate in the ventral part of the precentral gyre (face and tongue centre), course through the genu of the internal capsule and end, contralaterally, in relation with the facial and hypoglossal-nerve nuclei (also called the emissary speech tract).

   The cortico-sinal division arises from the remainder of the motor area, courses through the frontal two-thirds of the internal capsule, through crus ta, pons, and postoblongata, to form the pyramids, and undergoing partial decussation, forms the direct and the crossed pyramidal tracts described in the spinal cord.

   (b) The fronto-pontile tract (Arnold’s bundle) arises in the midfrontal cortex, courses through the internal capsule (caudal part of frontal limb), forms the mesial sector (one-fifth) of the crus ta, and ends in the nuclei pontis.

   (c) The temporo-pontile tract (Türek’s bundle) arises in the cortex of the temporo-lab, descends through the internal capsule (caudal segment), forms the ectal (one-fifth) sector of the crus ta, and ends in the nuclei pontis. The existence of occipito-pontile fibres is denied by Archambault in a recent contribution (1906).

   (d) The occipito-mesencephalic tract arises in the visual area (cuneus and calcaine formation), courses through the retrolenticular part of the internal capsule, to end in the pregem inum and in relation with the nuclei for movements of the eyeball.

   (e) Part of the fibres composing the optic radiation are corticipetal, arising in the occipital cortex and ending in the pulvinar of the thalamus and the pregeniculum.

2. **Ascending (corticopetal) Tracts** arise mostly from the nuclei of the thalamus and hypothalamus, mid-brain, and cerebellum.

   (a) The terminal or cerebral part of the general sensor pathway of the body comprises the axones arising in the cells of the lateral nucleus of the thalamus and the hypothalamic nucleus—interposed way-stations which transfer the impressions carried along the medial lemniscus from the nuclei of the gracile and
cuneate fasciculi in the myeloblongata transition. They convey sensor impressions from the body periphery to the somesthetic area of the cortex—chiefly the postcentral and parietal gyres.

(b) The terminal or cerebral part of the general sensor pathway of the head and neck comprises the axones which arise from the afferent cranial-nerve nuclei (excepting the auditory) and course along the medial lemniscus to the thalamus and hypothalamic nucleus, to be thence projected to the somesthetic cerebral cortex.

(c) The terminal or cerebral part of the auditory pathway from the postgeminum, postgeniculum, and the interposed nucleus of the lateral lemniscus, ending in the auditory sphere of the cerebral cortex.

(d) The terminal part of the visual pathway, described on pages 919.

(e) The terminal (ascending) cerebello-cortical pathway, arising as the fibres of the cerebellar prepeduncles, decussating and ending in the rubrum (red nucleus) and lateral nucleus of thalamus, is thence directly projected by new axones to the somesthetic cortical area, or indirectly projected via thalamus (lateral nucleus).

Connections of the Striatum.—The connections of the caudatum and lenticula with each other and with the cortex may be summarized as follows:

(a) Fibres from the cortex to caudatum and lenticula, entering into the formation of the corona radiata.

(b) Fibres from the caudatum and putamen of lenticula coursing to the thalamus and hypothalamic region. Those from the caudatum pass through the internal capsule to traverse the pallidum, are joined by the fibres from the putamen to again traverse the internal capsule and end in the thalamus, forming the striato-thalamic radiation.

(c) Fibres coursing ventrad in the medullary laminae of the lenticula, and reinforced by additional fibres from the pallidum, course mesad to the hypothalamic region to form the subthalamic radiation or ansa lenticularis (described on p. 957). This radiation is further reinforced by the ventral stalk of the thalamo-cortical radiation to form the ansa peduncularis (described on p. 957).

The Olfactory Pathways. 1. Peripheral Pathway.—Impressions from the upper portion of the Schneiderian mucous membrane pass along the olfactory fila (central processes of the intra-epithelial bipolar olfactory cells) to the glomeruli olfactorii in the olfactory bulb (Fig. 634).

2. Central Pathway.—In the glomeruli the impression is transmitted to the brush-like, dendritic endings of the mitral cells and brush-cells; the axones of these cells carry the impression centrad to the gray masses of the olfactory tract, trigonum olfactorium, preperforatum, and adjacent parts (Fig. 630). These constitute the primary centres.

Fig. 634.—Schema of the olfactory bulb and tract neurones.
The primary centres are connected with secondary or cortical centres (hippocampus, gyrus dentatus, uncus) by the following tracts:

1. Lateral olfactory striae, from the olfactory trigone to the uncus, ending in the gyrus ambiens and gyrus semilunaris (p. 935).

2. Axones from cells in the olfactory trigonal gray through the fornix to hippocampus.

3. Striae medialis (Lancisii) from the trigone into gyrus subcallosus around the callosum to gyrus dentatus and hippocampus.

The amygdala is by some regarded a cortical centre to which impressions are carried by the tendia semicircularis.

The fornix fibres arise from the pyramidal cells in the hippocampus and the polymorphous cells of the dentate gyre. Some fibres traverse the median plane as the fornix commissure to the opposite hippocampus; the remainder end in the albicans gray nucleus or, in small part, are retroflexed as the stria medullaris thalami to the habenal ganglion.

In the albicans impressions are transmitted to the cells of two nuclear masses; from the medial nucleus arise axones constituting the fasciculus albicaninus principecs, each axone bifurcating and the diverging bundles forming, respectively, the albicantholamal and the albicanthotegmental fasciculi (p. 916).

The stria medullaris thalami consists of the following bundles ending in the habenal ganglion:

(a) Axones from hippocampus via fornix—the cortico-habenal tract; (b) axones from the hemiseptum and olfactory gray—the olfacto-habenal tract; (c) axones from the thalamus to the habenal ganglion—the thalamo-habenal tract.

In the habenal ganglion axones arise which pass as a distinct bundle ventrad through the tegmentum to the gray of the postperforatum (ganglion interpedunculare [intercerebrale] of Gudden)—the fasciculus retroflexus of Meynert.

The primary olfactory centres of the two sides are connected by the pars olfactoria of the precommissure, a bundle of fibres passing from side to side to end in the tract, granular stratum, and glomerular layer of the bulb.

Further connections are established with the tuber, mid-brain, and even spinal centres; one division has been named the olfacto-mesencephalic tract (Wallenberg).

The cingulum or fornix periphericus is an arcuate association bundle, or rather an arcuate series of short bundles which establishes the connections of the rhinencephalon with the adjacent cortical areas. (See p. 962.)

**Weight of the Brain.**—The average weight of the brain in the adult male is 1400 grams; that of the female 1250 grams. Among 1500 brains of males the brain-weights ranged from 960 grams to over 1900 grams; the great majority of this series ranged from 1250 grams to 1500 grams. The average weight in the newborn is 400 grams in the male and 350 grams in the female. The weight is doubled at the end of the first and trebled at the end of the fourth or fifth year, the female brain growing less rapidly than the male brain. Brain-growth generally ceases in the eighteenth or twentieth year, earlier in the female than the male. After the sixtieth year the brain loses weight, at first slowly, but more rapidly in advanced senescence. Other factors, besides age and sex, which influence brain-weight are stature, body-weight, cranial form, and race. Persons of large stature average heavier brains than those of short stature in absolute figures, but not relatively. Brachycephalic persons average heavier brains than the dolichocephalic. A most profound influence upon brain-weight appears to be exerted by racial differences. Representatives of the white race have heavier brains than those of the other races; although data are not sufficient to make a positive statement. Thus the few Eskimo brains that have been secured so far are notable for their size and weight. The following table gives approximately accurate averages based upon greater or lesser numbers of brain-weights:
The intellectual status is in some way reflected in the mass and weight of the brain. The average brain-weight of 100 men eminent in the professions, arts, and sciences, with an average age of 62 years, was 1470 grams, exceeding the average weight of the ordinary population of about the same age by more than 100 grams. A further analysis shows that the brains of men devoted to the higher intellectual occupations, such as the mathematical sciences, involving the most complex mechanisms of the mind, those of men who have devised original lines of research and those of forceful character are among the heaviest of all.

The brains of microcephalic idiots are far under the minimal size necessary for mental integrity, which is about 1000 grams in the male and 900 grams in the female. Certain idiotic individuals possess brains of normal size or even abnormally large brains, but structural defects underlie these forms of idiocy.

The whale, porpoise, dolphin, and elephant possess larger brains than man, but relative to the size and weight of the body the human brain is proportionately larger.

### Cortical Localization of Function

Patient researches conducted along clinico-pathologic, experimental, physiologic, and developmental lines have furnished us with a topographic map of the somesthetic and sense areas and, inferentially, of the association areas of the cerebral cortex. The somesthetic and sense areas constitute less than one-third of the cortical area, while the remainder is presumed to be devoted to the elaboration of the higher mental activities manifested by abstract thought, ideation, reasoning, and language. The acquisition of these specifically human mental attributes has been the chief factor in bringing about the superior structure of the human brain, and those cortical regions which were subjected to increased associations rose in functional dignity and increased in size. With over nine billion functional nerve-cells in the human cerebral cortex devoted to the mental processes and less than one-third of these concerned with emissary and receptive functions, the intricacy and capacity of the human brain for the manifold registration of sensations and the numerous transformations that characterize man's mental process far exceed that of any other animal.

The delineation of areas called motor, visual, auditory, etc., is not to be deemed as mathematically accurate or sharply defined as the boundaries of a State, county, or township. The areas rather shade off in a diffuse manner and the arbitrary demarcations employed in the appended figures merely show the maximum concentration of those cortical parts which most distinctly pertain to the function alleged for them.

The principal areas that are known to be functionally differentiated are the following:

1. **Motor Area.**—The motor area comprises the precentral gyr and parts of the frontal gyres adjacent thereto, together with the paracentral gyr and the adjacent portion of the superfrontal gyr on its medial face. Stimulation of various parts of this area causes movement, while their destruction impairs or abolishes voluntary movements. Within this motor area may be defined districts which are cortical projections of the muscular systems of the body. Thus, movements of the lower limb seem to be controlled by the dorsal part of the precentral and the paracentral
gyre: the trunk musculature by the area lying frontad both on the mesal aspect and in the dorsal superfrontal; the upper limb seems to be controlled by the mid-portion of the precentral; while the facial musculature is projected in the ventral part. The motor regions for the tongue, larynx, muscles of mastication, and pharynx lie in the frontal opercular part; and the movement of the head and eye are dominated by the medifrontal gyre, adjacent to the precentral. Recalling the fact that the pyramidal (motor) tract decussates in its course to the primary motor centres, it follows that the motor centres in one hemicerebrum control the movements of the opposite side of the body. As elsewhere in the cortex, these motor areas gradually pass one into the other and the boundaries are indeterminate. The localization of motor function is rather
for coördinated groups of muscles than for individual muscles; as a rule the most powerful articulation, as the thigh and the shoulder, is localizable frontal in the respective limb centres, while the smaller articulations and those more differentiated as regards motility (digits, etc.) are localizable more posteriorly.

2. Sensor Areas.—(a) The area for tactile and temperature impressions is more intensely localized in the postcentral gyre and in corresponding order with its neighboring precentral motor areas; that is to say, there is the most intimate intercommunication between the sensor and the motor regions which preside over corresponding parts of the body. So closely coupled are the related sensor and motor cells in the highest category of the reflex arc system represented in the cerebral cortex that both sensor and motor areas are included under the term somesthetic or senso-motor area, devoted to the registration of cutaneous impressions, impressions from the muscles, tendons, and joints; in short, the sense of movement. The cortical area embraced by the parietal gyre, together with its extension in the precuneous on the mesial aspect, appears to be devoted to the concrete perception of the form and solidity of objects and is therefore termed the stereognostic sense area.

(b) The auditory area is localized in the middle third of the supertemporal gyre and in the adjacent transtemporal gyres in the sylvian cleft.

(c) The visual area is most intensely localizable in the region of the calcarine fissure as well as in the cuneus as a whole. There seems to be an interrelation between the visual function and the special type of cortex already described, and chiefly characterized by the stripe of Gennari.

(d) The olfactory area comprises the uncus, frontal part of hippocampus, indusium, callosal gyre, parolfactory area, and preperforatum.

(e) The gustatory area has not yet been accurately localized; presumably it lies in the neighborhood of the olfactory area in the temporal lobe (uncinate and hippocampal gyre?).

3. The Language Areas.—The cortical zone of language comprises certain specialized areas which take part in the intimate relations of speech to thought-expression, to memory, in its reading form to sight, in writing to manual muscular innervation, and in "word-understanding" to hearing.

(a) The emissive (articular) centre for speech is localized in the region of the junction of the subfrontal gyre with the precentral gyre—a region known to be intimately related to the control of the muscles used in speech (larynx, tongue, jaw muscles). Destruction of this region at least causes a loss or disturbance of articulation of words.

(b) The auditory receptive centre, clinically known as the centre of "word-deafness," is localized in the marginal gyre and adjacent part of supertemoral gyre. A patient suffering with a lesion of this area may clearly hear but not understand the spoken word. The centre might also be called the lalognostic (word-understanding) centre.

(c) The visual receptive centre, clinically known as the centre of "word-blindness," is
localized in the angular gyre. Lesions of this area renders the patient incapable of understanding the significance of the words and objects which he sees.

(d) An emissive "writing" centre, not positively proven to exist, has been localized in the medifrontal gyre, frontad of the motor area for the upper limb.

(e) Of not a little importance with reference to the intellectual control of the faculty of language is the insula, purely an association centre, serving to connect the various receptive sense-areas relating to the understanding of the written and spoken word with the somesthetic emissary centres related to articulate speech and writing.

The union of the various centres enumerated above forms the cortical zone of language and is most intensely, if not exclusively, localized in the left hemicerebrum in right-handed persons, and vice versa in left-handed persons.

4. The Association Areas.—The remaining area of the cerebral cortex is presumably the organic substratum for the higher psychic activities. At the present time not much is known about them, but broadly stated the frontal association area is concerned rather with the powers of thought in the abstract; creative, constructive, and philosophic. The parieto-occipito-temporal association area, on the other hand, seems to be concerned more with the powers of conception of the concrete, for the comprehension of analogies, comparing, generalizing, and systematizing things heard, observed, and felt.

The great extent of the association areas in the human brain is a somatic expression of man's possession of an associative memory or ability to register and compare sensations far greater than that of the highest ape. The pattern of the fissures and gyres in the brains of the higher anthropoids and man present the same general features in all these types. In the course of evolution, however, the regions known as association areas assumed a greater energy of growth and expanded in proportion to the rise in functional dignity of these areas. They are regions of "unstable equilibrium" which afford greater and more complex associations as mental development
goes on in the species, and concomitant with this great cortical expansion the associating or coordinating fibre systems became more elaborate, complex, and far-reaching.

With the aid of the microscope the maturing of the brain-elements can be followed from the earliest stages of embryonic life to the adult period. The Flechsig method has shown how the function of nerve-fibres within the brain is only established when the myelin-sheath has developed. But this development of mature nerve-fibres does not occur simultaneously throughout the brain, but step by step in a definite order of succession: equally important bundles are myelinated simultaneously, but those of dissimilar importance develop one after another in accordance with Flechsig's law. The successive myelinization of fibre-bundles to and from the cerebral cortex corresponds to the successive awakenings of mental activities and faculties in the growing child. Flechsig's method of investigation has been of great service in the elucidation of the problems of cerebral localization.

Craniocerebral Topography.—The position of the principal fissures and convolution of the cerebrum and their relation to the outer surface of the scalp (Fig. 638) have been the subject of much investigation, and many systems have been devised by which one may localize these parts from an explanation of the external surface of the head.

These plans can only be regarded as approximately correct for several reasons: in the first place, because the relations of the convolutions and fissures to the surface are found to be quite variable in different individuals; secondly, because the surface area of the scalp is greater than the surface area of the brain, so that lines drawn on the one cannot correspond exactly to fissures or convolutions on the other; thirdly, because the fissures and convolutions in two individuals are never precisely alike. Nevertheless, the principal fissures and convolutions can be mapped out with sufficient accuracy for all practical purposes, so that any particular convolution can be generally exposed by removing with the trephine a certain portion of the skull's area. An excellent method is given by Chipault in his Chirurgie opératoire du système nerveux, 1894, vol. 1. The following systems have been the longest in vogue.

The various landmarks on the outside of the skull, which can be easily felt, and which serve as indications of the position of the parts beneath, have been already referred to, and the relation of the fissures and convolutions to these landmarks is as follows:

**Intercerebral or Longitudinal Fissure (Fig. 639).—** This corresponds to a line drawn from the glabella at the root of the nose to the external occipital protuberance.

**The Sylvian Fissure (Fig. 639).—** The position of the sylvian fissure is marked by a line starting from a point 3 cm. horizontally behind the external angular process of the frontal bone to a point 2 cm. below the most prominent point of the parietal eminence. The first 2 cm. will represent the basisylvian fissure, the remainder the sylvian fissure proper. The sylvian point is therefore
5 cm. behind and about 1 cm. above the level of the external angular process. The presylvian ramus of the fissure passes upward from this point parallel to, and immediately behind, the coronal suture.

The Tentorial Hiatus or Transverse Fissure.—This is between the cerebrum and cerebellum and corresponds to a line drawn from the inion to the external auditory meatus (the line $BC$ in Fig. 639).

Central Fissure.—To find the dorsal end of the central fissure, a measurement should be taken from the glabella to the external occipital protuberance. The position of the top of the fissure will be, measuring from in front, 53.6 per cent of the whole distance from the glabella to the external occipital protuberance. Professor Thane adopts a somewhat simpler method. He divides the distance from the glabella to the external occipital protuberance over the top of the head into two equal parts, and, having thus defined the middle point of the vertex, he takes a point half an inch behind it as the top of the sulus. This is not quite so accurate as the former method; but it is sufficiently so for all practical purposes, and on account of its simplicity is very generally adopted. From this point the fissure runs downward and forward for 9 to 10 cm., its axis making an angle of 67 degrees with the middle line. Cunningham states that this angle more nearly averages 71.5 degrees. In order to mark this groove, two strips of metal may be employed—one, the shorter, being fixed to the middle of the other at the angle mentioned. If the longer strip is now placed along the sagittal suture so that the junction of the two strips is over the point corresponding to the top of the furrow, the shorter, oblique strip will indicate the direction and 9 to 10 cm. will mark the length of the furrow. Dr. Wilson has devised an instrument, called a cyrrometer, which combines the scale of measurements for localizing the fissure with data for representing
its length and direction. Professor Thane gives the lower end of the furrow as close to the sylvian fissure, and about 1.5 cm. behind the sylvian point. So that, according to this anatomist, a line drawn from a point 1.5 cm. behind the mid-point between the glabella and external occipital protuberance to this spot would mark out the central fissure. Dr. Reid adopts a different method (Fig. 639). He first indicates on the surface the longitudinal fissure and the sylvian fissure (as above). He then draws two perpendicular lines from his "base-line" (that is, a line from the lowest part of the infraorbital margin through the middle of the external auditory meatus to the back of the head) to the top of the cranium, one (D E, Fig. 639) from the depression in front of the external auditory meatus, and the other (F G, Fig. 639) from the posterior border of the mastoid process at its root. He has thus described on the surface of the head a four-sided figure (F D G E, Fig. 639), and a diagonal line from the posterior superior angle to the anterior perpendicular line where it is crossed by the sylvian fissure will represent the furrow.

The Occipital Fissure on the dorsal surface of the cerebrum runs outward at right angles to the great longitudinal fissure for about 2 to 3 cm., from a point 0.5 cm. in front of the lambda (posterior fontanelle). Reid states that if the sylvian fissure be continued onward to the sagittal suture, the last 2 to 3 cm. of this line will indicate the position of the fissure (Fig. 639).

The Precentral Sulcus begins 2 cm. in front of the middle of the central fissure and extends nearly, but not quite, to the sylvian fissure.

The Supraorbital Fissure runs backward from the supraorbital notch, parallel with the line of the longitudinal fissure to 1 cm. in front of the line indicating the position of the central fissure. The Subfrontal Fissure follows the course of the supertemporal ridge on the frontal bone.

The Intraparietal Fissure, comprising the parietal, subcentral and paroccipital fissures, begins on a level with the junction of the middle and lower third of the central fissure, on a line carried across the head from the back of the root of one occipital to that of the other. After passing upward it curves backward, lying parallel to the longitudinal fissure, midway between it and the parietal eminence; then curves downward to end midway between the posterior fontanelle and the parietal eminence.

Kronlein's method for determining the portions of certain fissures of the brain is very useful and easy of application (Fig. 640). It is as follows: (1) The base line, Z M, is a horizontal line running at the level of the lower border of the orbit and the upper border of the external auditory meatus. (2) Another horizontal line, K K', is drawn parallel to Z M. The second horizontal line is on a level with the supraorbital ridge. (3) A vertical line, Z K, is erected from Z M at the middle of the zygotha and is carried to the line, K K'. (4) Another vertical line, A R, is erected from the base-line at the level of the articulation of the mandible and is carried to R. (5) A third vertical line, M P, is erected from the base-line at the posterior border of the mastoid process and is carried to the middle line of the skull, which is marked P. (6) A line is drawn from K to P. The portion of this line between R and P corresponds to the central fissure. (7) The angle P K K' is bisected by the line K S. K S corresponds to the sylvian fissure, and K is directly over the sylvian point. To reach the anterior branch of the middle meningeal, apply the trephine at K; to reach the posterior branch, apply it at K'. In absence of the temporal lobe the trephine should be applied, according to von Bergmann, in the region Aa K M.

THE MENINGES OR MENINGEAL MEMBRANES OF THE BRAIN (MENINGES ENCEPHALI).

Dissection.—To examine the brain with its membranes, the skull-cap must be removed. In order to effect this, saw through the external table, the section commencing, in front, about 2 cm. (1 in.) above the margin of the orbit, and extending, behind, to a little above the level with the occipital protuberance. Then break the internal table with the chisel and hammer, to avoid injuring the investing membranes or brain; loosen and forcibly detach the skull-cap, and dura will be exposed. The adhesion between the bone and the dura is very intimate, and much more so in the young subject than in the adult.

The membranes of the brain are from without inward: the dura, arachnoid, and the pia.

The Dura of the Brain (Dura Mater Encephali) (Figs. 641, 642, 643, 644).

The dura of the brain is a thick and dense, inelastic, fibrous membrane which lines the interior of the skull. It is a covering for the brain and is also the internal

1 Lancet, 1888, vol. i, p 408.
periosteum. Its outer surface is rough and fibrillated, and adheres closely to the inner surface of the bones by fibrous processes and blood-vessels. The adhesion is most marked on bony projections, opposite the sutures, and at the base of the skull. Except at the sutures the adhesions are not dense, and between the fibrous processes which pass to the bone are spaces which are thought to be lymph-spaces, and are called epidural spaces. At these points the outer surface of the dura is covered with endothelium. Fibrous tissue passes through the open sutures and joins the outer layer of the dura to the external periosteum. It is known as the sutural membrane. The inner surface of the dura limits the subdural space. It is smooth and lined by a layer of endothelium. The dura sends four processes inward, into the cavity of the skull, for the support and protection of the different parts of the brain, and is prolonged to the outer surface of the skull through the various foramina which exist at the base, and thus becomes continuous with the perioranum; its fibrous layer forms sheaths for the nerves which pass through these apertures. At the base of the skull it sends a fibrous prolongation into the foramen caecum; it sends a series of tubular prolongations around the filaments of the olfactory nerves as they pass through the cribiform plate, and also around the nasal nerve as it passes through the nasal slit; a prolongation is also continued through the sphenoidal fissure into the orbit, and another is continued into the same cavity through the optic foramen, forming a sheath for the optic nerve, where it is continued as far as the eyeball. In the posterior fossa it sends a process into the internal auditory

Fig. 641.—The structure of the dura. Section through the cranial vault of a child, slightly enlarged. (Poirier and Charpy.)

meatus, ensheathing the facial and auditory nerves; another through the jugular foramen, forming a sheath for the structures which pass through this opening; and a third through the anterior condyloid foramen. Around the margin of the foramen magnum it is closely adherent to the bone, and is continuous with the dura lining the spinal canal. The cavity or cave of Meckel (caveum Meckeli) (Fig. 641) is an osteo-fibrous recess near the apex of the petrous portion of the temporal bone, formed by folding of the dura in a bony depression. It contains the Gasserian ganglion. In certain situations, as already mentioned (p. 736), the fibrous layers of this membrane separate to form sinuses for the passage of venous blood. Upon the outer surface of the dura, in the situation of the longitudinal sinus, may be seen numerous small, whitish bodies, the arachnoid villi (p. 979).

Structure (Fig. 641).—The dura consists of white fibrous tissue with connective-tissue cells and elastic fibers arranged in flattened laminae, which are imperfectly separated by lacunae spaces and blood-vessels into two layers, endosteal and meningeal. The endosteal layer is the internal periosteum for the cranial bones and contains the blood vessels for their supply. At the margin of the foramen magnum it becomes continuous with the periosteum lining the spinal canal. The meningeal or supporting layer is lined on its inner surface by a layer of nucleated endothelium, similar to that found on serous membranes. By its reduplication the meningeal layer forms the falc, the tentorium and fascula, and the diaphragma sellae. The two layers are connected by fibers which intersect each other obliquely.
The Arteries of the Dura (see section on Arteries).—The arteries of the dura are very numerous, but are chiefly distributed to the bones. Those found in the anterior fossa are the predural branches of the anterior and posterior ethmoidal and internal carotid, and a branch from the medidural or middle meningeal. In the middle fossa are the medi- and parvidural branches of the internal maxillary, a branch from the ascending pharyngeal, which enters the skull through the foramen lacerum medium basis cranii, branches from the internal carotid, and a recurrent branch from the lacrimal. In the posterior fossa are dural branches from the occipital, one of which enters the skull through the jugular foramen, and the other through the mastoid foramen; the postdural or posterior meningeal, from the vertebral; occasionally dural branches from the ascending pharyngeal, which enter the skull, one at the jugular foramen, the other at the anterior condyloid foramen, and a branch from the medidural.

The Veins of the Dura.—The veins which return the blood from the dura (see p. 734), and partly from the bones, anastomose with the diploic veins (see p. 733). These vessels terminate in the various sinuses, with the exception of two which accompany the medidural artery, and pass out of the skull at the foramen spinosum to join the internal maxillary vein; above, the dural veins communicate with the superior longitudinal sinus. The sinuses are considered on pages 736 to 743 inclusive. On either side of the superior longitudinal sinus, especially near its middle, and also near the lateral and straight sinuses, are numerous spaces in the dura which communicate with the sinus, either by a small opening or a distinct venous channel. These spaces are the parasinoidal sinuses (lacunae laterales) (Fig. 642). Many of the dural veins do not open directly into the sinuses, but indirectly through the parasinoidal sinuses. These venous lacunae are often invaginated by arachnoid villi, and they communicate with the underlying cerebral veins, and also with the diploic and emissary veins.

The Lymphatics of the Dura.—The existence of lymphatic vessels is not proved. Some anatomists claim to have injected such vessels along the middle meningeal arteries (Mascagni, Arnold). Perivascular lymph-spaces do exist.

The Nerves of the Dura.—The nerves of the dura are filaments from the trochlear, the ophthalmic division of the trigeminal, the semilunar or Gasserian ganglion, the vagus, the hypoglossal, and the sympathetic.
Processes of the Dura (processus durae matris).—The processes of the dura sent inward into the cavity of the skull, are four in number: the falx, the tentorium, the falcula, and the diaphragma sellae.

The Falx (Figs. 642 and 644).—The falx or falx cerebri, so named from its sickle-like form, is a strong arched process of the dura, which descends vertically in the intercerebral fissure between the two hemispheres of the brain. It is narrow in front, where it is attached to the crista galli of the ethmoid bone, and broad behind, where it is connected with the upper surface of the tentorium. Its upper margin is convex, and attached to the inner surface of the skull, in the middle line, as far back as the internal occipital protuberance; it contains the superior or great longitudinal sinus (sinus sagittalis superior). Its lower margin is free, concave, and presents a sharp, curved edge, which contains the falcial or inferior longitudinal sinus (sinus sagittalis inferior). The tentorial or straight sinus (sinus rectus) is formed by the attachment of the falx to the tentorium.

The Tentorium (Figs. 642, 643, and 644).—The tentorium is an arched lamina of dura, elevated in the middle and slightly inclined toward the circumference. It intervenes between the upper surface of the cerebellum and the occipital lobes of the cerebrum. It is attached, behind, by its convex border to the transverse ridges upon the inner surface of the occipital bone, and there encloses on each side the transverse or lateral sinus (sinus transversus); frontad, to the superior margin of the petrous portion of the temporal bone on either side, there enclosing the superpetrosal sinus (sinus petrosus superior); and at the apex of this bone the free or internal border and the attached or external border meet, and, crossing one another, are continued forward, to be attached to the anterior and posterior clinoid processes respectively. Along the middle line of its upper surface the posterior border of the
falx is attached, the tentorial or straight sinus being placed at their point of junction. Its frontal border is free and concave, and with the dorsum sellae forms a large oval opening. This opening is called the incisura tentorii and transmits the mesencephalon.

The Falcula (Fig. 642).—The falcula is a small triangular process of dura received into the indentation between the two lateral lobes of the cerebellum behind. Its base is attached, above, to the under and back part of the tentorium; its posterior margin, to the lower division of the vertical crest on the inner surface of the occipital bone. As it descends it sometimes divides into two smaller folds, which are lost on the sides of the foramen magnum.

The Diaphragma Sellæ (Fig. 643).—The diaphragma sellae is a horizontal process formed by a reduplication of the meningeal layer of the dura. It forms a small circular fold, which constitutes a roof for the sella turcica. This almost completely covers the hypophysis, presenting merely a small central opening (foramen diaphragmatis sellae) for the passage of the infundibulum.

The Arachnoid (Arachnoidea Encephali) (Fig. 645).

The term arachnoid is from the Greek ἄραχνη εἰδος, like a spider’s web, so named for its extreme thinness. The cranial arachnoid is a delicate membrane which envelops the brain, lying between the pia internally and the dura externally; from this latter membrane it is separated by a very fine slit or space, the subdural space (cavum subdurale). The subdural space contains a very minute quantity of fluid of the nature of lymph. This fluid obtains exit by way of the

**Fig. 644.—Falx and tentorium, left lateral view. (Testut.)**

**Fig. 645.**
parasinoidal sinuses. The subdural space is prolonged upon emerging nerves and joins the lymph spaces of the nerves. The subdural space does not communicate with the subarachnoid space.

The arachnoid invests the brain loosely, being separated from direct contact with the cerebral substance by the pia, and a quantity of loose areolar tissue, the subarachnoidean areolar tissue. On the upper surface of the cerebrum the arachnoid is thin and transparent, and may be easily demonstrated by injecting a stream of air beneath it by means of a blowpipe; it passes over the convolutions without dipping down into the fissures between them, but does pass into the sylvian and intercerebral fissures and is prolonged upon the nerves as a sheath. At the base of the brain the arachnoid is thicker, and slightly opaque toward the central part; it covers the orbital surface of the anterior lobes, and extends across between the two temporal lobes so as to leave a considerable interval between it and the brain, the cisterna basalis.

The Subarachnoid Space (cavum subarachnoideale) (Fig. 646).—The subarachnoid space is the interval between the arachnoid and pia. It is not only on the surface, but dips between the convolutions. It is not, properly speaking, a space, for it is occupied everywhere by a spongy tissue consisting of trabecula of delicate connective tissue covered with endothelium, which pass from the pia to the arachnoid, and in the meshes of which the subarachnoid fluid is contained.
This so-called space is small on the surface of the cerebrum; but at the base of the brain the subarachnoid tissue is less abundant and its meshes larger.

In certain regions the arachnoid and pia are farther apart than was previously indicated, and these spaces are called subarachnoid cisternæ (cisternæ subarachnoïdalis). The largest space is the continuation of the posterior part of the subarachnoid space of the spinal cord. It is called the postcisterna (cisterna cerebellomedullaris). It is a space formed by the arachnoid passing across the back and under portions of the oblongata and cerebellum. It communicates with the fourth ventricle by three foramina. The largest opening is the metapore or foramen of Majendie (apertura medialis ventriculi quarti). It is in the middle line of the metatela. At the end of each recessus lateralis of the fourth ventricle there is also an opening, and each opening is called the foramen of Luschka or of Key and Retzius (apertura lateralis ventriculi quarti). The cisterna pontis is the continuation upward of the anterior part of the subarachnoid space of the cord. About the oblongata it is continuous with the postcisterna, so this important nerve-centre is surrounded by a large subarachnoid space. The crural cisterna or cisterna basalis (cisterna interpeduncularis) is formed by the arachnoid extending between the two temporal lobes, and contains the arteries forming the circulus.

![Diagram](image)

**Fig. 646.—The subarachnoid space. (Schematic.) (Poirier and Charpy.)**

The anterior subarachnoid space (cisterna pontis, interpeduncularis et chiasmatis) includes the cisterna pontis, the cisterna basalis, and the cisterna of the chiasm. There is a cisterna between the inferior edge of the falx and the superior surface of the callosum which contains the precerebral arteries, a cisterna in the sylvian fissure (cisterna sylviana) which contains the precerebral artery, and a cisterna between the quadrigemina which contains the vena magna Galeni.

The cerebro-spinal fluid (coeliolymph; liquor cerebrospinalis) fills the subarachnoid space. It is a clear, limpid fluid, having a saltish taste and a slightly alkaline reaction. According to Lassaigne, it consists of 98.5 parts of water, the remaining 1.5 per cent. being solid matters, animal and saline. It varies in quantity, being most abundant in old persons, and is quickly reproduced. Its chief use is probably to afford mechanical protection to the nervous centres, and to prevent the effects of concussions communicated from without.

**Structure.**—The arachnoid consists of bundles of connective tissue, the fine fibres of which form one layer and cross each other in every direction. At the level of the large fissures, and especially around the circulus, it is reinforced by thick fibrous tissue. Both surfaces are covered with endothelium. There are no blood-vessels in the arachnoid; the vessels which appear to be in it are really in the pia. There is no positive proof that nerves are present in the
arachnoid. It is true that Bochdalek and Luschka long ago described arachnoid nerves, but these observations have never been corroborated.

The Arachnoid Villi or Pacchionian Bodies (Granulationes Arachnoideales).

The arachnoid villi, erroneously called glandulae Pacchioni, are numerous small whitish or purplish projections, usually collected into clusters of variable size, which are found in the following situations: (1) Upon the outer surface of the dura, in the vicinity of the superior longitudinal sinus, being received into little depressions on the inner surface of the calvarium. (2) On the inner surface of the dura. (3) In the superior longitudinal sinus and the other sinuses.

A hasty examination would lead us to suppose that these bodies spring from the dura, but, as a matter of fact, they originate from the arachnoid. They are not glandular in structure, but are simply enlarged normal villi of the arachnoid. In their growth they appear to perforate the dura, and when a group of villi is of large size it causes absorption of the bone, and comes to be lodged in a pit or depression (foveola granularis [Pacchioni]) on the inner table of the skull. Their manner of growth is as follows: At an early period they project through minute holes in the inner layer of the dura, which open into large venous spaces situated in the tissues of the membrane, on either side of the longitudinal sinus and communicating with it. In their onward growth the villi push the outer layer of the dura before them, and this forms over them a delicate membranous sheath. In structure they consist of spongy trabecular tissue, covered over by a membrane, which is continuous with the arachnoid. The space between these two coverings, derived from the dura and arachnoid respectively, corresponds to and is continuous with the subdural space. The spongy tissue of which they are composed is continuous with the trabecular tissue of the subarachnoid space; so that fluid injected into the subarachnoid space finds its way into the Pacchionian bodies, and through their coverings filters into the superior longitudinal sinus. They are supposed to be a means of getting rid of an excess of cerebro-spinal fluid, when its quantity is increased above normal or

![Fig. 647.-Velum. (Poirier and Charpy.)](image-url)
for replenishing the cerebro-spinal fluid from the blood plasma when needed. Another means of getting rid of cerebro-spinal fluid is absorption by the lymph-spaces of the cranial nerves, which possess sheaths of arachnoid up to the points at which they emerge from the skull.

These bodies are not found in infancy, and very rarely until the third year. They are usually found after the tenth year; and from this period they increase in number as age advances. Occasionally they are wanting.

The Pia of the Brain (Pia Mater Encephali) (Figs. 646 and 647).

The pia of the brain is a vascular membrane, and derives its blood from the internal carotid and vertebral arteries. It consists of a minute plexus of blood-vessels, held together by an extremely fine areolar tissue. It invests the entire surface of the brain, dipping down between the convolutions and laminae, and is prolonged into the interior, forming the velum and the choroid plexuses of the lateral and fourth ventricles.
The Velum or the Tela Chorioidea Superior (tela chorioidea ventriculi tertii) (Fig. 647).—The velum is the prolongation of the pia into the interior of the brain through the medium of the transverse fissure. It is a double triangular vascular fold, that lies between the body of the fornix above and the optic thalami and the epithelial roof of the third ventricle below, and passes forward to the porta. At each edge of the velum is the paraplexus or choroid plexus (plexus chorioideus ventriculi lateralis) of the corresponding lateral ventricle. In front the two plexuses join behind the porta, and at the point of junction two lesser choroid plexuses pass back along the under surface of the velum to the third ventricle, the diaplexus or median plexus (plexus chorioideus ventriculi tertii). The velar veins or veins of Galen (p. 947) are two veins which lie on either side of the middle of the velum and pass back. Each velar vein is formed by the union of the vein from the striatum and the choroid vein from the choroid plexuses. The two velar veins unite and form the vena magna (Galen), which empties into the straight sinus.

The pia of the surfaces of the hemispheres, where it covers the gray matter of the convolutions, is very vascular, and gives off from its inner surface a multitude of minute vessels, which extend perpendicularly for some distance into the cerebral substance. At the base of the brain, in the situation of the pre- and post-perforatum, a number of long, straight vessels are given off, which pass through the white substance to reach the gray substance in the interior. On the cerebellum the membrane is more delicate, and the vessels from its inner surface are shorter. The pia of the spinal cord is thicker, firmer, and less vascular than that of the brain, and as it is traced upward over the oblongata it is seen to preserve these characters. At the upper border of the oblongata it is prolonged over the lower half of the fourth ventricle, forming, before it is reflected on to the under surface of the cerebellum, a covering for the fourth ventricle called the metatela or tela chorioidea inferior (tela chorioidea ventriculi quarti); this carries the choroid plexus of the fourth ventricle (plexus chorioideus ventriculi quarti).
The arteries of the pia (see pp. 628, 629, and 630) (Figs. 648 and 649) are the precerebrels, medicerebrels, postcerebrels, prechoroids, postchoroids, the precerebellars, medicerebellars, and posterebellars. (The vessels of the cerebral ganglionic system and of the cortical arterial system are considered on p. 632.)

The veins of the pia (see pp. 734, 735, and 736) are the basilar vein, the velar veins (Fig. 647), the veins constituting the choroid plexuses of the third ventricle, the lateral ventricles, and the fourth ventricle; the cerebral veins (Fig. 645) and the cerebellar veins (Fig. 645).

The nerves of the pia accompany the branches of the arteries and are derived chiefly from the sympathetic. A few fibres are derived from certain cranial nerves, all of which are probably of the afferent variety.

THE SPINAL NERVES (NERVI SPINALES).

The spinal nerves are so called because they apparently originate from the spinal cord, and are transmitted through the intervertebral foramina on either side of the spinal column. There are thirty-one pairs of spinal nerves, which are arranged into the following groups, corresponding to the region of the spine through which they pass:

<table>
<thead>
<tr>
<th>Region</th>
<th>Number of Pairs</th>
</tr>
</thead>
<tbody>
<tr>
<td>Cervical</td>
<td>8 pairs</td>
</tr>
<tr>
<td>Thoracic</td>
<td>12 &quot;</td>
</tr>
<tr>
<td>Lumbar</td>
<td>5 &quot;</td>
</tr>
<tr>
<td>Sacral</td>
<td>5 &quot;</td>
</tr>
<tr>
<td>Coccygeal</td>
<td>1 pair</td>
</tr>
</tbody>
</table>

It will be observed that each group of nerves corresponds in number with the vertebrae in that region, except the cervical and coccygeal. Sometimes there is no thirty-first pair. Occasionally below the thirty-first pair there may be one or even two filamentous pairs which do not pass out of the vertebral canal.

Each spinal nerve arises by two roots, a ventral or motor root and a dorsal or sensor root, the latter being distinguished by a ganglion termed the spinal ganglion.

The Roots of the Spinal Nerves (Figs. 540, 541, 650, 651, 652).

The Ventral Root (radix anterior).—The superficial origin is from the ventro-lateral columns of the cord, corresponding to the situation of the ventral cornu of gray matter. Each root is composed of from four to eight filaments.

The deep origin can be traced from cells in the gray substance of the ventral cornu of the same as well as of the opposite side. The majority of the axones arise from the various groups of cells in the ventral cornu of the same side, while others arise from the large cells of the ventral cornu of the opposite side, the axones passing across the median plane in the ventral white commissure. The axone bundles, after leaving the gray substance, penetrate horizontally through the longitudinal bundles of the ventro-lateral column to emerge as described above.

The Dorsal Root (radix posterior).—The superficial origin is by filaments (filar radiculairia), from the dorso-lateral fissure of the cord. The real origin of these fibres is from the nerve-cells in the dorsal-root ganglion, from which they can be traced into the cord in two main bundles, the course of which has already been studied (p. 849).

The ventral roots are smaller than the dorsal, devoid of ganglionic enlargement,
and their component fibrils are collected into two bundles near the intervertebral foramina.

The dorsal roots of the nerves are larger, but the individual filaments are finer and more delicate than those of the ventral. The cells of the ganglion upon each dorsal root give rise to central and peripheral processes; the central processes constitute the dorsal roots, the peripheral processes are modified dendrites (p. 827) which join the ventral efferent axones and form the spinal nerve trunk ensheathed by a tubular process of the dura and pia.

The dorsal root of the first cervical nerve forms an exception to these characters. It is smaller than the ventral, has occasionally no ganglion developed upon it, and when the ganglion exists it is often situated within the dura. The first cervical may have a rudimentary dorsal root or no dorsal root.

Within the vertebral canal the nerve-roots are separated from each other by the ligamentum denticulatum (Fig. 651). In the cervical region the spinal portion of the accessory nerve separates the roots. Each root obtains a covering of pia, which becomes continuous with the neurilemma; "the arachnoid invests each root as far as the point where it meets with the dura; the two roots, after piercing the dura separately, are enclosed by it in a single tubular sheath, in which is included the spinal ganglion of the dorsal root." (Cunningham.)

The Ganglia of the Spinal Nerves (Ganglia Spinales) (Figs. 650, 651, 652).

A ganglion is developed upon the dorsal root of each of the spinal nerves. The ganglion upon the dorsal root of the first cervical nerve may be rudimentary or absent. These ganglia are of an oval form and of a reddish color; they bear a proportion in size to the nerves upon which they are formed, and are placed in the intervertebral foramina, ectad of the point where the nerves perforate the dura. Each ganglion is bifid internally, where it is joined by the two bundles of the dorsal root, the two portions being united into a single mass externally. The ganglia upon the first and second cervical nerves form an exception to these characters, being placed on the arches of the vertebra over which the nerves pass. The ganglia of the sacral nerves are placed within the vertebral canal; and that on the coccygeal nerve, also in the canal, is situated at some distance from the origin of the dorsal root.

The ganglion in an embryo is composed of bipolar nerve-cells. In an adult the bipolar nerve-cells by fusion of their two poles form unipolar elements. The process of each unipolar cell divides into two a short distance from the cell. One of the processes from each cell passes to the spinal cord, and the other passes into the spinal nerve. On the dorsal roots of the lumbar and sacral nerves, between the spinal ganglia and the cord, small cellular masses occasionally exist. They are called accessory or aberrant ganglia (ganglia aberrantia).
Distribution of the Spinal Nerves.

Immediately beyond the ganglion the two roots coalesce, their fibres intermingle, and the trunk thus formed constitutes the spinal nerve; it passes out of the intervertebral foramen, and divides into a dorsal primary division for the supply of the dorsal part of the body, and a ventral primary division for the supply of the ventral part of the body (Fig. 651). Each division contains fibres from both roots.

![Diagram of spinal nerve constitution](image)

Before dividing, each spinal nerve gives off a small recurrent or meningeal branch (ramus meningeus) (Fig. 651), which is joined by a filament from the communicating branch of the sympathetic (ramus communicans) (Fig. 651), which connects the ganglion with the ventral division. The meningeal branches unite and form one nerve, which passes inward through the intervertebral foramen and supplies the dura, sending branches to the vertebrae and vertebral ligaments.

The Dorsal Primary Divisions (rami posteriores) (Fig. 631).—The dorsal primary divisions of the spinal nerves are generally smaller than the ventral; they arise from the trunk resulting from the union of the roots, in the intervertebral foramina; and, passing dorsad, divide into internal and external branches, which are distributed to the muscles and integument behind the spine. The dorsal primary divisions of the spinal nerves form two smallplexuses, the dorsal cervical plexus and the dorsal sacral plexus. The first cervical, the fourth and fifth sacral, and the coccygeal nerves do not divide into external and internal branches.
The Ventral Primary Divisions (rami anteriores) (Fig. 651).—The ventral primary divisions of the spinal nerves supply the parts of the body ventrad of the spine, including the limbs. They are for the most part larger than the dorsal primary divisions. Each division, soon after its origin, receives a slender filament from the sympathetic, which is called the gray ramus communicans. In the thoracic region the ventral primary divisions of the spinal nerves are quite separate from each other, and are uniform in their distribution; but in the cervical, lumbar, and sacral regions they form intricate plexuses previous to their distribution. The ventral primary divisions of certain thoracic, lumbar, and sacral nerves give off a delicate collection of nerve-filaments to the sympathetic cord. These are called the white rami communicantes or the visceral branches of the spinal nerves.

Points of Emergence of the Spinal Nerves.

The roots of the spinal nerves from their origin in the cord run obliquely caudad to their point of exit from the intervertebral foramina, the amount of obliquity varying in different regions of the spine, and being greater in the lower than the
upper part. The level of their emergence from the cord is within certain limits variable, and of course does not correspond to the point of emergence of the nerve from the intervertebral foramina (Fig. 653).

THE CERVICAL NERVES (NN. CERVICALES).

The Roots of the Cervical Nerves.

The roots of the cervical nerves increase in size from the first to the fifth, and then remain the same size to the eighth. The dorsal roots bear a proportion to the ventral as 3 to 1, which is much greater than in any other region, the individual filaments being also much larger than those of the ventral roots. The dorsal root of the first cervical is an exception to this rule; it is smaller than the ventral root. In direction the roots of the cervical are less oblique than those of the other spinal nerves. The first cervical nerve is directed a little cephalad and ectad; the second is horizontal; the others are directed obliquely caudad and ectad, the lowest being the most oblique, and consequently longer than the upper, the distance between their place of origin and their point of exit from the vertebral canal never exceeding the depth of one vertebra.

The First Cervical or Suboccipital Nerve (n. suboccipitalis) (Fig. 654).—The dorsal root may be rudimentary or absent. The trunk of the first cervical nerve leaves the vertebral canal between the occipital bone and the dorsal arch of the atlas (Figs. 16 and 202).

The Trunk of the Second Cervical Nerve leaves the vertebral canal between the dorsal arch of the atlas and the lamina of the axis; and the eighth (the last) between the last cervical and first thoracic vertebrae.

Each nerve, at its exit from the intervertebral foramen, divides into a dorsal and a ventral division. The ventral divisions of the four upper cervical nerves form the cervical plexus. The ventral divisions of the four lower cervical nerves, together with the first thoracic, form the brachial plexus.

The Dorsal Divisions of the Cervical Nerves (Rami Postiores).

The Dorsal Division of the First Cervical Nerve (Fig. 654) differs from the dorsal divisions of the other cervical nerves in not dividing into an internal and external branch. It is larger than the ventral division, and escapes from the vertebral canal between the occipital bone and the dorsal arch of the atlas, lying beneath the vertebral artery. It enters the suboccipital triangle formed by the Rectus capitis posticus major, the Obliquus superior and Obliquus inferior, and, by muscular branches, supplies the Recti and Obliqui muscles, and the Complexus. From the branch which supplies the Inferior oblique a communicating filament is given off which joins the second cervical nerve. This nerve also occasionally gives off a cutaneous filament, which accompanies the occipital artery and communicates with the occipitalis major and minor nerves.

The Dorsal Division of the Second Cervical Nerve is three or four times greater in diameter than the ventral division, and the largest of all the dorsal cervical divisions. It emerges from the vertebral canal between the dorsal arch of the atlas and lamina of the axis, below the Inferior oblique. It supplies a twig to this muscle, and receives a communicating filament from the first cervical. It then divides into an internal and an external branch.

The internal branch called, from its size and distribution, the great occipital nerve (occipitalis major) (Fig. 654), ascends obliquely inward between the Obliquus
inferior and Complexus, and pierces the latter muscle and the Trapezius near their attachments to the cranium. It is now joined by a filament from the dorsal division of the third cervical nerve, the anastomotic, and, ascending on the back part of the head with the occipital artery, divides into two branches, which supply the integument of the scalp as far forward as the vertex, communicating with the occipitalis minor. It gives off an auricular branch to the back part of the ear and muscular branches to the Complexus.

The external branch is often joined by the external branch of the dorsal division of the third cervical nerve, and supplies the Splenius, Trachelo-mastoid, and Complexus.

The Dorsal Division of the Third Cervical Nerve (Fig. 654) is smaller than the preceding, but larger than the fourth; it differs from the dorsal divisions of the remaining cervical nerves in its supplying an additional filament, the third occipital nerve, to the integument of the occiput. The dorsal division of the third nerve, like the others, divides into an internal and external branch.

The internal or cutaneous branch passes between the Complexus and Semispinalis, and, piercing the Splenius and Trapezius, supplies the skin over the latter muscle.

The external branch joins with that of the dorsal division of the second to supply the Splenius, Trachelo-mastoid, and Complexus.

The third or least occipital nerve (n. occipitalis minimus or n. occipitalis tertius) (Fig. 654) arises from the internal or cutaneous branch of the dorsal division of the third cervical nerve, beneath the Trapezius; it then pierces that muscle, and supplies the skin on the lower and back part of the head. It lies to the inner side of the occipitalis major, with which it is connected.

The dorsal division of the suboccipital nerve and the internal branches of the dorsal divisions of the second and third cervical nerves are occasionally joined beneath the Complexus by communicating branches. This communication is described by Cruveilhier as the dorsal cervical plexus.

The Dorsal Divisions of the Fourth, Fifth, Sixth, Seventh, and Eighth Cervical Nerves pass dorsad, and divide, behind the Intertransversales muscles, into internal and external branches.

The internal branches, the larger, are distributed differently in the upper and lower part of the neck. Those derived from the fourth and fifth nerves pass between the Complexus and Semispinalis muscles, and, having reached the spinous
processes, perforate the aponeurosis of the Splenius and Trapezius, and are continued outward to the integument over the Trapezius, whilst those derived from the three lowest cervical nerves are the smallest, and are placed beneath the Semispinalis colli, which they supply, and then pass into the Interspinalis, Multifidus spinae, and Complexus, and send twigs through this latter muscle to supply the integument near the spinous processes (Hirschfeld).

The external branches supply the muscles at the side of the neck—viz., the Cervicalis ascendens, Transversalis colli, and Trachelo-mastoid.

The Ventral Divisions of the Cervical Nerves (Rami Anteriores).

The Ventral Division of the First Cervical Nerve (Fig. 656) is of small size. It escapes from the vertebral canal through a groove upon the dorsal arch of the atlas. In this groove it lies beneath the vertebral artery, to the inner side of the Rectus capitis lateralis. As it crosses the foramen in the transverse process of the atlas it receives a filament from the sympathetic. It then descends ventrad of the transverse process, to communicate with an ascending branch from the second cervical nerve.

Communicating filaments from the loop between this nerve and the second cervical nerve join the vagus, the hypoglossal, and sympathetic, and some branches are distributed to the Rectus lateralis and the two Anterior recti. The fibres which communicate with the hypoglossal simply pass through the latter nerve to become for the most part the descendens hypoglossi. According to Valentin, the ventral division of the suboccipital nerve distributes filaments to the occipito-atlantal articulation and to the mastoid process of the temporal bone.

The Ventral Division of the Second Cervical Nerve (Fig. 656) escapes from the vertebral canal, between the dorsal arch of the atlas and the lamina of the axis, and, passing forward on the outer side of the vertebral artery, divides ventrad of the Intertransverse muscle into an ascending branch, which joins the first cervical; and one or two descending branches, which join the third cervical. It gives off the small occipital; a branch to assist in forming the great auricular; another to assist in forming the superficial cervical; one of the communicantes hypoglossi, and a filament to the Sterno-mastoid, which communicates in the substance of the muscle with the spinal accessory.

The Ventral Division of the Third Cervical Nerve (Fig. 656) is double the size of the preceding. At its exit from the intervertebral foramen it passes caudad and outward beneath the Sterno-mastoid muscle, and divides into two branches. The ascending branch joins the ventral division of the second cervical; the descending branch passes down ventrad of the Scalenus anticus muscle and communicates with the fourth cervical. It gives off the larger part of the great auricular and superficial cervical nerves; one of the communicantes hypoglossi; a branch to the supraclavicular nerves; a filament to assist in forming the phrenic; and muscular branches to the Levator anguli scapulae and Trapezius; this latter nerve communicates beneath the muscle with the accessory nerve. Sometimes the nerve to the Scalenus medius is derived from this source.

The Ventral Division of the Fourth Cervical Nerve (Fig. 656) is of the same size as the preceding. It receives a branch from the third, sends a communicating branch to the fifth cervical, and, passing caudad and outward, divides into numerous filaments, which cross the dorsal triangle of the neck, forming the supraclavicular nerves. It gives a branch to the phrenic nerve, while it is contained in the intertransverse space, and sometimes a branch to the Scalenus medius muscle. It also gives a branch to the Levator anguli scapulae and to the Trapezius, which unites with the branch given off from the third nerve, and communicates beneath the muscle with the accessory nerve.
The Ventral Divisions of the Fifth, Sixth, Seventh, and Eighth Cervical Nerves are remarkable for their size. They are much larger than the preceding nerves, and are all of equal dimensions. They assist in the formation of the brachial plexus.

The Cervical Plexus (Plexus Cervicalis) (Figs. 655 and 656).

The cervical plexus is formed by the ventral divisions of the four upper cervical nerves. It is situated opposite the four upper cervical vertebrae, resting upon the Levator anguli scapulae and Scalenus medius muscles, and covered in by the Sterno-mastoid.

Its branches may be divided into two groups, superficial and deep, which may be thus arranged:

Superficial

- Ascending
  - Occipitalis minor.
  - Auricularis magnus.
  - Superficialis colli.

- Descending
  - Supracleavicular
  - Supracleavicular.
  - Communicating.
  - Muscular.
  - Communicantes hypoglossi.
  - Phrenic.

Deep

- Internal
  - Communicating.

- External
  - Communicating.
  - Muscular.

The Superficial Branches of the Cervical Plexus. The Small Occipital Nerve (n. occipitalis minor) (Fig. 655).—The small occipital nerve arises from the second cervical nerve, sometimes also from the third; it curves round the dorsal border of the Sterno-mastoid, and ascends, running parallel to the dorsal border of the muscle, to the back part of the side of the head. Near the cranium it perforates the deep fascia, and is continued cephalad along the side of the head behind the ear, supplying the integument, and communicating with the occipitalis major, auricularis magnus, and with the dorsal auricular branch of the facial.

This nerve gives off an auricular branch, which supplies the integument of the upper and back part of the auricle, communicating with the mastoid branch of the auricularis magnus. The auricular branch is occasionally derived from the great occipital nerve. The occipitalis minor varies in size; it is occasionally double.

The Great Auricular Nerve (n. auricularis magnus) (Fig. 655).—The great auricular nerve is the largest of the ascending branches. It arises from the second and third cervical nerves, winds around the dorsal border of the Sterno-mastoid, and, after perforating the deep fascia, ascends upon that muscle beneath the Platysma to the parotid gland, where it divides into facial, auricular, and mastoid branches.

The Facial Branches pass across the parotid, and are distributed to the integument of the face over the parotid gland; others penetrate the substance of the gland and communicate with the facial nerve.

The Auricular Branches ascend to supply the integument of the back of the pinna, except at its upper part, communicating with the auricular branches of the facial and vagus nerves. A filament pierces the pinna to reach its outer surface, where it is distributed to the lobule and lower part of the concha.
The Mastoid Branch communicates with the occipitalis minor and the dorsal auricular branch of the facial, and is distributed to the integument behind the ear.

The Superficial Cervical Nerve or the Superficialis Colli (n. cutaneus colli) (Fig. 655).—The superficial cervical nerve or the superficialis colli arises from the second and third cervical nerves, turns around the dorsal border of the Sterno-mastoid about its middle, and, passing obliquely forward beneath the external jugular vein to the ventral border of the muscle, perforates the deep cervical fascia, and divides beneath the Platysma into two branches, which are distributed to the ventro-lateral parts of the neck.

The Ascending Branch or Branches (rami superiores) gives a filament which accompanies the external jugular vein; it then passes cephalad to the submaxillary region, and divides into branches, some of which form a plexus with the cervical branches of the facial nerve beneath the Platysma; others pierce that muscle and are distributed to the integument of the upper half of the neck, at its forepart, as high as the chin.
The Descending Branches (*rami inferiores*), usually represented by two or more filaments, pierce the Platysma, and are distributed to the integument of the side and front of the neck, as low as the sternum.

**The Descending or Supracleavicularch Branches (nn. *supraclavicales*)** (Fig. 655).— The descending or supraclavicular branches arise from the third and fourth cervical nerves; emerging beneath the dorsal border of the Sterno-mastoid, they descend in the dorsal triangle of the neck beneath the Platysma and deep cervical fascia. Near the clavicle they perforate the fascia and Platysma to become cutaneous, and are arranged, according to their position, into three groups.

The **Internal or Suprasternal Branches (nn. *supraclavicales anteriores*)** cross obliquely over the external jugular vein and the clavicular and sternal attachments of the Sterno-mastoid muscle, and supply the integument as far as the median line. They furnish one or two filaments to the sterno-clavicular joint.

The **Middle or Supracleaviocular Branches (nn. *supraclavicales medii*)** cross the clavicle, and supply the integument over the Pectoral and Deltoid muscles, communicating with the cutaneous branches of the upper intercostal nerves.
THE NERVE SYSTEM

The External or Supra-acromial Branches (nn. supraclaviculares posteriores) pass obliquely across the outer surface of the Trapezius and the acromion, and supply the integument of the upper and back part of the shoulder.

The Deep Branches of the Cervical Plexus (Fig. 656). Internal Series.
The Communicating Branches.—The communicating branches consist of several filaments which pass from the loop between the first and second cervical nerves ventrad of the atlas to the vagus, hypoglossal, and sympathetic; of branches from all four cervical nerves to the superior cervical ganglion of the sympathetic, together with a branch from the fourth to the fifth cervical.

Muscular Branches.—Muscular branches supply the Anterior recti and Rectus lateralis muscles; they proceed from the first cervical nerve, and from the loop formed between it and the second.

The Communicantes Hypoglossi (Fig. 656).—The communicantes hypoglossi consist usually of two filaments, one being derived from the second and the other from the third cervical. These filaments pass caudad on the outer side of the internal jugular vein, cross ventrad of the vein a little below the middle of the neck, and form a loop with the descendens hypoglossi ventrad of the sheath of the carotid vessels. Occasionally, the junction of these nerves takes place within the sheath.

The Phrenic or the Internal Respiratory Nerve of Bell (n. phrenicus) (Figs. 656 and 657).—The phrenic nerve arises chiefly from the fourth cervical nerve, with a few filaments from the third and a communicating branch from the fifth. It descends to the root of the neck, running obliquely across the front of the Scalenus anticus muscle, and beneath the Sterno-mastoid muscle, the posterior belly of the Omohyoid muscle, and the Transversalis colli and suprascapular vessels. It next passes over the first part of the subclavian artery, between it and the subclavian vein, and, as it enters the chest, crosses the internal mammary artery near its origin. Within the chest it descends nearly vertically ventrad of the root of the lung and by the side of the pericardium, between it and the mediastinal portion of the pleura, to the Diaphragm, where it divides into branches, some few of which are distributed to its thoracic surface, but most of which separately pierce that muscle and are distributed to its under surface (rami phrenicoabdominales). A ramus pericardicus is distributed to the pericardium. The two phrenic nerves differ in their length, and also in their relations at the upper part of the thorax.

The right phrenic nerve is situated more deeply, and is shorter and more vertical in direction than the left; it lies on the outer side of the right vena innominata and postcava.

The left phrenic nerve is farther longer than the right, from the inclination of the heart to the left side, and from the Diaphragm being lower on this than on the opposite side. It enters the thorax behind the left innominate vein, and crosses ventrad of the vagus and the arch of the aorta and the root of the lung. In the thorax each phrenic nerve is accompanied by a branch of the internal mammary artery, the comes nervi phrenici.

Each nerve supplies filaments to the Diaphragm, pericardium, and pleura, and near the chest is joined by a filament from the sympathetic, and, occasionally, by one from the union of the descendens hypoglossi with the spinal nerves; this filament is found, according to Swan, only on the left side. The phrenic frequently receives a filament from the nerve to the Subclavius muscle. Branches have been described as passing to the peritoneum.

From the right nerve one or two filaments pass to join in a small ganglion with phrenic branches of the solar plexus; and branches from this ganglion are distributed to the hepatic plexus, the adrenal gland, and postcava.

From the left nerve filaments pass to join the phrenic plexus of the sympathetic, but without any ganglionic enlargement.
Surgical Anatomy.—Irritation of the phrenic nerve causes hiccup and persistent cough. Bilateral paralysis of the phrenic causes death from paralysis of the Diaphragm. This form of death is seen by the surgeon in fracture-dislocation of the third cervical vertebra. Division of the phrenic on one side is not fatal, and is occasionally practised by the surgeon in removing a tumor of the neck. In Hearn's and Franklin's cases of removal of the vagus, the phrenic was also divided. Unilateral division of the phrenic nerve causes paralysis of the corresponding half of the Diaphragm, which is difficult of recognition, because, as Gowers points out, the patient can still take deep inspirations, the thoracic muscles not being paralyzed.

The Deep Branches of the Cervical Plexus. External Series. Communicating Branches.—The deep branches of the external series of the cervical plexus communicate with the accessory nerve, in the substance of the Sterno-mastoid muscle, in the dorsal triangle, and beneath the Trapezius.

Muscular Branches.—Muscular branches are distributed to the Sterno-mastoid, Trapezius, Levator anguli scapulae, and Scalenus medius. The branch for the Sterno-mastoid is derived from the second cervical; the Trapezius and Levator anguli scapulae receive branches from the third and fourth.
The Scalenus medius is derived sometimes from the third, sometimes the fourth, and occasionally from both nerves.

**Surgical Anatomy.**—The cervical plexus may be damaged by wounds or contusions, which may or may not be associated with fracture of the clavicle. Paralysis ensues, the extent depending on the degree of damage. After a contusion the paralysis is apt to be temporary and to be followed by pain and muscular spasm in the arm. Paralysis of the arm due to plexus injury may be partial or complete. In some cases there is complete motor palsy and partial sensor palsy, the sensor impulses passing along undamaged collaterals. In certain spasmatic difficulties the surgeon occasionally stretches the cervical plexus. It is reached by an incision at the dorsal margin of the Sternocleidomastoid muscle. This incision begins two inches below the level of the tip of the mastoid and is carried downward for three inches.

![Diagram of the Nerve System](image)

**The Brachial Plexus (Plexus Brachialis) (Figs. 658, 659, 660).**

The brachial plexus is formed by the union of the ventral divisions of the four lower cervical and the greater part of the first thoracic nerves, receiving usually a fasciculus from the fourth cervical nerve, and frequently one from the second thoracic nerve. It extends from the lower part of the side of the neck to the axilla. It is very broad, and presents little of a plexiform arrangement at its commencement. It is narrow opposite the clavicle, becomes broad and forms a more dense interlacement in the axilla, and divides opposite the coracoid process into numerous branches for the supply of the upper limb. The nerves which form the plexus are all similar in size, and their mode of communication is subject to considerable variation, so that no one plan can be given as applying to every case.¹ The follow-

¹ Kerr, Bardeen, and Elting, from a study of 175 brachial plexuses, recognized seven types. In 58 percent, the outer cord was formed from the fourth to the seventh, the inner cord from the eighth to the ninth spinal nerves, and the dorsal or posterior cord from the fourth to the ninth. In 30 percent, the outer cord was formed from the fifth to the seventh, the inner cord from the eighth to the ninth, and the dorsal cord from the fifth to the ninth.
ing appears, however, to be the most constant arrangement: above the clavicle (pars supraclavicularis) the fifth and sixth cervical unite soon after their exit

**Fig. 659.**—The right brachial plexus (infraclavicular portion) in the axillary fossa, viewed from below and in front. The pectoralis major and minor muscles have been in large part removed; their attachments have been reflected. (Spalteholz.)

**Fig. 660.**—Plan of the brachial plexus. (Gerrish.)
from the intervertebral foramina to form a common trunk. The eighth cervical and first thoracic also unite to form one trunk. So that the nerves forming the plexus, as they lie on the Scalenus medius ectad to the outer border of the Scalenus anticus muscle, are blended into three trunks—an upper one, formed by the junction of the fifth and sixth cervical nerves; a middle one, consisting of the seventh cervical nerve; and a lower one, formed by the junction of the eighth cervical and first thoracic nerves. As they pass beneath the clavicle, to compose the infraclavicular part of the plexus (pars infraclavicularis), each of
these three trunks divides into two branches, a ventral and a dorsal.¹ The ventral divisions of the upper and middle trunks then unite to form a common cord, which is situated on the outer side of the middle part of the axillary artery, and is called the outer cord of the brachial plexus (fasciculus lateralis). The ventral division of the lower trunk passes caudad on the inner side of the axillary artery in the middle of the axilla, and forms the inner cord of the brachial plexus (fasciculus medialis). The dorsal divisions of all three trunks unite to form the dorsal cord of the brachial plexus (fasciculus posterior), which is situated behind the second portion of the axillary artery. From this dorsal cord are given off the two lower subscapular nerves, the upper subscapular nerve being given off from the dorsal division of the upper trunk prior to its junction with the dorsal division of the lower and middle trunks. The dorsal cord divides into the circumflex and musculospiral nerves.

The brachial plexus communicates with the cervical plexus by a branch from the fourth to the fifth cervical nerve, and with the phrenic nerve by a branch from the fifth cervical, which joins that nerve on the Anterior scalenus muscle; the fifth and sixth cervical nerves are joined by filaments to the middle cervical ganglion of the sympathetic, the seventh and eighth cervical to its inferior ganglion, and the first thoracic nerve to its first thoracic ganglion. Close to their exit from the intervertebral foramina the nerves give off the filaments to the ganglia.

¹ The dorsal division of the lower trunk is very much smaller than the others, and is frequently derived entirely from the eighth cervical nerve.—Ed. of 15th English edition.
**Relations.**—In the neck, the brachial plexus lies in the posterior triangle, being covered by the skin, Platysma, and deep fascia; it is crossed by the posterior belly of the Omo-hyoid muscle and by the transversalis colli artery. When the dorsal scapular artery arises from the third part of the subclavian it usually passes between the roots of the plexus. The plexus lies at first between the Anterior and Middle scaleni muscles, and then above and to the outer side of the subclavian artery; it next passes behind the clavicle and Subclavius muscle, lying upon the first serration of the Serratus magnus, and the Subscapularis muscles. It is in close relation with the apex of the lung (Luschka). In the axilla it is placed on the outer side of the first portion of the axillary artery; it surrounds the artery in the second part of its course, one cord lying upon the outer side of that vessel, one on the inner side, and one behind it, and at the lower part of the axillary space gives off its terminal branches to the upper extremity.

**Branches.**—The branches of the brachial plexus are arranged in two groups—viz., those given off above the clavicle, and those below the clavicle.

**Branches above the Clavicle** (Figs. 658 and 660).—The branches above the clavicle, from the pars supracleavicularis, are—

- Communicating.
- Muscular.
- Long thoracice.
- Suprascapular.

**The Communicating Branch** (Figs. 657 and 660).—The communicating branch with the phrenic is derived from the fifth cervical nerve or from the loop between the fifth and sixth; it joins the phrenic on the Anterior scalenus muscle. The communications with the sympathetic have already been referred to.

**The Muscular Branches** (*rami musculares*).—The muscular branches supply the Longus colli, Scaleni, Rhomboidei, and Subclavius muscles. Those for the
Longus colli and Scaleni arise from the four lower cervical nerves at their exit from the intervertebral foramina. The Rhomboid branch, called the dorsal
scapular nerve (n. dorsalis scapulae) (Figs. 658 and 660), arises from the fifth cervical, pierces the Scaenus medius, and passes beneath the Levator anguli scapulae, which it occasionally supplies, to the Rhomboid muscles. The nerve to the Subclavius (n. subclavius) is a small filament which arises from the fifth cervical at its point of junction with the sixth nerve; it descends in front of the third part of the subclavian artery to the Subclavius muscle, and is usually connected by a filament with the phrenic nerve.

The Long Thoracic or the External Respiratory Nerve of Bell or Posterior Thoracic Nerve (n. thoracis longus) (Figs. 658, 659, 660, and 665).—The long thoracic supplies the Serratus magnus muscle, and is remarkable for the length of its course. It sometimes arises by two roots from the fifth and sixth cervical nerves immediately after their exit from the intervertebral foramina, but generally by three roots from the fifth, sixth, and seventh nerves. These unite in the substance of the Middle scalenus muscle, and, after emerging from it, the nerve passes caudad behind the brachial plexus and the axillary vessels, resting on the outer surface of the Serratus magnus. It extends along the side of the chest to the lower border of that muscle, supplying filaments to each of the muscular digitations.

The Suprascapular Nerve (n. suprascapularis) (Figs. 658, 660, and 665).—The suprascapular nerve arises from the cord formed by the fifth and sixth cervical nerves; passing obliquely outward beneath the Trapezius and the Omo-hyoid, it enters the suprascapular fossa below the transverse or suprascapular ligament, and, passing beneath the Supraspinatus muscle, curves around the external border of the spine of the scapula to the infraspinous fossa. In the suprasciposus fossa it gives off two branches to the Supraspinatus muscle, and an articular filament to the shoulder-joint; and in the infraspinous fossa it gives off two branches to the Infraspinatus muscle, besides some filaments to the shoulder-joint and scapula.

Branches below the Clavicle (Figs. 659 and 660).—The branches below the clavicle, that is, the branches from the pars subclavicularis of the brachial plexus, are derived from the three cords of the brachial plexus, in the following manner:

From the Outer Cord.—From the outer cord arise the external anterior thoracic nerve, the musculo-cutaneous, and the outer head of the median.

From the Inner Cord.—From the inner cord arise the internal anterior thoracic nerve, the medial nerve of the forearm or internal cutaneous, the medial nerve of the upper arm or lesser internal cutaneous (nerve of Wrisberg), the ulnar, and inner head of the median.

From the Dorsal Cord.—From the dorsal cord arise two of the three subscapular nerves, the third taking origin from the dorsal division of the trunk formed by the fifth and sixth cervical nerves; the cord then divides into the musculo-spiral and circumflex nerves.

These branches from below the clavicle may be arranged according to the parts they supply:

To the chest . . . . . . . . . . Anterior thoracic.

To the shoulder . . . . . . . . . .

To the arm, forearm, and hand . . . .

Anterior thoracic.

Subscapular.

Circumflex.

Musculo-cutaneous.

Internal cutaneous or medial nerve of the upper arm.

Lesser internal cutaneous or medial nerve of the forearm.

Median.

Ulnar.

Musculo-spiral.
The fasciculi of which these nerves are composed may be traced through the plexus to the spinal nerves from which they originate. They are as follows:

<table>

</table>

**NOTE.**—In this the reconstructive period of anatomic nomenclature the terms "anterior" and "posterior" are yet retained in the description of the relations of structures in the extremities, for "ventral" and "dorsal" are not uniformly applicable in the same strict sense as in the trunk and neck regions. Further, the designations "in front of" and "behind" are applied only to the position of structures when the body is standing erect and with the volar surface of the hand turned "forward." The employment of the word "dorsum" for the back of the hand is already quite general.

**The Anterior Thoracic Nerves** *(nn. thoracales anteriores)* *(Figs. 658, 659, and 660).*—The anterior thoracic nerves, two in number, supply the Pectoral muscles.

The **External** or **Superficial Anterior Thoracic Nerve** *(Figs. 658 and 665)*, the larger of the two, *arises* from the outer cord of the brachial plexus, through which its fibres may be traced to the fifth, sixth, and seventh cervical nerves. It passes inward, across the axillary artery and vein, pierces the costo-coracoid membrane, and is distributed to the under surface of the Pectoralis major muscle. It sends caudal a communicating filament to join the internal anterior thoracic nerve, and this communicating filament forms a loop around the inner side of the axillary artery.

The **Internal** or **Deep Anterior Thoracic Nerve** *arises* from the inner cord and through it from the eighth cervical and first thoracic nerves. It passes behind the first part of the axillary artery, then curves forward between the axillary artery and vein, and joins with the filament from the anterior nerve. It then passes to the under surface of the Pectoralis minor muscle, where it divides into a number of branches, which supply the muscle on its under surface. Some two or three branches pass through the muscle and reach the Pectoralis major.

The **Subscapular Nerves** *(nn. subscapulares)* *(Figs. 659 and 660).*—The subscapular nerves *arise* from the dorsal cord of the plexus. There are three subscapular nerves, and they supply the Subscapularis, Teres major, and Latissimus dorsi muscles, and give filaments to the shoulder-joint. The fasciculi of which they are composed may be traced to the fifth, sixth, seventh, and eighth cervical nerves.

The **First, Short, or Upper Subscapular Nerve**, the smallest, *arises* from the dorsal division of the upper trunk of origin of the brachial plexus, and enters the upper part of the Subscapularis muscle; this nerve is frequently represented by two branches.

The **Second or Lower Subscapular Nerve** *arises* from the dorsal cord of the brachial plexus, enters the axillary border of the Subscapularis and terminates in the Teres major. The latter muscle is sometimes supplied by a separate branch.
The Third, Middle or Long Subscapular Nerve (n. thoracodorsalis) (Fig. 659), the largest of the three, arises from the dorsal cord of the brachial plexus and follows the course of the subscapular artery, along the dorsal wall of the axilla to the Latissimus dorsi muscle, through which it may be traced as far as its lower border.

The Circumflex Nerve (n. axillaris) (Figs. 660 and 666).—The circumflex nerve supplies some of the muscles, the shoulder-joint, and the integument of the shoulder (Figs. 661 and 662). It arises from the dorsal cord of the brachial plexus, in common with the musculo-spiral nerve, and its fibres may be traced through the dorsal cord to the fifth and sixth cervical nerves. It is at first placed behind the axillary artery, between it and the Subscapularis muscle, and passes caudad and outward to the lower border of that muscle. It then winds dorsal in company with the posterior circumflex artery, through a quadrilateral space bounded above by the Teres minor muscle, below by the Teres major muscle, internally by the long head of the Triceps muscle, and externally by the neck of the humerus. The nerve then divides into two branches.

The Upper Branch (Fig. 666) winds dorsad around the surgical neck of the humerus, beneath the Deltoid, with the posterior circumflex vessels, as far as the anterior border of that muscle, supplying it, and giving off cutaneous branches, which pierce the muscle and ramify in the integument covering its lower part (Fig. 663).

The Lower Branch (Fig. 666), at its origin, distributes filaments to the Teres minor and back part of the Deltoid muscles. Upon the filaments to the former muscle an oval enlargement usually exists. The nerve then pierces the deep fascia, and supplies the integument over the lower two-thirds of the posterior surface of the Deltoid (n. cutaneus brachii lateralis), as well as that covering the long head of the Triceps (caput longum n. tricipitis brachii) (Fig. 664).

The circumflex nerve, before its division, gives off an articular filament, which enters the shoulder-joint below the Subscapularis muscle.

The Musculo-cutaneous or the External Cutaneous Nerve or the Perforating Nerve of Casserius¹ (n. musculocutaneus) (Figs. 659, 660, and 665).—The musculo-cutaneous or the external cutaneous nerve supplies some of the muscles of the arm and the integument of the forearm. It arises from the outer cord of the brachial plexus, opposite the lower border of the Pectoralis minor muscle, receiving filaments from the fifth, sixth, and seventh cervical nerves. It perforates the coraco-brachialis muscle (Fig. 665), passes obliquely between the Biceps and Brachialis anticus muscles to the outer side of the arm, and, a little above the elbow, winds around the outer border of the tendon of the Biceps, and, perforating the deep fascia, becomes cutaneous (Fig. 661). This nerve, in its course through the arm, supplies the Coraco-brachialis, Biceps, and the greater part of the Brachialis anticus muscles. The branch to the Coraco-brachialis is given off from the nerve close to its origin, and in some instances, as a separate filament from the outer cord of the plexus. The branches to the Biceps and Brachialis anticus are given off after the nerve has pierced the Coraco-brachialis. The nerve also sends a small branch to the humerus, which enters the nutrient foramen with the accompanying artery, and a filament from the branch supplying the Brachialis anticus, goes to the elbow-joint. The musculo-cutaneous furnishes the chief nerve supply to this joint.

The Cutaneous Portion of the Musculo-cutaneous Nerve (n. cutaneus antibrachii lateralis) passes behind the median cephalic vein, and divides, opposite the elbow-joint, into an anterior and a posterior branch.

The anterior branch descends along the radial border of the forearm to the wrist, and supplies the integument over the outer half of the anterior surface. At

¹ See foot-note, page 1042.
THE BRACHIAL PLEXUS

the wrist-joint it is placed in front of the radial artery, and some filaments, piercing the deep fascia, accompany that vessel to the dorsum of the wrist, supplying the carpus. The nerve then passes distal to the ball of the thumb, where it terminates in cutaneous filaments. It communicates with a branch from the radial nerve and with the palmar cutaneous branch of the median.

The posterior branch passes distal along the back part of the radial side of the forearm to the wrist. It supplies the integument of the lower third of the forearm, communicating with the radial nerve and the external cutaneous branch of the musculo-spiral. The cutaneous areas supplied by the musculo-cutaneous nerve are indicated in Figs. 663 and 664.

The musculo-cutaneous nerve presents frequent irregularities. It may adhere for some distance to the median and then pass outward, beneath the Biceps, instead of through the Coraco-brachialis. Frequently some of the fibres of the median run for some distance in the musculo-cutaneous and then leave it to join their proper trunk. Less frequently the reverse is the case, and the median sends a branch to joint the musculo-cutaneous. Instead of piercing the Coraco-brachialis muscle the nerve may pass under it or through the Biceps. Occasionally it gives a filament to the Pronator radii teres muscle, and it has been seen to supply the back of the thumb when the radial nerve was absent.

The Internal Cutaneous Nerve (n. cutaneus antibrachii medialis) (Figs. 659, 660, and 663).—The internal cutaneous nerve or medial cutaneous nerve of the forearm is one of the smallest branches of the brachial plexus. It arises from the inner cord in common with the ulnar nerve and internal head of the median nerve, and, at its commencement, is placed on the inner side of the axillary artery, and afterward of the brachial artery. It derives its fibres from the eighth cervical and first thoracic nerves. It passes down the inner side of the arm, pierces the deep fascia with the basilic vein, about the middle of the limb, and, becoming cutaneous, divides into two branches, anterior and posterior.

This nerve gives off, near the axilla, a cutaneous filament, which pierces the fascia and supplies the integument covering the Biceps muscle nearly as far as the elbow. This filament lies a little external to the common trunk, from which it arises.

The anterior branch, the larger of the two, passes usually in front of, but occasionally behind, the median basilic vein. It then descends on the anterior surface of the ulnar side of the forearm, distributing filaments to the integument as far as the wrist, and communicating with a cutaneous branch of the ulnar nerve (Fig. 661).

The posterior branch passes obliquely distal on the inner side of the basilic vein, passes in front of, or over, the internal condyle of the humerus to the back of the forearm, and descends on the posterior surface of its ulnar side as far as the wrist, distributing filaments to the integument (Fig. 662). It communicates, above the elbow, with the lesser internal cutaneous nerve, and above the wrist with the dorsal cutaneous branch of the ulnar nerve (Swan). The cutaneous areas supplied by the internal cutaneous nerve are indicated in Figs. 663 and 664.

The Lesser Internal Cutaneous Nerve or the Nerve of Wrisberg (n. cutaneus brachii medialis) (Figs. 659, 660, and 665).—The lesser internal cutaneous nerve or medial cutaneous nerve of the upper arm is distributed to the integument on the inner side of the arm. It is the smallest of the branches of the brachial plexus, and, arising from the inner cord, receives its fibres from the first thoracic nerve. It passes through the axillary space, at first lying behind, and then on the inner side of the axillary vein, and communicates with the intercosto-brachial nerve. It descends along the inner side of the brachial artery to the middle of the arm, where it pierces the deep fascia, and is distributed to the integument of the back of the lower third of the arm, extending as far as the elbow (Figs. 661, 662, and
663), where some filaments are lost in the integument ventrad of the inner condyle, and others over the olecranon. It communicates with the posterior branch of the internal cutaneous nerve.

In some cases the nerve of Wrisberg and the intercosto-brachial or intercosto-humeral nerve are connected by two or three filaments which form a plexus at the back part of the axilla. In other cases the intercosto-brachial is of large size, and takes the place of the nerve of Wrisberg, receiving merely a filament of communication from the brachial plexus, which filament represents the latter nerve. In other cases this filament is wanting, the place of the nerve of Wrisberg being supplied entirely by the intercosto-brachial.

The Median Nerve (n. medianus) (Figs. 659, 660, and 665).—The median nerve has received its name from the course it takes along the middle of the arm and forearm to the hand, lying between the ulnar and musculo-spiral nerves, and the ulnar and the radial nerves. It arises by two roots, one from the outer and one from the inner cord of the brachial plexus; these embrace the lower part of the axillary artery, uniting either in front or on the outer side of that vessel. The median nerve receives filaments from the sixth, seventh, and eighth cervical and the first thoracic nerves and sometimes from the fifth cervical as well. As it descends through the arm, it lies at first on the outer side of the brachial artery, crosses that vessel in the middle of its course, usually in front, but occasionally behind it, and lies on its inner side to the bend of the elbow, where it is placed beneath the bicipital fascia, and is separated from the elbow-joint by the Brachialis anticus muscle. In the forearm it passes between the two heads of the Pronator radii teres muscle, and descends beneath the Flexor sublimis muscle, lying on the Flexor profundus muscle, to within two inches (3 cm.) above the annular ligament, where it becomes more superficial, lying between the tendons of the Flexor sublimis and Flexor carpi radialis muscles, beneath, and rather to the radial side or under the tendon of the Palmaris longus, covered by the integument and fascia. It then passes through the carpal canal (canalis carpi) beneath the annular ligament into the hand. In its course through the forearm it is accompanied by the arteria comnis nervi mediani, a branch of the anterior interosseous artery.

Branches.—With the exception of the nerve to the Pronator radii teres muscle, which sometimes arises above the elbow-joint, and filaments to the elbow-joint, the median nerve gives off no branches in the arm. In the forearm its branches are muscular, anterior interosseous, and palmar cutaneous, and two articular twigs to the elbow-joint.

The Muscular Branches (rami musculares) supply all the superficial muscles on the front of the forearm except the Flexor carpi ulnaris. These branches are derived from the nerve near the elbow.

The Volar Interosseous or Anterior Interosseous (n. interosseus [antibrachii] volaris) (Fig. 665) supplies the deep muscles on the front of the forearm, except the inner half of the Flexor profundus digitorum. It accompanies the volar interosseous artery along the interosseous membrane, in the interval between the Flexor longus pollicis and Flexor profundus digitorum muscles, both of which it supplies, and terminates below in the Pronator quadratus muscle, sending filaments to the inferior radio-ulnar articulation and the wrist-joint.

The Palmar Cutaneous Branch (ramus cutaneus palmaris n. mediani) arises from the median nerve at the lower part of the forearm. It pierces the fascia above the annular ligament, and, descending over that ligament, divides into two branches; of which the outer branch supplies the skin over the ball of the thumb, and communicates with the anterior cutaneous branch of the musculo-cutaneous nerve; and the inner branch supplies the integument of the palm of the hand, communicating with the cutaneous branch of the ulnar.

In the palm of the hand the median nerve is covered by the integument and palmar fascia and is crossed by the superficial palmar arch. It rests upon the
tendons of the flexor muscles. In this situation it becomes enlarged, somewhat flattened, of a reddish color, and divides into two branches. Of these, the **external branch** supplies a muscular branch to some of the muscles of the thumb and digital branches to the thumb and index finger; the **internal branch** supplies digital branches to the contiguous sides of the index and middle and of the middle and ring fingers. The digital branches, before they subdivide, are called **common palmar digital branches of the median nerve** (nn. digitales volares communes).

The branch to the muscles of the thumb (ramus muscularis) is a short nerve which divides to supply the Abductor, Opponens, and the superficial head of the Flexor brevis pollicis muscles, the remaining muscles of this group being supplied by the ulnar nerve.

The **Collateral Palmar Digital** or the **Digital Branches** (nn. digitales volares proprii) are five in number. The **first** and **second** pass along the borders of the thumb, the external branch communicating with branches of the radial nerve. The **third** passes along the radial side of the index finger, and supplies the First lumbricalis muscle. The **fourth** subdivides to supply the adjacent sides of the index and middle fingers, and sends a branch to the Second lumbricalis muscle. The **fifth** supplies the adjacent sides of the middle and ring fingers, and communicates with a branch from the ulnar nerve.

Each digital nerve, opposite the base of the first phalanx, gives off a dorsal branch, which joins the dorsal digital nerve from the radial nerve and runs along the side of the dorsum of the finger, to end in the integument over the last phalanx. At the end of the finger the digital nerve divides into a palmar and a dorsal branch, the former of which supplies the extremity of the finger, and the latter ramifies around and beneath the nail. The digital nerves, as they run along the fingers, are placed superficial to the digital arteries. The cutaneous areas supplied by the median nerve are shown in Figs. 663 and 664.

**The Ulnar Nerve** (n. ulnaris) (Figs. 659, 660, and 665).—The ulnar nerve is placed along the inner or ulnar side of the upper limb, and is distributed to the muscles and integument of the forearm and hand. It is smaller than the median, behind which it is placed, diverging from it in its course down the arm. It **arises** from the inner cord of the brachial plexus, in common with the inner head of the median and the internal cutaneous nerve, and derives its fibres from the eighth cervical and first thoracic nerves. At its commencement it lies to the inner side of the axillary artery, and holds the same relation with the brachial artery to the middle of the arm. From this point it runs obliquely across the internal head of the Triceps, pierces the internal intermuscular septum, and descends to the groove between the internal condyle and the olecranon, accompanied by the inferior profunda artery. **At the elbow** it rests upon the back of the inner condyle, and passes into the forearm between the two heads of the Flexor carpi ulnaris muscle. **In the forearm** it descends in a perfectly straight course along the ulnar side of the extremity, lying upon the Flexor profundus digitorum muscle, its upper half being covered by the Flexor carpi ulnaris muscle, its lower half lying on the outer side of the muscle, being covered by the integument and fascia. The ulnar artery, in the upper third of its course, is separated from the ulnar nerve by a considerable interval, but in the rest of its extent the nerve lies to its inner side. **At the wrist** the ulnar nerve crosses the annular ligament on the outer side of the pisiform bone, to the inner side of and a little behind the ulnar artery, and immediately beyond this bone divides into two branches, the superficial and the deep palmar.

**Branches.**—The branches of the ulnar nerve are—

In the forearm

- Articular.
- Muscular.
- Cutaneous.
- Dorsal cutaneous.

In the hand

- Superficial palmar.
- Deep palmar.
The **Articular Branches** distributed to the elbow-joint consist of several small filaments. They arise from the nerve as it lies in the groove between the inner condyle of the humerus and the olecranon process of the ulnar.

The **Muscular Branches** (*rami musculares*) are two in number—one supplying the Flexor carpi ulnaris; the other, the inner half of the Flexor profundus digitorum. They arise from the trunk of the nerve near the elbow.

The **Cutaneous Branch** arises from the ulnar nerve about the middle of the forearm, and divides into two branches.

One branch (frequently absent) pierces the deep fascia near the wrist, and is distributed to the integument, communicating with a branch of the internal cutaneous nerve.

The second branch, the **palmar cutaneous** (*ramus cutaneus palmaris*) lies on the ulnar artery, which it accompanies to the hand, some filaments entwining around the vessel; it ends in the integument of the palm, communicating with branches of the median nerve.

The **Dorsal Cutaneous Branch** (*ramus dorsalis manus*) arises about two inches above the wrist; it passes dorsal beneath the Flexor carpi ulnaris muscle, perforates the deep fascia, and, running along the ulnar side of the back of the wrist and hand, divides into branches (*nn. digitales dorsales*); one of these supplies the inner side of the little finger; a second supplies the adjacent sides of the little and ring fingers; a third joins the branch of the radial nerve which supplies the adjoining sides of the middle and ring fingers, and assists in supplying these parts; a fourth is distributed to the metacarpal region of the hand, communicating with a branch of the radial nerve.

On the little finger the dorsal digital branches extend only as far as the base of the terminal phalanx, and on the ring finger as far as the base of the second phalanx; the more distal parts of these digits are supplied by dorsal branches derived from the palmar digital branches of the ulnar.

The **Superficial Palmar Branch** (*ramus superficialis n. ulnaris*) supplies the Palmaris brevis and the integument on the inner side of the hand, and terminates in two digital branches, which are distributed, one to the ulnar side of the little finger, the other to the adjoining sides of the little and ring fingers, the latter communicating with a branch from the median. The digital branches are distributed to the fingers in the same manner as the digital branches of the median.

The **Deep Palmar Branch** (*ramus profundus n. ulnaris*), accompanied by the deep branch of the ulnar artery, passes between the Adductor and Flexor brevis minimi digitii muscles; it then perforates the Opponens minimi digitii and follows the course of the deep palmar arch beneath the flexor tendons. At its origin it supplies the muscles of the little finger. As it crosses the deep part of the hand it sends two branches to each intersosseous space, one for the Dorsal and one for the Palmar intersosseous muscle, the branches to the Second and Third palmar intersosseal supplying filaments to the two inner Lumbrical muscles. At its termination between the thumb and index finger, it supplies the Adductores transversus et obliquus pollicis and the inner head of the Flexor brevis pollicis. It also sends articular filaments to the wrist-joint, and to the bones and joints of the hand.

It will be remembered that the inner part of the Flexor profundus digitorum muscle is supplied by the ulnar nerve; the two inner Lumbricales, which are connected with the tendons of this part of the muscle, are therefore supplied by the same nerve. The outer part of the Flexor profundus is supplied by the median nerve; the two outer Lumbricales, which are connected with the tendons of this part of the muscles, are therefore supplied by the same nerve. Brooks states that in twelve instances out of twenty-one he found that the third lumbrical received a twig from the median nerve, in addition to its branch from the ulnar. The palmar branches of the ulnar which go to the fingers are called by
Toldt before division common palmar digital branches, and after division collateral palmar digital branches. The cutaneous areas supplied by the ulnar nerve are shown in Figs. 663 and 664.

The Musculo-spiral Nerve (n. radiolus) (Figs. 660, 665, and 666).—The musculospiral nerve, the largest branch of the brachial plexus, supplies the muscles of the back part of the arm and forearm, and the integument of the same parts, as well as that of the back of the hand (Figs. 663 and 664). It arises from the posterior cord of the brachial plexus, of which it may be regarded as the continuation. It receives filaments from the sixth, seventh, and eighth, and sometimes also from the fifth cervical and first thoracic nerves. At its commencement it is placed behind the axillary artery and the upper part of the brachial artery, passing down in front of the tendons of the Latissimus dorsi and Teres major muscles. It winds around the humerus in the musculo-spiral groove with the superior profunda artery, passing from the inner to the outer side of the bone, between the internal and external heads of the Triceps muscle (Fig. 666). It pierces the external intermuscular septum, and descends between the Brachialis anticus and Supinator longus muscles to the front of the external condyle of the humerus, where it sends filaments to the elbow-joint and divides into the radial and posterior interosseous nerves.

Branches.—The branches of the musculo-spiral nerve are—

Cutaneous.

The Muscular Branches (rami musculares n. radialis) are divided into internal, posterior, and external; they supply the Triceps, Aneoneus, Supinator longus, Extensor carpi radialis longior, and Brachialis anticus muscles. These branches are derived from the nerve at the inner side, back part, and outer side of the arm.
The **internal muscular branches** supply the inner and middle heads of the Triceps muscle. That to the inner head of the Triceps is a long, slender filament which lies close to the ulnar nerve, as far as the lower third of the arm, and is therefore frequently spoken of as the **ulnar collateral branch**.

The **posterior muscular branch**, of large size, arises from the nerve in the groove between the Triceps muscle and the humerus. It divides into branches which supply the outer and inner heads of the Triceps and the Anconeus muscles. The branch for the latter muscle is a long, slender filament which descends in the substance of the Triceps to the Anconeus.

The **external muscular branches** supply the Supinator longus, Extensor carpi radialis longior, and (usually) the outer part of the Brachialis anticus muscles.

The **Cutaneous Branches** are three in number, one **internal** and two **external**.

The **internal cutaneous branch** (n. cutaneus brachii posterior) arises in the axillary space with the inner muscular branch. It is of small size, and passes through the axilla to the inner side of the arm, supplying the integument on its posterior aspect nearly as far as the olecranon. In its course it crosses beneath the intercosto-brachial nerve, with which it communicates.

The **external cutaneous branch** (n. cutaneus antibrachii dorsalis) divides into two branches, and each one perforates the outer head of the Triceps muscle at its attachment to the humerus. The **upper** and smaller one passes to the front of the elbow, lying close to the cephalic vein, and supplies the integument of the lower half of the arm on its anterior aspect. The **lower branch** pierces the deep fascia below the insertion of the Deltoid muscle, and passes down along the outer side of the arm and elbow, and then along the back part of the radial side of the forearm to the wrist, supplying the integument in its course, and joining, near its termination, with the posterior cutaneous branch of the musculo-cutaneous nerve.

The **Radial Nerve** (ramus superficialis n. radialis) (Fig. 665), passes along the front of the radial side of the forearm to the commencement of its lower third. It lies at first a little to the outer side of the radial artery, concealed beneath the Supinator longus muscle. In the middle third of the forearm it lies beneath the same muscle, in close relation with the outer side of the artery. It leaves the artery about three inches above the wrist, passes beneath the tendon of the Supinator longus muscle, and, piercing the deep fascia at the outer border of the forearm, divides into two branches.

The **external branch**, the smaller of the two, supplies the integument of the radial side and ball of the thumb, joining with the anterior branch of the musculo-cutaneous nerve.

The **internal branch** communicates, above the wrist, with the posterior cutaneous branch from the musculo-cutaneous, and on the back of the hand forms an arch with the dorsal cutaneous branch of the ulnar nerve. It then divides into four **digital nerves** (nn. digitales dorsales), which are distributed as follows: The first supplies the ulnar side of the thumb; the second, the radial side of the index finger; the third, the adjoining sides of the index and middle fingers; and the fourth, the adjacent borders of the middle and ring fingers.¹ The latter nerve communicates with a filament from the dorsal branch of the ulnar nerve.

The **Dorsal or Posterior Interosseous Nerve** (n. interosseus [antibrachii]dorsalis) (Figs. 665 and 666).—The dorsal interosseous nerve winds to the back of the forearm around the outer side of the radius, passes between the two planes of fibres of the Supinator brevis muscle, and is prolonged distad between the superficial and deep layer of muscles, to the middle of the forearm. Considerably diminished in size, it descends on the interosseous membrane, beneath the Extensor longus pollicis muscle, to the back of the carpus, where it presents a gangliform

---

¹ According to Hutchinson, the digital nerve to the thumb reaches only as high as the root of the nail; the one to the forefinger as high as the middle of the second phalanx, and the one to the middle and ring fingers not higher than the first phalangeal joint (London Hospital Gazette, vol. iii, p. 319).—En. 18th English edition.
enlargement from which filaments are distributed to the inferior radio-ulnar articulation, to the wrist-joint, and to the ligaments and articulations of the carpus. It supplies all the muscles of the radial and posterior brachial regions, excepting the Anconeus, Supinator longus, and Extensor carpi radialis longior.

**Surgical Anatomy.**—The brachial plexus may be ruptured by traction on the limb, leading to complete paralysis. Bristow has reported three cases of avulsion of the plexus and has described twenty-four cases. In these cases it is generally believed that the lesion is rather a tearing away of the nerves from the spinal cord than a solution of continuity of the nerve-fibres themselves. In a case operated upon by Bristow it was found that the plexus had given way where the four cervical nerves and the first thoracic nerve unite to form three trunks. In supraclavicular division of the brachial plexus, not only will there be motor and sensor paralysis in the limb, but the Serratus magnus muscle will probably be paralyzed, because of injury to the dorsal thoracic nerves. In the axilla any of the nerves forming the brachial plexus may be injured by a wound of this part, the median being the one which is most frequently damaged from its exposed position. The musculo-spiral, on account of its sheltered and deep position, is least often wounded. The brachial plexus in the axilla is often damaged from the pressure of a crutch, producing the condition known as *crutch paralysis*. In these cases the musculo-spiral is the nerve most frequently implicated; the ulnar nerve being the one that appears to suffer next in frequency.

The *circumflex nerve* is of particular surgical interest. On account of its course around the surgical neck of the humerus, it is liable to be torn in fractures of this part of the bone, and in dislocations of the shoulder-joint, leading to paralysis of the deltoid, and, according to Erb, inflammation of the shoulder-joint is liable to be followed by a neuritis of this nerve from extension of the inflammation to it.

Mr. Hilton takes the circumflex nerve as an illustration of a law which he lays down, that “the same trunks of nerves whose branches supply the groups of muscles moving a joint furnish also a distribution of nerves to the skin over the insertions of the same muscles, and the interior of the joint receives its nerves from the same source.” In this way he explains the fact that an inflamed joint becomes rigid, because the same nerves which supply the interior of the joint supply the muscles which move that joint.

The *median nerve* is liable to injury in wounds of the forearm. When paralyzed, there is loss of flexion of the second phalanges of all the fingers and of the terminal phalanges of the index and middle fingers. Flexion of the terminal phalanges of the ring and middle fingers can still be effected by that portion of the Flexor profundus digitorum which is supplied by the ulnar nerve. There is power to flex the proximal phalanges through the Interossei. The thumb cannot be flexed or opposed, and is maintained in a position of extension and adduction. All power of pronation is lost. The wrist can be flexed, if the hand is first adducted, by the action of the Flexor carpi ulnaris. There is loss or impairment of sensation on the palmar surface of the thumb, index, middle, and outer half of the ring fingers, and on the dorsal surface of the same fingers over the last two phalanges; except in the thumb, where the loss of sensation is limited to the back of the last phalanx. In order to expose the median nerve for the purpose of *stretching* it an incision should be made along the radial side of the tendon of the Palmaris longus muscle, which serves as a guide to the nerve.

The *ulnar nerve* is liable to be injured in wounds of the forearm. When paralyzed, there is loss of power of flexion in the ring and little fingers; there is impaired power of ulnar flexion and adduction of the hand; there is inability to spread out the fingers from paralysis of the Interossei; and there is inability to adduct the thumb. The fingers cannot be flexed at the first joints, and cannot be extended at the other joints. A *claw-hand* develops, the first phalanges being overextended and the others flexed. Sensation is lost or impaired in the skin of the ulnar side of the hand anteriorly and posteriorly, involving the little finger, the ring finger, and the ulnar half of the middle finger posteriorly, and anteriorly involving the little finger and the ulnar half of the ring finger. In order to expose the nerve in the lower part of the forearm, an incision should be made along the outer border of the tendon of the Flexor carpi ulnaris, and the nerve will be found lying on the ulnar side of the ulnar artery.

The *musculo-spiral nerve* is probably more frequently injured than any other nerve of the upper extremity. In consequence of its close relationship to the humerus as it lies in the musculo-spiral groove, it is frequently torn or injured in fractures of this bone, or subsequently involved in the callus that may be thrown out around a fracture, and thus pressed upon and its functions interfered with. It is also liable to be squeezed against the bone by kicks or blows and it may be divided by wounds of the arm. When paralyzed, the hand is flexed at the wrist and lies flaccid. This condition is known as *drop-wrist*. The fingers are also flexed, and on an attempt being made to extend them the last two phalanges only will be extended through the action of the Interossei, the first phalanges remaining flexed. There is no power of extending the wrist. Supination is completely lost when the forearm is extended on the arm, but is.

---

1 Annals of Surgery, September, 1902.
possible to a certain extent if the forearm is flexed so as to allow of the action of the Biceps. The power of extension of the forearm is lost on account of paralysis of the Triceps. Loss of sensation may be considerable or slight. Its area is shown in Fig. 664. The best position in which to expose the nerve for the purpose of stretching is to make an incision along the inner border of the Supinator longus muscle, just above the level of the elbow-joint. The skin and superficial structures are to be divided and the deep fascia exposed. The white line in this structure indicating the border of the muscle is to be defined, and the deep fascia divided in this line. By now raising the Supinator longus the nerve will be found lying beneath it, on the Brachialis anticus muscle.

Post-anesthetic paralysis. When a person emerges from the influence of a general anesthetic palsy of the arm may be found to exist. The brachial plexus may have been compressed during the operation by drawing the arm strongly from the body or elevating it by the side of the head. In such a case the plexus was compressed by the head of the humerus (Braun).

The median nerve is stretched when the arm is rotated externally and drawn backward and outward. The ulnar nerve is stretched when the forearm is flexed and supinated (Braun). Garrigues believes that in most cases of post-anesthetic paralysis the brachial plexus was squeezed between the collar bone and the first rib by the head of the patient being drawn to the opposite side or being allowed to fall back.

THE THORACIC NERVES (NN. THORACALES).

The thoracic nerves are twelve in number on each side. The first appears between the first and second thoracic vertebrae, and the last between the last thoracic and first lumbar.

The Roots of the Thoracic Nerves.

The roots of the thoracic nerves are of small size, and vary but slightly from the second to the last. Both roots are very slender, the dorsal roots slightly exceeding the ventral in thickness. They gradually increase in length from above downward, and in the lower part of the thoracic region pass down in contact with the spinal cord for a distance equal to the height of at least two vertebrae, before they emerge from the vertebral canal. They then join in the intervertebral foramen, and at their exit divide into two primary divisions, a dorsal (posterior) and a ventral (intercostal).

The Dorsal Divisions of the Thoracic Nerves (Rami Posteriores).

The dorsal divisions of the thoracic nerves are smaller than the ventral, pass dorsal between the transverse processes, and divide into medial or internal and lateral or external branches.

The Medial Branches.—The medial branches of the six upper nerves pass inward between the Semispinalis dorsi and Multifidius spine muscles, which they supply, and then, piercing the origins of the Rhomboidei and Trapezius muscles, become cutaneous by the side of the spinous processes and ramify in the integument. The medial branches of the six lower nerves are distributed to the Multifidus spine, without giving off any cutaneous filaments.

The Lateral Branches.—The lateral branches increase in size from above caudal. They pass through the Longissimus dorsi muscle to the cellular interval between it and the Iliocostalis muscle, and supply those muscles, as well as their continuations cephalad to the head, and also the Levatores costarum muscles; the five or six lower nerves also give off cutaneous filaments, which pierce the Serratus posticus inferior and Latissimus dorsi muscles in a line with the angles of the ribs, and then ramify in the integument.

The Cutaneous Branches.—The cutaneous branches of the dorsal primary divisions of the thoracic nerves are twelve in number. From each ramus medialis of the upper six nerves comes a ramus cutaneus medialis, and from each ramus
lateralis of the lower six nerves comes a ramus cutaneus lateralis. The six upper cutaneous nerves are derived from the medial branches of the dorsal divisions of the thoracic nerves. They pierce the origins of the Rhomboidei and Trapezius muscles, and become cutaneous by the side of the spinous processes, and then ramify in the integument. They are frequently furnished with gangliform enlargements. The six lower cutaneous nerves are derived from the lateral branches of the dorsal divisions of the thoracic nerves. They pierce the Serratus posticus inferior and Latissimus dorsi muscles in a line with the angles of the ribs, and then ramify in the integument.

The Ventral Divisions of the Thoracic Nerves or the Intercostal Nerves (Rami Anteriores).

The ventral divisions of the thoracic nerves or the intercostal nerves (nn. intercostales) are twelve in number on each side. They are, for the most part, distributed to the parietes of the thorax and abdomen, separately from each other, without being joined in a plexus; in which respect they differ from the other spinal nerves. Each nerve is connected with the adjoining ganglion of the sympathetic by one or two filaments (ramus communicans). The intercostal nerves may be divided into two sets, from the difference they present in their distribution. The six upper, with the exception of the first and the intercosto-brachial branch of the second, are limited in their distribution to the parietes of the chest. The six lower supply the parietes of the chest and abdomen, the last one sending a cutaneous filament to the buttock.

The Ventral Division of the First Thoracic Nerve.—The ventral division of the first thoracic nerve divides into two branches: one, the larger, leaves the thorax ventrad of the neck of the first rib, and enters into the formation of the brachial plexus; the other and smaller branch runs along the first intercostal space, forming the first intercostal nerve (n. intercostalis I), giving off muscular branches, and terminates on ventral part of the chest by forming the first ventral cutaneous nerve (ramus cutaneus anterior n. intercostalis I) of the thorax. Occasionally this ventral cutaneous branch is wanting. The first intercostal nerve, as a rule, gives off no lateral cutaneous branch, but sometimes a small branch is given off which communicates with the intercosto-brachial. It frequently receives a connecting twig from the second thoracic nerve, which passes upward over the neck of the second rib.

The Ventral Divisions of the Upper Thoracic Nerves (nn. intercostales).

—The ventral divisions of the second, third, fourth, fifth, and sixth thoracic nerves and the small branch from the first thoracic are confined to the parietes of the thorax, and are named upper or pectoral intercostal nerves. They pass forward in the intercostal spaces with the intercostal vessels, being situated below them. At the back of the chest they lie between the pleura and the External intercostal muscle, but are soon placed between the two planes of Intercostal muscles as far as the middle of the rib. They then enter the substance of the Internal intercostal muscles, and, running amidst their fibres as far as the costal cartilages, they gain the inner surface of the muscles and lie between them and the pleura. Near the sternum, they cross ventrad of the internal mammary artery and Triangularis sterni muscle, pierce the Internal intercostal muscles, the anterior intercostal membrane, and Pectoralis major muscle, and supply the integument of ventral wall of the chest and over the mammary gland, forming the ventral cutaneous nerves of the thorax; the branch from the second nerve is joined with the suprACLAVICULAR nerves of the cervical plexus.

Branches.—Numerous slender muscular filaments (rami musculares) supply the Intercostals, the InfraCostales, the Levatores costarum, Serratus posticus superior,
and Triangularis sterni muscles. Some of these branches, in the ventral wall of the chest, cross the costal cartilages from one to another intercostal space.

**Lateral Cutaneous Nerves of the Thorax** (*rami cutanei laterales* [*pectorales]*) (Fig. 659).—These are derived from the intercostal nerves, midway between the vertebrae and sternum; they pierce the External intercostal and Serratus magnus muscles, and divide into two branches, **ventral** and **dorsal**.

The **Ventral Branches** (*rami anteriores*) are reflected forward to the side and the forepart of the chest, supplying the integument of the chest and mamma; those of the fifth and sixth nerves supply the upper digitations of the External oblique muscle.

The **Dorsal Branches** (*rami posteriores*) are reflected dorsad to supply the integument over the scapula and over the Latissimus dorsi muscle.

The **Lateral Cutaneous Branch of the Second Intercostal Nerve** (*n. intercosto-brachialis*) is of large size, and does not divide, like the other nerves, into a ventral and dorsal branch. It may unite with a branch of the third intercostal. The single nerve or the united nerve is named, from its origin and distribution, the
intercosto-brachial or intercosto-humeral nerve (Figs. 659 and 665). It pierces the External intercostal muscle, crosses the axilla to the inner side of the arm, and joins with a filament from the medial cutaneous nerve of the upper arm (nerve of Wrisberg). It then pierces the fascia, and supplies the skin of the upper half of the inner and back part of the arm (Figs. 663 and 664), communicating with the internal cutaneous branch (n. cutaneus antibrachii medialis) of the musculo-spiral nerve. The size of this nerve is in inverse proportion to the size of the other cutaneous nerves, especially the nerve of Wrisberg. A second intercosto-brachial nerve is frequently given off from the third intercostal. It supplies filaments to the armpit and inner side of the arm. It may or may not send a branch to the intercosto-brachial.

The Ventral Divisions of the Lower Thoracic Nerves.—The ventral divisions of the seventh, eighth, ninth, tenth, and eleventh thoracic nerves are continued ventrad from the intercostal spaces into the abdominal wall, and the twelfth thoracic is continued throughout its whole course in the abdominal wall, since it is placed below the last rib; hence these nerves are named lower or abdominal intercostal nerves. They have (with the exception of the last) the same arrangement as the upper ones as far as the anterior extremities of the intercostal spaces, where they pass behind the costal cartilages, and between the Internal oblique and Transversalis muscles, to the sheath of the Rectus, which they perforate. They supply the Rectus muscle, and terminate in branches which become subcutaneous near the linea alba. These branches are named the ventral or anterior cutaneous nerves of the abdomen. They are directed outward as far as the lateral cutaneous nerves, supplying the integument of the front of the belly. The lower intercostal nerves supply the Intercostals, Serratus posticus inferior, and Abdominal muscles, and, about the middle of their course, give off lateral cutaneous branches which
pierce the External intercostal and External oblique muscles, in the same line as the lateral cutaneous nerves of the thorax, and divide into ventral and dorsal branches, which are distributed to the integument of the abdomen and back; the ventral branches supply the digitations of the External oblique muscle and extend caudal and forward nearly as far as the margin of the Rectus muscle; the dorsal branches pass dorsad to supply the skin over the Latissimus dorsi muscle.

The Last Thoracic Nerve.—The last thoracic is larger than the other thoracic nerves. Its ventral division runs along the lower border of the last rib, and passes under the external arcuate ligament of the Diaphragm. It then runs ventrad of the Quadratus lumborum muscle, perforates the Transversalis muscle, and passes distad between it and the Internal oblique muscle, to be distributed in the same manner as the lower intercostal nerves. It communicates with the iliohypogastric branch of the lumbar plexus, and is frequently connected with the first lumbar nerve by a slender branch, the thoraco-lumbar nerve, which descends in the substance of the Quadratus lumborum muscle. It gives a branch to the Pyramidalis muscle.

The Cutaneous Branches.—There are two cutaneous branches, a ventral and a lateral.

The Ventral Cutaneous Branch is a terminal branch and is a direct prolongation of the intercostal. It supplies an area of skin of the abdominal wall between the umbilicus and pubis.

The Lateral Cutaneous Branch (ramus cutaneus lateralis [abdominalis] intercostalis XII) is remarkable for its large size; it perforates the Internal and External oblique muscles, passes over the crest of the ilium ventrad of the iliac branch of the iliohypogastric, and is distributed to the integument of the front part of the glutal region, some of its filaments extending as low down as the trochanter major. It does not divide into a ventral and a dorsal branch, like the other lateral cutaneous branches of the intercostal nerves.

Surgical Anatomy.—The lower seven intercostal nerves and the iliohypogastric from the first lumbar nerve supply the skin of the abdominal wall. They run caudal and inward fairly equidistant from each other. The sixth and seventh supply the skin over the “pit of the stomach,” the eighth corresponds to about the position of the middle line transversa; the tenth to the umbilicus; and the iliohypogastric supplies the skin over the pubes and external abdominal ring. There are several points of surgical significance about the distribution of these nerves, and it is important to remember their origin and course, for in many diseases affecting the nerve-trunks at or near their origin the pain is referred to their peripheral origins. Thus in Pott’s disease of the spine children will often be brought to the surgeon suffering from pain in the belly. This is due to the fact that the nerves are irritated at the seat of disease as they issue from the spinal canal. When the irritation is confined to a single pair of nerves, the sensation complained of is often a feeling of constriction, as if a cord were tied around the abdomen; and in these cases the situation of the sense of constriction may serve to localize the disease in the spinal column. In other cases, where the bone disease is more extensive and two or more nerves are involved, a more diffused pain in the abdomen is complained of. A similar condition is sometimes present in affections of the cord itself, as in tabes dorsalis.

Again, it must be borne in mind that the same nerves which supply the skin of the abdomen supply also the muscles which constitute the greater part of the abdominal wall. Hence, it follows that any irritation applied to the peripheral terminations of the cutaneous branches in the skin of the abdomen is immediately followed by reflex contraction of the abdominal muscles. A good practical illustration of this may sometimes be seen in watching two surgeons examine the abdomen of the same patient. One, whose hand is cold, causes the muscles of the abdominal wall to at once contract and the belly to become rigid, and thus not nearly so suitable for examination; the other, who has taken the precaution to warm his hand, examines the abdomen without exciting any reflex contraction. The supply of both muscles and skin from the same source is of importance in protecting the abdominal viscera from injury. A blow on the abdomen, even of a severe character, will do no injury to the viscera if the muscles are in a condition of firm contraction; whereas in cases where the muscles have been taken unawares, and the blow has been struck while they were in a state of rest, an injury insufficient to produce any lesion of the abdominal wall has been attended with rupture of some of the abdominal contents. The importance, therefore, of immediate reflex contraction upon the receipt of an injury.
THE VENTRAL DIVISIONS OF THE LUMBAR NERVES

cannot be overestimated, and the intimate association of the cutaneous and muscular fibres in the same nerve produces a much more immediate response on the part of the muscles to any peripheral stimulation of the cutaneous filaments than would be the case if the two sets of fibres were derived from independent sources.

Again, the nerves supplying the abdominal muscles and skin are derived from the lower intercostal nerves and are intimately connected with the sympathetic supplying the abdominal viscera through the lower thoracic ganglia from which the splanchnic nerves are derived. In consequence of this, in rupture of the abdominal viscera and in acute peritonitis the muscles of the belly-wall become firmly contracted, and thus as far as possible preserve the abdominal contents in a condition of rest.

THE LUMBAR NERVES (NN. LUMBALES).

The lumbar nerves are five in number on each side. The first lumbar nerve appears between the first and second lumbar vertebrae, and the last between the last lumbar vertebra and the base of the sacrum.

The Roots of the Lumbar Nerves.

The roots of the lumbar nerves are the largest, and their filaments the most numerous, of all the spinal nerves, and they are closely aggregated together upon the lower end of the cord. The ventral roots are the smaller, but there is not the same disproportion between them and the dorsal roots as in the cervical nerves. The roots of these nerves have a vertical direction, and are of considerable length, more especially the lower ones, since the spinal cord does not extend beyond the first lumbar vertebra. The roots become joined in the intervertebral foramina, and the nerves so formed divide at their exit into two divisions, dorsal and ventral.

The Dorsal Divisions of the Lumbar Nerves (Rami Posteriores).

The dorsal divisions of the lumbar nerves diminish in size from above downward; they pass dorso-laterad between the transverse processes, and divide into medial and lateral branches.

The Medial Branches (rami mediales).—The medial branches, the smaller, pass inward close to the articular processes of the vertebrae, and supply the Multifidus spine and Interspinales muscles.

The Lateral Branches (rami laterales).—The lateral branches supply the Erector spinae and Intertransverse muscles. From the three upper branches cutaneous nerves are derived which pierce the aponeurosis of the Latissimus dorsi muscle and descend over the dorsum of the crest of the ilium, to be distributed to the integument of the gluteal region, some of the filaments passing as far as the trochanter major (Fig. 672).

The dorsal division of the fifth lumbar nerve usually sends a branch which forms a loop with the dorsal division of the first sacral nerve.

The Ventral Divisions of the Lumbar Nerves (Rami Anteriores).

The ventral divisions of the lumbar nerves increase in size from above caudad. At their origin they communicate with the lumbar ganglia of the sympathetic by long, slender filaments, which accompany the lumbar arteries around the sides of the bodies of the vertebrae, beneath the Psoas muscle. The nerves pass obliquely outward behind the Psoas magnus or between its fasciculi, distributing filaments to it and the Quadratus lumborum. The ventral divisions of the five lumbar, five sacral, and first coccygeal nerve constitute the lumbo-sacral plexus (plexus lumbosacralis). This is subdivided into the lumbar plexus, the sacral plexus, and the pudendal plexus. The ventral divisions of the four upper nerves.
are connected together in this situation by anastomotic loops, and form the lumbar plexus. The ventral division of the fifth lumbar, joined with a branch from the fourth, descends across the base of the sacrum to join the ventral division of the first sacral nerve and assists in the formation of the sacral plexus. The cord resulting from the union of the fifth lumbar and the branch from the fourth is called the lumbo-sacral cord (truncus lumbosacralis) (Figs. 670 and 675).

**The Lumbar Plexus (Plexus Lumbalis) (Figs. 669, 670).**

The lumbar plexus is formed by the loops of communication between the ventral divisions of the four upper lumbar nerves. The plexus is narrow above, and often connected with the last thoracic nerve by a slender branch, the dorsi-lumbar nerve. The plexus is broad below, where it is joined to the sacral plexus by the lumbo-sacral cord. The lumbar plexus is situated in the substance of the Psoas muscle near its dorsal part, in front of the transverse processes of the lumbar vertebrae.

The mode in which the plexus is arranged varies in different subjects.\(^1\) It differs from the brachial plexus in not forming an intricate interlacement, but the several nerves of distribution arise from one or more of the spinal nerves in the following manner: The first lumbar nerve receives a branch from the last thoracic, gives off a larger branch, which subdivides into the ilio-hypogastric and ilio-inguinal nerves; the first lumbar also gives off a communicating branch which passes down to the second lumbar nerve, and a third branch which unites with a branch of the second lumbar, to form the genito-femoral nerve. The second, third, and fourth lumbar nerves divide into ventral and dorsal divisions. The ventral division of the second divides into two branches, one of which joins with the above-mentioned branch of the first nerve to form the genito-femoral; the other unites with the ventral division of the third nerve, and a part of the ventral division of the fourth nerve to form the obturator nerve. The remainder of the ventral division of the fourth nerve passes down to communicate with the fifth lumbar nerve. The dorsal divisions of the second and third nerves divide into two branches, a smaller branch from each uniting to form the lateral or external cutaneous nerve, and a larger branch from each, which join the whole of the dorsal division of the fourth lumbar nerve to form the femoral or anterior crural nerve. The accessory obturator, when it exists, is formed by the union of two small branches given off from the third and fourth nerves.

From this arrangement it follows that the ilio-hypogastric and ilio-inguinal are derived entirely from the first lumbar nerve; the genito-femoral from the first

---

\(^1\) For statistical studies of the variations encountered in different individuals, see the article by Bardeen in the American Journal of Anatomy.
and second nerves; the lateral cutaneous from the second and third; the femoral and obturator by fibres derived from the second, third, and fourth; and the accessory obturator, when it exists, from the third and fourth.

**Branches** (Figs. 669 and 670).—The branches of the lumbar plexus are—the

- Ilio-hypogastric.
- Ilio-inguinal.
- Genito-femoral.
- Lateral cutaneous.
- Obturator.
- Accessory obturator.
- Femoral (Anterior crural).

**The Ilio-hypogastric Nerve** (*n. iliohypogastricus*) (Figs. 669 and 670).—The ilio-hypogastric nerve *arises* from the first lumbar nerve. It emerges from the outer border of the Psoas muscle at its upper part, and crosses obliquely ventrad of the Quadratus lumborum to the crest of the ilium. It then perforates the Transversalis muscle dorsally near the crest of the ilium. It gives off **muscular branches** (*rami musculares*) to the abdominal wall, and divides between the Transversalis and the Internal oblique into two cutaneous branches, **iliac** and **hypogastric**.

---

**Fig. 670.**—The lumbar plexus and its branches.

The **Iliac Branch** (*ramus cutaneus lateralis*) pierces the Internal and External oblique muscles immediately above the crest of the ilium, and is distributed to the integument of the gluteal region, behind the lateral cutaneous branch of the last thoracic nerve (Fig. 676). The size of this nerve bears an inverse proportion to that of the cutaneous branch of the last thoracic nerve.
The Hypogastric Branch (ramus cutaneus anterior) (Fig. 671) continues onward between the Internal oblique and Transversalis muscles. It then pierces the Internal oblique, and becomes cutaneous by perforating the aponeurosis of the External oblique, about an inch (2 cm.) above and a little lateral of the external abdominal ring, and is distributed to the integument of the hypogastric region. The ilio-hypogastric nerve communicates with the last thoracic and ilio-inguinal nerves.

The Ilio-inguinal Nerve (n. ilioinguinalis) (Figs. 669, 670, and 671).—The ilio-inguinal nerve, smaller than the preceding, arises with it from the first lumbar nerve. It emerges from the outer border of the Psoas muscle just below the ilio-hypogastric nerve, and, passing obliquely across the Quadratus lumborum and Iliacus muscles, perforates the Transversalis near the forepart of the crest of the ilium, and communicates with the ilio-hypogastric nerve between that muscle and the Internal oblique. The nerve then pierces the Internal oblique, distributing muscular branches (rami musculares) to it, and, accompanying the spermatic cord through the external abdominal ring, is distributed to the integument of the upper and inner part of the thigh, and to the scrotum in the male (nn. scrotales anteriores) and to the labium majus in the female (nn. labiales anteriores). The size of this nerve is in inverse proportion to that of the ilio-hypogastric. Occasionally it is very small, and ends by joining the ilio-hypogastric; in such cases a branch from the ilio-hypogastric takes the place of the ilio-inguinal, or the ilio-inguinal nerve may be altogether absent.

The Genito-femoral or Genito-crural Nerve (n. genitofemoralis) (Figs. 669 and 670) arises from the first and second lumbar nerves. It passes obliquely through the substance of the Psoas muscle, and emerges from its inner border at a level corresponding to the intervertebral substance between the third and fourth lumbar vertebrae; it then descends on the surface of the Psoas muscle, under cover of the peritoneum, and divides into a genital and a femoral branch.

The Genital Branch or External Spermatic Nerve (n. spermaticus externus) passes outward on the Psoas magnus, and pierces the fascia transversalis, or passes through the internal abdominal ring; in the male it then descends along the back part of the spermatic cord to the scrotum, and supplies the Cremaster muscle. In the female it accompanies the round ligament, and is lost upon it.

The Femoral Branch or Lumbo-inguinal Nerve (n. lumboinguinalis) (Fig. 671) descends on the external iliac artery, sending a few filaments around it, and, passing beneath Poupart's ligament to the thigh, enters the sheath of the femoral vessels, lying superficial and a little external to the femoral artery. It pierces the anterior layer of the sheath of the vessels, and, becoming superficial by passing through the fascia lata, it supplies the skin of the anterior aspect of the thigh as far as midway between the pelvis and knee. On the front of the thigh it communicates with the outer branch of the middle cutaneous nerve, derived from the femoral nerve. A few filaments from this nerve may be traced on to the femoral artery; they are derived from the nerve as it passes beneath Poupart's ligament.

The Lateral Cutaneous Nerve (n. cutaneus femoris lateralis) (Figs. 669, 670, 671, and 672).—The lateral cutaneous nerve arises from the second and third lumbar nerves. It emerges from the outer border of the Psoas muscle about its middle, and crosses the Iliacus muscle obliquely, toward the anterior1 superior spine of the ilium. It then passes under Poupart's ligament and over the Sartorius muscle into the thigh, where it divides into two branches, anterior and posterior.

The Anterior Branch descends in an aponeurotic canal formed in the fascia lata, becomes superficial about four inches below Poupart's ligament, and divides into branches which are distributed to the integument along the anterior and outer part of the thigh, as far down as the knee. This nerve occasionally communicates with a branch of the long saphenous nerve in front of the knee-joint.

Fig. 671.—Cutaneous nerves of lower extremity. Front view.

Fig. 672.—Nerves of the lower extremity. Front view.
The **Posterior Branch** pierces the fascia lata, and subdivides into branches which pass dorsad across the outer and posterior surface of the thigh, supplying the integument from the crest of the ilium as far as the knee.

The **Obturator Nerve** (*n. obturatorius*) (Figs. 669, 670, and 672).—The obturator nerve supplies the Obturator externus and Adductor muscles of the thigh, the articulations of the hip and knee, and occasionally the integument of the thigh and leg. It arises by three branches—from the second, the third, and the fourth lumbar nerves. Of these, the branch from the third is the largest, while that from the second is often very small. It descends through the inner fibres of the Psoas muscle, and emerges from its inner border near the brim of the pelvis; it then runs along the lateral wall of the pelvis, above the obturator vessels, to the upper part of the obturator foramen, where it enters the thigh, and divides into an anterior and a posterior branch, separated by some of the fibres of the Obturator externus muscle, and lower down by the Adductor brevis muscle.

The **Anterior Branch** (*ramus anterior*) (Fig. 672) passes down in front of the Adductor brevis, being covered by the Pectineus and Adductor longus, and at the lower border of the latter muscle communicates with the internal cutaneous and saphenous nerves, forming a kind of plexus. It then descends upon the femoral artery, upon which it is finally distributed. The nerve, near the obturator foramen, gives off an articular branch to the hip-joint. Behind the Pectineus it distributes muscular branches to the Adductor longus and Gracilis, and usually to the Adductor brevis, and in rare cases to the Pectineus, and receives a communicating branch from the accessory obturator nerve.

Occasionally the communicating branch to the internal cutaneous and saphenous nerves is continued down, as a **cutaneous branch** (*ramus cutaneus*), to the thigh and leg. When this is so, this occasional cutaneous branch emerges from beneath the lower border of the Adductor longus, descends along the posterior margin of the Sartorius to the inner side of the knee, where it pierces the deep fascia, communicates with the long saphenous nerve, and is distributed to the integument of the inner side of the leg as low down as its middle. When this communicating branch is small its place is supplied by the internal cutaneous nerve.

The **Posterior Branch** (*ramus posterior*) pierces the Obturator externus, sending branches to supply it, and passes behind the Adductor brevis on the front of the Adductor magnus, where it divides into numerous muscular branches, which supply the Adductor magnus, and the Adductor brevis when the latter does not receive a branch from the anterior division of the nerve. One of the branches gives off a filament to the knee-joint.

The **Articular Branch for the Knee-joint** is sometimes absent; it perforates the lower part of the Adductor magnus, and enters the popliteal space; it then descends upon the popliteal artery, as far as the back part of the knee-joint, where it perforates the posterior ligament, and is distributed to the synovial membrane. It gives filaments to the popliteal artery in its course.

The **Accessory Obturator Nerve or the Accessory Anterior Femoral Nerve of Winslow** (*n. obturatorius accessorius*) (Fig. 675).—The accessory obturator nerve is not constantly present. It is of small size, and arises by separate filaments from the third and fourth lumbar nerves. It descends along the inner border of the Psoas muscle, crosses the ascending ramus of the os pubis, and passes under the outer border of the Pectineus muscle, where it divides into numerous branches. One of these supplies the Pectineus, penetrating its under surface; another is distributed to the hip-joint; while a third communicates with the anterior branch of the obturator nerve. When this nerve is absent the hip-joint receives two branches from the obturator nerve. Occasionally the articular branch is very small, and becomes lost in the capsule of the hip-joint.
The Femoral or Anterior Crucial Nerve (n. femoralis) (Figs. 669, 670, and 672).—The femoral nerve is the largest branch of the lumbar plexus. It supplies muscular branches to the Iliacus, Pectineus, and all the muscles on the front of the thigh, excepting the Tensor fasciae latae; cutaneous filaments to the front and inner side of the thigh, and to the leg and foot (Fig. 667); and articular branches to the hip and knee. It arises from the second, third, and fourth lumbar nerves, sometimes from the first or fifth as well. It descends through the fibres of the Psoas muscle, emerging from this muscle at the lower part of its outer border, and passes caudad between it and the Iliacus muscle, and beneath Poupart’s ligament, into the thigh, where it becomes somewhat flattened, and divides into an anterior and a posterior part. Under Poupart’s ligament it is separated from the femoral artery by a portion of the Psoas muscle, and lies beneath the iliac fascia.

Within the abdomen the femoral nerve gives off from its outer side some small muscular branches to the Iliacus, and a branch to the femoral artery which is distributed upon the upper part of that vessel. The origin of this branch varies; it occasionally arises higher than usual, or it may arise lower down in the thigh.

External to the pelvis the following branches are given off:

The middle and internal cutaneous branches of the femoral nerve are the rami cutanei anteriores n. femoralis of the new nomenclature.

The Middle Cutaneous Nerve (Figs. 671 and 672) pierces the fascia lata (generally the Sartorius muscle also) about three inches (8 cm.) below Poupart’s ligament, and divides into two branches (Fig. 671), which descends in immediate proximity along the forepart of the thigh, to supply the integument as low as the front of the knee, where it communicates with the internal cutaneous nerve and the patellar branch of the saphenous nerve, to form the patellar plexus. In the upper part of the thigh the outer division of the middle cutaneous nerve communicates with the femoral branch of the genito-femoral nerve.

The Internal Cutaneous Nerve (Fig. 671) passes obliquely across the upper part of the sheath of the femoral artery, and divides in front or at the inner side of that vessel into two branches, anterior and posterior or internal.

The anterior branch runs caudad on the Sartorius, perforates the fascia lata at the lower third of the thigh, and divides into two branches, one of which supplies the integument as low down as the inner side of the knee; the other crosses to the outer side of the patella, communicating in its course with the nervus cutaneus patellae, a branch of the saphenous nerve.

The posterior or internal branch descends along the inner border of the Sartorius muscle to the knee, where it pierces the fascia lata, communicates with the long saphenous nerve, and gives off several cutaneous branches. The nerve then passes down the inner side of the leg, to the integument of which it is distributed. This nerve, beneath the fascia lata, at the lower border of the Adductor longus, joins in a plexiform network by uniting with branches of the saphenous and obturator nerves (Fig. 672). When the communicating branch from the obturator nerve is large and continued to the integument of the leg, the inner branch of the internal cutaneous is small and terminates at the plexus, occasionally giving off a few cutaneous filaments.

The internal cutaneous nerve, before dividing, gives off a few filaments, which pierce the fascia lata, to supply the integument of the inner side of the thigh.
One of these filaments passes through the saphenous opening; a second becomes subcutaneous about the middle of the thigh (Fig. 671); and a third pierces the fascia at its lower third (Fig. 671).

The Muscular Branches of the Anterior Division (rami musculares).—The nerve to the Pectineus is often duplicated; it arises from the femoral nerve immediately below Poupart’s ligament, and passes inward behind the femoral sheath to enter the anterior surface of the muscle. The nerve to the Sartorius arises in common with the middle cutaneous.

The Saphenous, Long Saphenous or Internal Saphenous Nerve (n. saphenus) (Figs. 671 and 672) is the largest of the cutaneous branches of the femoral nerve. It approaches the femoral artery where this vessel passes beneath the Sartorius, and lies ventrad of it, beneath the aponeurotic covering of Hunter’s canal, as far as the opening in the lower part of the Adductor magnus. It then leaves the artery, and proceeds distally along the inner side of the knee, beneath the Sartorius muscle, pierces the fascia lata opposite the interval between the tendons of the Sartorius and Gracilis muscles, and becomes subcutaneous. The nerve then passes along the inner side of the leg (Fig. 671), accompanied by the internal saphenous vein, descends behind the internal border of the tibia, and, at the lower third of the leg, divides into two branches: one continues its course along the margin of the tibia, terminating at the inner ankle; the other passes in front of the ankle, and is distributed to the integument along the inner side of the foot, as far as the great toe, communicating with the internal branch of the musculo-cutaneous nerve.

The saphenous nerve about the middle of the thigh gives off a communicating branch which joins the plexus formed by the obturator and internal cutaneous nerves.

At the inner side of the knee it gives off a large patellar branch, the nervus cutaneus patellae (ramus infrapatellarius), which pierces the Sartorius and fascia lata, and is distributed to the integument in front of the patella. This nerve communicates above the knee with the anterior branch of the internal cutaneous and with the middle cutaneous; below the knee, with other branches of the saphenous; and on the outer side of the joint, with branches of the external cutaneous nerve, forming a plexiform network, the patella plexus (plexus patellae). The cutaneous nerve of the patella is occasionally small, and terminates by joining the internal cutaneous, which supplies its place in front of the knee.

Below the knee the branches of the saphenous nerves are distributed to the integument of the front and inner side of the leg, communicating with the cutaneous branches from the internal cutaneous or from the obturator nerve. The nerve also sends filaments to the ankle-joint.

The Muscular Branches of the Posterior Division.—The muscular branches of the posterior division supply the four parts of the Quadriceps extensor muscle.

The branch to the Rectus muscle enters its under surface high up, sending off a small filament to the hip-joint.

The branch to the Vastus externus muscle, of large size, follows the course of the descending branch of the external circumflex artery to the lower part of the muscle. It gives off an articular filament to the knee-joint.

The branch to the Vastus internus muscle is a long branch which runs down on the outer side of the femoral vessels in company with the saphenous nerve for its upper part. It enters the muscle about its middle, and gives off a filament which can usually be traced caudad on the surface of the muscle to the knee-joint.

The branch to the Crureus muscle enters the muscle on its anterior surface about the middle of the thigh, and sends a filament through the muscle to the Subcrureus and the knee-joint.
The articular branch to the hip-joint is derived from the nerve to the Rectus muscle.

The articular branches to the knee-joint are three in number. One, a long, slender filament, is derived from the nerve to the Vastus externus muscle; it penetrates the capsular ligament of the joint on its anterior aspect. Another is derived from the nerve to the Vastus internus muscle. It can usually be traced downward on the surface of this muscle to near the joint; it then penetrates the muscle and accompanies the deep branch of the anastomotica magna artery, pierces the capsular ligament of the joint on its inner side, and supplies the synovial membrane. The third branch is derived from the nerve to the Crureus.

THE SACRAL AND COCCYGEAL NERVES (NN. SACRALES ET COCCYGEUS).

The sacral nerves are five in number on each side. The four upper ones pass from the sacral canal through the sacral foramina; the fifth through the foramina between the sacrum and coccyx.

The Roots of the Upper Sacral Nerves.

The roots of the upper sacral nerves are the largest of all the spinal nerves; while those of the lower sacral and the coccygeal nerve are the smallest. They are longer than those of any of the other spinal nerves, on account of the spinal cord not extending beyond the first lumbar vertebra. From their great length, and the appearance they present in connection with their attachment to the spinal cord, the roots of origin of these nerves are called collectively the cauda equina.

Each sacral and coccygeal nerve separates into two divisions, dorsal and ventral.

The Dorsal Divisions of the Sacral Nerves (Rami Posteriorum) (Fig. 673).

The dorsal divisions of the sacral nerves are small, diminish in size from above caudad, and emerge, except the last, from the sacral canal by the dorsal sacral foramina.

The Upper Sacral Nerves.—Each of the three upper ones is covered, at its exit from the sacral canal, by the Multifidus spine muscle, and divides into a medial branch and a lateral branch.

The Medial Branches (ramus medialis).—The medial branches are small, and supply the Multifidus spine muscle.

The Lateral Branches (ramus lateralis).—The lateral branches join with one another, and with the last lumbar and fourth sacral nerves, in the form of loops on the dorsal surface of the sacrum, constituting the dorsal sacral plexus. From these loops branches pass to the outer surface of the great sacro-ischiatic ligament, where they form a second series of loops beneath the Gluteus maximus muscle. Cutaneous branches from this second series of loops, usually two or three in number, pierce the Gluteus maximus muscle along a line drawn from the posterior superior spine of the ilium to the tip of the coccyx. They supply the integument over the dorsal part of the gluteal region.

The Lower Sacral Nerves.—The dorsal divisions of the two lower sacral nerves are situated below the Multifidus spine muscle. They are of small size, and do not divide into medial and lateral branches, but join with each other, and with the dorsal division of the coccygeal nerve to form the dorsal sacro-coccygeal nerve, which passes through the sacro-sciatic ligament, and forms loops on the back of the sacrum, filaments from which supply the Extensor coccygeus and the integument over the coccyx.
THE NERVE SYSTEM

FIG. 673.—The posterior sacral nerves.

FIG. 674.—Side view of pelvis, showing sacral nerves.
The Ventral Divisions of the Sacral Nerves (Rami Anteriores) (Fig. 675).

The ventral divisions of the sacral nerves diminish in size from above downward. The four upper ones emerge from the anterior sacral foramina; the ventral division of the fifth, after emerging from the vertebral canal through its terminal opening, curves forward between the sacrum and the coccyx. All the ventral sacral nerves at their exit from the sacral foramina communicate with the sacral ganglia of the sympathetic. The first nerve (Fig. 674), of large size, unites with the lumbo-sacral cord (truneus lumbosacralis), formed by the fifth lumbar, and a branch from the fourth lumbar (n. furcalis). The second (Fig. 674), equal in size to the preceding, and the third (n. bigeminus) (Fig. 674), about one-fourth the size of the second, unite with this trunk, and form, with a small fasciculus from the fourth, the sacral plexus, a visceral branch being given off from the third nerve to the bladder (Fig. 675).

The Fourth Ventral Sacral Nerve sends a branch to join the sacral plexus. The remaining portion of the nerve divides into visceral and muscular branches, and a communicating filament descends to join the fifth sacral nerve.

The visceral branches are distributed to the viscera of the pelvis, communicating with the sympathetic nerve. These branches ascend upon the rectum and bladder, and in the female upon the vagina, communicating with branches of the sympathetic from the pelvic plexus. The visceral branches of the third and fourth sacral do not join the gangliated cord.

The muscular branches are distributed to the Levator ani, Coccygeus, and Sphincter ani. The branch to the Sphincter ani pierces the Levator ani, so as to reach the ischio-rectal fossa, where it is found lying in front of the coccyx. Cutaneous filaments arise from the latter branch, which supply the integument between the anus and coccyx. Another cutaneous branch is frequently given off from this nerve, though sometimes from the pudic (Schwalbe). It perforates the great sacro-sciatic ligament, and, winding around the lower border of the Gluteus maximus, supplies the skin over the lower and inner part of this muscle.

The Fifth Ventral Sacral Nerve, after passing from the lower end of the sacral canal, curves forward through the fifth sacral foramen, formed between the lower part of the sacrum and the transverse process of the first piece of the coccyx. It pierces the Coccygeus muscle, and descends upon its anterior surface to near the tip of the coccyx, where it again perforates the muscle, to be distributed to the integument over the back part and side of the coccyx. This nerve communicates above with the fourth sacral and below with the coccygeal nerve, and supplies the Coccygeus muscle.

The Dorsal Division of the Coccygeal Nerve.

The coccygeal nerve divides into its ventral and dorsal divisions in the vertebral canal. The dorsal division is the smaller. It does not divide, but receives, as already mentioned, a communicating branch from the last sacral, and is lost in the integument over the back of the coccyx.

The Ventral Division of the Coccygeal Nerve.

The ventral division of the coccygeal nerve is a delicate filament which escapes at the termination of the sacral canal; it passes caudad behind the rudimentary transverse process of the first piece of the coccyx, and curves ventrad through the notch between the first and second pieces, piercing the Coccygeus muscle and descending on its ventral surface to near the tip of the coccyx, where it again
pierces the muscle, to be distributed to the integument over the back part and side of the coccyx. It is joined by a branch from the fifth ventral sacral as it descends on the surface of the Coccygeus muscle.

The Pudendal Plexus (plexus pudendus).—The pudendal plexus is formed by fibres obtained from the ventral divisions of the first three sacral nerves and by the ventral divisions of the two lower sacral nerves and the coccygeal nerve. It is, so to speak, interpolated in the sacral plexus and is considered as a portion of it.

The Sacral or Sciatic Plexus (Plexus Sacralis) and the Pudic or Pudendal Plexus (Plexus Pudendalis) (Fig. 675).

The sacral plexus is formed by the lumbo-sacral cord, the ventral divisions of the three upper sacral nerves, and a branch from the fourth. The pudic or pudendal plexus is considered with the sacral plexus. It is usually composed of the ventral divisions of the second, third, fourth and fifth sacral nerves and the coccygeal nerve. It is irregular in composition. Prof. Cunningham says: "There is no distinct point of separation between the two plexuses. On the contrary, there is considerable overlapping, so that two and sometimes three of the principal nerves derived from the pudendal plexus have their origin in common with nerves of the sacral plexus." The nerves of these two plexuses proceed in different directions: the upper ones obliquely caudad and outward, the lower ones nearly horizontally outward, and they all unite into two cords; an upper and larger cord, which is formed by the lumbo-sacral cord with the first, second, and the greater part of the third sacral nerves; and a lower and smaller cord, formed by the remainder of the third, with a portion of the fourth sacral nerve. The upper cord is prolonged into the great sciatic nerve and the lower into the pudic. Frequently a small filament is given off from the second sacral nerve to join the lower cord.
THE SACRAL OR SCIATIC PLEXUS

Each of the nerves which form the plexus joins the sympathetic by gray rami communicantes. White rami communicantes join the third sacral and sometimes also the second and fourth sacrals to the sympathetic.

The sacro-pudendal plexus is triangular in form, its base corresponding with the exit of the nerves from the sacrum, its apex with the lower part of the great sacro-sciatic foramen. It rests upon the anterior or ventral surface of the Pyriformis, and is covered ventrad by the pelvic fascia, which separates it from the sciatic and pudic branches of the internal iliac artery and from the viscera of the pelvis. The sacral plexus proper sends branches to the lower extremity; the pudendal plexus proper is largely limited to supplying the perineum.

Branches.—The branches of the sacro-pudendal plexus are divided into collateral and terminal branches.

The Muscular Branches (rami musculares).—The muscular branches supply the Pyriformis, Obturator internus, the two Gemelli and the Quadratus femoris. The branch to the Pyriformis muscle arises from the upper two sacral nerves before they enter the plexus; the branch to the Obturator internus muscle arises at the junction of the lumbo-sacral and first sacral nerves; it passes out of the pelvis through the great sacro-sciatic foramen below the Pyriformis, crosses the spine of the ischium, and re-enters the pelvis through the lesser sacro-sciatic foramen to enter the inner surface of the Obturator internus; the branch to the Gemellus superior muscle arises in common with the nerve to the Obturator internus muscle; it enters the muscle at the upper part of its dorsal surface; the small branch to the Gemellus inferior and Quadratus femoris muscles also arises from the upper part of the plexus; it passes through the great sacro-sciatic foramen below the Pyriformis, and courses down beneath the great sciatic nerve, the Gemelli and tendon of the Obturator internus, supplies the muscles on their deep or ventral surface, and gives off an articular branch to the hip-joint. A second articular branch is occasionally derived from the upper part of the sacral plexus.

The Superior Gluteal Nerve (n. gluteus superior) (Figs. 675 and 677).—The superior gluteal nerve arises from the back part of the lumbo-sacral cord, with some filaments from the first sacral nerve; it passes from the pelvis through the great sacro-sciatic foramen above the Pyriformis muscle, accompanied by the gluteal vessels, and divides into a superior and an inferior branch.

The Superior Branch follows the line of origin of the Gluteus minimus, and supplies the Gluteus medius muscle.

The Inferior Branch crosses obliquely between the Gluteus minimus and medius, distributing filaments to both these muscles, and terminates in the Tensor fasciae femoris muscle, extending nearly to its lower end.

The Inferior Gluteal Nerve (n. gluteus inferior) (Fig. 675).—The inferior gluteal nerve arises from the lumbo-sacral cord and first and second sacral nerves, and is intimately connected with the small sacrotuberous at its origin. It passes out of the pelvis through the great sciatic notch, beneath the Pyriformis muscle, and, dividing into a number of branches, enters the Gluteus maximus muscle on its under surface.

The Small Sciatic Nerve (n. cutaneus femoris posterior) (Figs. 675, 676, and 677).—The small sciatic or postfemoral cutaneous nerve supplies the integument of the perineum and back part of the thigh and leg. It is usually formed by the union of
two branches, which arise from the second and third nerves of the sacral plexus. It issues from the pelvis through the great sacro-sciatic foramen below the Pyriformis muscle, descends beneath the Gluteus maximus with the sciatic artery, and at the lower border of that muscle passes along the back part of the thigh, beneath the fascia lata and over the long head of the Biceps, to the lower part of the popliteal region, where it pierces the fascia and becomes cutaneous. It then accompanies the external saphenous vein (v. saphena parva) to about the middle of the leg, its terminal filaments communicating with the sural or external saphenous nerve.

The Branches of the small sciatic nerve are all cutaneous, and are grouped as follows: gluteal, perineal, and femoral.

The Gluteal Cutaneous Branches (nn. clunium inferiores [laterales]) consist of two or three ascending filaments, which turn upward around the lower border of the Gluteus maximus to supply the integument covering the lower and outer part of that muscle.

The Perineal Cutaneous Branches (rami perineales) are distributed to the skin at the upper and inner side of the thigh, on its posterior aspect. One branch, longer than the rest, the inferior pudendal or long scrotal nerve (Fig. 677), curves forward below the tuber ischii, pierces the fascia lata, and passes forward beneath the superficial fascia of the perineum to be distributed to the integument of the scrotum in the male and the labium in the female, communicating with the superficial perineal and inferior hemorrhoidal nerves.

The Femoral Cutaneous Branches are numerous descending filaments, derived from both sides of the nerves, which are distributed to the back, inner, and outer sides of the thigh, to the skin covering the popliteal space, and to the upper part of the leg.

The Perforating Cutaneous Nerve (n. clunium inferior medialis) (Fig. 675).—The perforating cutaneous nerve usually arises from the second and third sacral nerves, and is of small size. It is continued dorsad through the great sacro-sciatic ligament, and, winding around the lower border of the Gluteus maximus, supplies the integument covering the inner and lower part of that muscle.

The Pudic Nerve (n. pudendus) (Figs. 675 and 677).—The pudic nerve is the direct continuation of the lower cord of the sacral plexus, and derives its fibres from the third and fourth sacral nerves, and frequently from the second also. It leaves the pelvis through the great sacro-sciatic foramen, below the Pyriformis. It then crosses the spine of the ischium, and re-enters the pelvis through the lesser sacro-sciatic foramen. It accompanies the pudic vessels upward and forward along the outer wall of the ischio-rectal fossa, being contained in a sheath of the obturator fascia, termed Alcock’s canal, and divides into two terminal branches, the perineal nerve and the dorsal nerve of the penis or clitoris. Before its division it gives off the inferior hemorrhoidal nerve.

The Inferior Hemorrhoidal Nerve (n. haemorrhoidalis inferior) is occasionally derived separately from the sacral plexus. It passes across the ischio-rectal fossa, with its accompanying vessels, toward the lower end of the rectum, and is distributed to the Sphincter ani externus and to the integument around the anus. Branches of this nerve communicate with the inferior pudendal and superficial perineal nerves at the forepart of the perineum.

The Perineal Nerve (n. perinei), the inferior and larger of the two terminal branches of the pudic, is situated below the pudic artery. It accompanies the superficial perineal artery in the perineum, dividing into cutaneous and muscular branches.

The cutaneous branches (superficial perineal) are two in number, posterior and anterior. The posterior or external branch pierces the base of the triangular liga-

ment of the urethra, and passes forward along the outer side of the urethral triangle in company with the superficial perineal artery; it is distributed to the

FIG. 676.—Cutaneous nerves of lower extremity. Posterior view.

FIG. 677.—Nerves of the lower extremity. Posterior view.

N. B.—In this diagram the external saphenous (or sural nerve) and communicans peronei are not in their normal position. They have been displaced by the removal of the superficial muscles.
skin of the scrotum (*nn. scrotales posteriores*). It communicates with the inferior hemorrhoidal, the inferior pudendal, and the other superficial perineal nerve. The anterior or internal branch also pierces the base of the triangular ligament, and passes forward nearer to the middle line, to be distributed to the inner and back part of the scrotum. Both these nerves supply the labia majora in the female.

The muscular branches are distributed to the Transversus perinaei, Accelerator urinae, Erector penis, and Compressor urethrae. A distant branch is given off from the nerve to the Accelerator urinae, which pierces this muscle, and supplies the corpus spongiosum, ending in the mucous membrane of the urethra. This is the nerve to the bulb.

The Dorsal Nerve of the Penis (*n. dorsalis penis*) is the deepest division of the pudic nerve; it accompanies the pudic artery along the ramus of the ischiium; it then runs forward along the inner margin of the ramus of the os pubis, between the superficial and deep layers of the triangular ligament. Piercing the superficial layer it gives a branch to the corpus cavernosum, and passes forward, in company with the dorsal artery of the penis, between the layers of the suspensory ligament, on to the dorsum of the penis, along which it is carried as far as the glans, to which it is distributed.

In the female the dorsal nerve is very small, and supplies the clitoris (*n. dorsalis clitoridis*).

The Great Sciatic Nerve (*n. ischiadicus*) (Figs. 675 and 677).—The great sciatic nerve supplies nearly the whole of the integument of the leg, the muscles of the back of the thigh, and those of the leg and foot. It is the largest nerve cord in the body, measuring three-quarters of an inch in breadth, and is the direct continuation of the upper division of the sacral plexus. It passes out of the pelvis through the great sacro-sciatic foramen, below the Pyriformis muscle. It descends between the trochanter major and tuberosity of the ischiium, along the back part of the thigh, to about its lower third, where it divides into two large branches, the internal or tibial and external popliteal or peroneal nerves (Fig. 677).

This division may take place at any point between the sacral plexus and the lower third of the thigh. When the division occurs at the plexus (in 10 per cent. of cases) the two nerves descend together side by side; or they may be separated, at their commencement, by the interposition of part or the whole of the Pyriformis muscle. As the nerve descends along the back of the thigh, it rests upon the dorsal surface of the ischiium, the nerve of the Quadratus femoris, and the External rotator muscles, in company with the small sciatic nerve and artery, being covered by the Gluteus maximus; lower down, it lies upon the Adductor magnus, and is covered by the long head of the Biceps. The great sciatic, even when apparently a single nerve, is really two nerves appearing as one.

**Branches.**—The branches of the nerve, before its division, are articular and muscular.

The Articular Branches (*rami articulares*) arise from the upper part of the nerve; they supply the hip-joint, perforating the posterior part of its fibrous capsule. These branches are sometimes derived from the sacral plexus.

The Muscular Branches (*rami musculares*) are distributed to the flexors of the leg—viz., the Biceps, Semitendinosus, and Semimembranosus, and a branch goes to the Adductor magnus. These branches are given off beneath the Biceps muscle.

The Internal Popliteal or Tibial Nerve (*n. tibialis*) (Figs. 675 and 677), in reality, arises from the fourth and fifth lumbar nerves and the first three sacral nerves, and becomes a part of the trunk of the great sciatic in the buttock, to emerge from it again at the bifurcation of the sciatic. It is the larger of the two terminal branches of the great sciatic, descends along the back part of the thigh, through the middle of the popliteal space, to the lower part of the Popliteus muscle, where it passes with the artery beneath the arch of the Soleus and becomes the posttibial. It is over-
lapped by the hamstring muscles above, and then becomes more superficial, and lies to the outer side of, and some distance from, the popliteal vessels; opposite the knee-joint it is in close relation with the vessels, and crosses to the inner side of the artery. Below, it is overlapped by the Gastrocnemius muscle.

The branches of this nerve are—articular, muscular, and a cutaneous branch, the communicating tibial nerve.

The articular branches (rami articulares), usually three in number, supply the knee-joint; two of these branches accompany the superior and inferior internal articular arteries, and a third, the azygos articular artery.

The muscular branches (rami musculares), four or five in number, arise from the nerve as it lies between the two heads of the Gastrocnemius muscle; they supply that muscle, and the Plantaris, Soleus, and Popliteus. The filaments which supply the Popliteus turn around its lower border and are distributed to its deep surface.

The tibial communicating nerve (n. cutaneus surae medialis) is the cutaneous branch. It descends between the two heads of the Gastrocnemius muscle, and about the middle of the back of the leg pierces the deep fascia, and joins the peroneal or fibular communicating nerve (ramus anastomoticus peronaeus) from the external popliteal nerve to form the sural nerve (external or short saphenous) (Fig. 677). The sural nerve, formed by the communicating branches of the internal and external popliteal nerves, passes downward and outward near the outer margin of the tendo Achillis, lying close to the small saphenous vein, to the interval between the external malleolus and the os calcis. It divides in two branches, the posterior of which breaks up into lateral calcaneal branches (rami calcanei laterales). The anterior branch (n. cutaneus dorsalis lateralis) winds around the outer malleolus, and is distributed to the integument along the outer side of the foot and little toe, communicating on the dorsum of the foot with the musculo-cutaneous nerve. In the leg its branches communicate with those of the small sciatic. The cutaneous area supplied by the sural nerve is indicated in Fig. 679.

The Posttibial Nerve (Fig. 677) is the terminal portion of the internal popliteal nerve. It commences at the lower border of the Popliteus muscle, and passes along the back part of the leg with the posterior tibial vessels to the interval between the inner malleolus and the heel, where it divides into the external and internal plantar nerves. It lies upon the deep muscles of the leg, and is covered in the upper part by the muscles of the calf, lower down by the skin and fascia. In the upper part of its course it lies to the inner side of the posterior tibial artery, but it soon crosses that vessel, and lies to its outer side as far as the ankle. In the lower third of the leg it is placed parallel with the inner margin of the tendo Achillis.

The branches of the posttibial nerve are muscular, medial or internal calcaneal or calcaneo-plantar, and articular.

The muscular branches (rami musculares) arise either separately or by a common trunk from the upper part of the nerve. They supply the Soleus, Tibialis posticus, Flexor longus digitorum, and Flexor longus hallucis muscles; the branch to the latter muscle accompanying the peroneal artery. The branch to the Soleus enters its deep surface, while the branch which this muscle receives from the internal popliteal enters its superficial aspect.

The medial or internal calcaneal or calcaneo-plantar branches (rami calcanei mediales) perforate the internal annular ligament, and supply the integument of the heel and inner side of the foot (Fig. 679).

The articular branch (ramus articularis ad articulationem talocruralen) is given off just above the bifurcation of the nerve and supplies the ankle-joint.

The Medial or Internal Plantar Nerve (n. plantaris medialis) (Fig. 678), the larger of the two terminal branches of the posttibial, accompanies the medial plantar artery along the inner side of the foot. From its origin at the inner ankle it passes
beneath the Abductor hallucis, and divides into the common plantar digital nerves (nn. digitales plantares communes), which pass distal between the Abductor hallucis and the Flexor brevis digitorum, dividing opposite the bases of the metatarsal bones into four collateral plantar digital branches, and communicating with the lateral plantar nerve.

In its course the medial plantar nerve gives off cutaneous branches, which pierce the plantar fascia and supply the integument of the sole of the foot (Fig. 679); muscular branches, which supply the Abductor hallucis and Flexor brevis digitorum; articular branches, to the articulations of the tarsus and metatarsus; and four collateral plantar digital branches (nn. digitales plantares proprii). The three outer branches pass between the divisions of the plantar fascia in the clefts between the toes; the first (innermost) branch becomes cutaneous more proximally between the Abductor hallucis and Flexor brevis digitorum. They are distributed in the following manner: The first supplies the inner border of the great toe, and sends a filament to the Flexor brevis hallucis muscle; the second bifurcates, to supply the adjacent sides of the great and second toes, sending a filament to the First lumbrical muscle; the third supplies the adjacent sides of the second and third toes; the fourth supplies the corresponding sides of the third and fourth toes, and receives a communicating branch from the external plantar nerve (Fig. 679). Each digital nerve gives off cutaneous and articular filaments; and opposite the last phalanx sends a dorsal branch, which supplies the structures around the nail, the continuation of the nerve being distributed to the ball of the toe. It will be observed that the distribution of these branches is precisely similar to that of the median nerve in the hand.

The Lateral or External Plantar Nerve (n. plantaris lateralis) (Fig. 678), the smaller of the two, completes the nerve supply to the structures of the sole of the foot (Fig. 679), being distributed to the little toe, and one-half of the fourth, as well as to most of the deep muscles, its distribution being similar to that of the ulnar in the hand. It passes obliquely distal with the lateral plantar artery to the outer side of the foot, lying between the Flexor brevis digitorum and Flexor accessorius, and in the interval between the former muscle and Abductor minimi digiti divides into a
superficial and a deep branch. Before its division it supplies the Flexor accessorius and Adductor minimi digiti.

The superficial branch (ramus superficialis) separates into two digital nerves. Before division they are called common plantar digital nerves (nn. digitales plantares communes), after division the collateral plantar digital nerves (nn. digitales plantares proprii): one, the external branch, the smaller of the two, supplies the outer side of the little toe, the Flexor brevis minimi digiti, and the two Interosseous muscles of the fourth metatarsal space; the other and larger digital branch supplies the adjoining sides of the fourth and fifth toes, and communicates with the medial plantar nerve.

The deep or muscular branch (ramus profundus) accompanies the lateral plantar artery into the deep part of the sole of the foot, beneath the tendons of the Flexor muscles and Adductor obliquus hallucis, and supplies all the Interossei (except those in the fourth metatarsal space), the three outer Lumbricales, the Adductor obliquus hallucis, and the Adductor transversus hallucis.

The External Popliteal or Common Peroneal Nerve (n. peroneaeus communis) (Figs. 675 and 677) in reality arises from the fourth and fifth lumbar and the first and second sacral nerves. It is about one-half the size of the internal popliteal, descends obliquely along the outer sides of the popliteal space to the head of the fibula, close to the inner margin of the Biceps muscle. It is easily felt beneath the skin behind the head of the fibula at the inner side of the tendon of the Biceps. It passes between the tendon of the Biceps and outer head of the Gastrocnemius muscle, winds around the neck of the fibula, between the Peroneus longus and the bone, and divides beneath the muscle into the deep peroneal (anterior tibial) and muscular cutaneous nerves.

The branches of the peroneal nerve, previous to its division, are articular and cutaneous.

The articular branches (rami articales) are three in number: two of these accompany the superior and inferior lateral articular arteries to the outer side of the knee. The upper one occasionally arises from the great sciatic nerve before its bifurcation. The third (recurrent) articular nerve is given off at the point of division of the peroneal nerve; it ascends with the anterior recurrent tibial artery through the Tibialis anticus muscle to the front of the knee, which it supplies.

The Sural or Lateral Cutaneous Branch (n. cutaneus surae lateralis).—There may be two or three of these branches. They supply the integument along the back part and outer side of the leg. The largest cutaneous branch of the peroneal is the peroneal communicating (ramus anastomoticus peroneaeus or communicans fibularis), arises near the head of the fibula, crosses the external head of the Gastrocnemius to the middle of the leg, and joins with the communicans tibialis to form the external saphenous. This nerve occasionally exists as a separate branch, which is continued as far down as the heel.

The Deep Peroneal or Anterior Tibial Nerve (n. peroneaeus profundus) (Fig. 672) commences at the bifurcation of the peroneal nerve, between the fibula and upper part of the Peroneus longus muscle, passes obliquely distad beneath the Extensor longus digitorum muscle to the forepart of the interosseous membrane, and gets into relation with the anterior tibial artery above the middle of the leg; it then descends with the artery to the front of the ankle-joint, where it divides into an external and an internal branch. This nerve lies at first on the outer side of the anterior tibial artery, then in front of it, and again at its outer side at the ankle-joint.

The branches of the anterior tibial nerve in its course through the leg are the muscular branches (rami musculares) to the Tibialis anticus, Extensor longus digitorum, Peroneus tertius, and Extensor proprius hallucis muscles, and an articular branch to the ankle-joint.
The external or tarsal branch of the anterior tibial passes outward across the tarsus, beneath the Extensor brevis digitorum, and, having become enlarged, like the posterior interosseous nerve at the wrist, supplies the Extensor brevis digitorum muscle. From the enlargement three minute interosseous branches are given off which supply the tarsal joints and the metatarso-phalangeal joints of the second, third, and fourth toes. The first of these sends a filament to the second dorsal interosseous muscle.

The internal branch, the continuation of the nerve, accompanies the dorsalis pedis artery along the inner side of the dorsum of the foot, and at the first interosseous space divides into two dorsal digital branches (mn. digitales dorsales hallucis lateralis et digitii secundi medialis), which supply the adjacent sides of the great and second toes, communicating with the internal branch of the musculo-cutaneous nerve. Before it divides it gives off an interosseous branch to the first space, which supplies the metatarso-phalangeal joint of the great toe and sends a filament to the First dorsal interosseous muscle.

The Musculo-cutaneous Nerve (n. peronaeus superficialis) (Fig. 672) supplies the muscles on the fibular side of the leg and the integument of the dorsum of the foot. It passes forward between the Peronei muscles and the Extensor longus digitorum, pierces the deep fascia at the lower third of the leg on its front and outer side, and divides into two branches. This nerve in its course between the muscles gives off muscular branches (rami musculares) to the Peroneus longus and brevis, and cutaneous filaments to the integument of the lower part of the leg.

The medial dorsal cutaneous branch (n. cutaneus dorsalis medialis) of the musculo-cutaneous nerve passes in front of the ankle-joint, and divides into two dorsal digital branches (mn. digitales dorsales pedis), one of which supplies the inner side of the great toe, the other the adjacent sides of the second and third toes. It also supplies the integument of the inner ankle and inner side of the foot, communicating with the saphenous nerve, and joining with the anterior tibial nerve, between the great and second toes.

The intermediate dorsal cutaneous branch (n. cutaneus dorsalis intermedius), the smaller, passes along the outer side of the dorsum of the foot, and divides into two dorsal digital branches, the inner being distributed to the contiguous sides of the third and fourth toes, the outer to the opposed sides of the fourth and fifth toes. It also supplies the integument of the outer ankle and outer side of the foot, communicating with the short saphenous nerve.

The branches of the musculo-cutaneous nerve supply all the toes excepting the outer side of the little toe, which is supplied by the small saphenous nerve. The adjoining sides of the great toe or second toe are also supplied by the internal branch of the anterior tibial. It frequently happens that some of the outer branches of the musculo-cutaneous are absent, their place being then taken by branches of the small saphenous nerve.

The Coccygeal Plexus.

The coccygeal plexus is a subdivision of the pudendal plexus, formed chiefly by the anterior division of the fifth sacral nerve, sometimes the fourth also, and the coccygeal nerve. From this plexus arise the anococcygeal nerves which pierce the great sacrosciatic ligament and supply the integument over the coccyx.

Surgical Anatomy.—The lumbar plexus passes through the Psoas muscle, and, therefore, in psoas abscess any or all of its branches may be irritated, causing severe pain in the parts to which the irritated nerves are distributed. The genito-femoral nerve is the one which is most frequently implicated. This nerve is also of importance, as it is concerned in one of the reflexes employed in the investigation of diseases of the spine. If the skin over the inner side of the thigh just below Poupart's ligament, the part supplied by the femoral branch of the genito-
The femoral nerve, being, by gentle tickling in a male child, the testicle will be noticed to be drawn upward through the action of the cremaster muscle, which is supplied by the genital branch of the same nerve. The same result may occasionally be noticed in adults, and can almost always be produced by severe stimulation. This reflex, when present, shows that the portion of the cord from which the first and second lumbar nerves are derived is in a normal condition.

The femoral or anterior crural nerve is in danger of being injured in fractures of the true pelvis, since the fracture most commonly takes place through the ascending rami of the os pubis, at or near the point where this nerve crosses the bone. It is also liable to be injured in fractures and dislocations of the femur, and is likely to be pressed upon, and its functions impaired, in some tumors growing in the pelvis. Moreover, on account of its superficial position, it is exposed to injury in wounds and stabs in the groin. When this nerve is paralyzed, the patient is unable to flex his hip completely, on account of the loss of motion in the iliacus; or to extend the knee on the thigh, on account of paralysis of the quadriceps extensor cruris; there are complete paralysis of the Sartorius and partial paralysis of the Pectineus. There is loss of sensation down the front and inner side of the thigh, except in that part supplied by the femoral branch of the genito-femoral nerve, and by the ilio-inguinal nerve. There is also loss of sensation down the inner side of the leg and foot as far as the ball of the great toe.

The obturator nerve is of special surgical interest. It is rarely paralyzed alone, but occasionally is paralyzed in association with the femoral. The principal interest attached to it is in connection with its supply to the knee; pain in the knee being symptomatic of many diseases in which the trunk of this nerve, or one of its branches, is irritated. Thus it is well known that in the earlier stages of hip-joint disease the patient does not complain of pain in that articulation, but on the inner side of the knee, or in the knee-joint itself, both these articulations being supplied by the obturator nerve, the final distribution of the nerve being to the knee-joint. Again, the same thing occurs in sacro-iliac disease: pain is complained of in the knee-joint or on its inner side. The obturator nerve is in close relationship with the sacro-iliac articulation, passing over it, and, according to some anatomists, distributing filaments to it. Again, in cancer of the sigmoid flexure, and even in cases where masses of hardened faeces are impacted in this portion of the gut, pain is complained of in the knee. The left obturator nerve lies beneath the sigmoid flexure, and is readily pressed upon and irritated when disease exists in this part of the intestine. Finally, pain in the knee forms an important diagnostic sign in obturator hernia. The hernial protrusion as it passes out through the opening in the obturator membrane presses upon the nerve and causes pain in the parts supplied by its peripheral filaments. When the obturator nerve is paralyzed, the patient is unable to press his knees together or to cross one leg over the other, on account of paralysis of the Adductor muscles. Rotation outward of the thigh is impaired from paralysis of the Obturator externus. Sometimes there is loss of sensation in the upper half of the inner side of the thigh.

The great sciatic nerve is liable to be pressed upon by various pelvic tumors, giving rise to pain along its trunk, to which the term sciatica is applied. Tumors growing from the pelvic viscerum, or bones, aneurisms of some of the branches of the internal iliac artery, calculus in the bladder when of large size, accumulation of faeces in the rectum, may all cause pressure on the nerve inside the pelvis, and give rise to sciatica. Outside the pelvis exposure to cold, violent movements of the hip-joint, exostoses or other tumors growing from the margin of the sacro-scatic foramen, may also give rise to the same condition. When paralyzed there is loss of motion in all the muscles below the knee, and loss of sensation in the same situation, except the upper half of the back of the leg, supplied by the small sciatic and the upper half of the inner side of the leg, when the communicating branch of the obturator is large.

The sciatic nerve has been frequently cut down upon and stretched, or has been acupuncture for the relief of sciatica. The nerve has also been stretched in cases of locomotor ataxia, the anaesthesia of leprosy, etc. In order to define it on the surface, a point is taken at the junction of the middle and lower third of a line stretching from the posterior superior spine of the ilium to the outer part of the tuber ischii, and a line is drawn from this point to the middle of the upper part of the popliteal space. This line must be slightly curved with its convexity outward, and as it passes downward to the lower border of the Gluteus maximus is slightly nearer the tuberosity of the ischium than to the great trochanter, as it crosses a line drawn between these two points. The operation of stretching the sciatic nerve is performed by making an incision over the course of the nerve about the centre of the thigh. The skin, superficial structures, and deep fascia having been divided, the interval between the inner and outer hamstrings is to be defined, and these muscles respectively pulled inward and outward with retractors. The nerve will be found a little to the inner side of the Biceps. It is to be separated from the surrounding structures, hooked up with the finger, and stretched by steady and continuous traction for two or three minutes. The sciatic nerve may also be stretched by what is known as the "dry" plan. The patient is laid on his back, the foot is extended, the leg flexed on the thigh, and the thigh strongly flexed on the abdomen. While the thigh is maintained in this position the leg is forcibly extended to its full extent, and the foot as fully flexed on the leg. This last-named method is uncertain.

The position of the external popliteal nerve, close behind the tendon of the Biceps on the outer side of the ham, should be remembered in subcutaneous division of the tendon. After it is divided,
THE CRANIAL NERVES (NERVI CEREBRALES).

The irregularities of origin and distribution of the cranial nerves, as compared with the relatively simple spinal nerves, is so great and their functions were formerly so little known that the older anatomists contented themselves with numbering them in order, beginning at the cephalic end of the brain, and named them with reference to their anatomical connections. The enumeration of the cranial nerves was as variously given, almost, as there were writers upon the subject; the systems of Willis and of Sömmering were most in vogue for a time, but the latter prevails to-day. In Sömmering’s arrangement twelve pairs of cranial nerves are recognized, but, on morphological and functional grounds, the nerves of the seventh and eighth pairs should each be considered as being composed of two nerves, the eleventh pair should be included with the nerves of the tenth, and the optic “nerve” is rather a diverticulum of the brain itself than a nerve in the strict sense. Furthermore, while some of the nerves are sensor or motor in a sense strictly comparable with the spinal nerves, others are “mixed” in function, and yet others constitute nerves of special sense, lacking general sensibility. The numerical names, based upon the order in which they pass through the foramina in the base of the cranium, are being abandoned gradually for the more appropriate functional names, but not yet entirely so. Thus glossopharyngeal has not yet given way to “gustatory;” “vagus” is shorter than “pneumogastric”—a term which is misleading for a nerve which is distributed not only to lungs and stomach, but also to the meninges, the pharynx and oesophagus, larynx and trachea, heart and pericardium, liver and spleen.

The cranial nerves, as usually enumerated, together with their superficial “origin” or attachment to the brain and their foramina of exit from the skull, are tabulated on p. 866. The central olfactory pathway is described on p. 938, and the central connections of the optic tracts are given on p. 921. The central connections of the remaining cranial nerves are described on pp. 892 to 914.

The following is a brief summary of the twelve pairs of cranial nerves, indicating their functional nature:

THE FIRST OR OLFACTORY NERVE (N. OLFACTORIUS).

The olfactory nerves or fila are the special nerves of the sense of smell, and are about twenty in number on each side. These filaments constitute the first or olfactory nerves and are the axones of the olfactory cells, lying in the small olfactory region in the upper part of the superior concha and corresponding portion of the septum and are macroscopically differentiated from the respiratory region in being of a more brownish hue (Fig. 680). The olfactory fila are amyelinic and exhibit a plexiform arrangement in the deeper layers. After piercing the cribrosa (cribriform plate) of the ethmoid they become attached to the under surface of the olfactory bulb, an oval mass of a grayish color, which rests on the cribiform plate of the ethmoid bone and forms the anterior expanded extremity or a slender process of brain-substance, named the olfactory tract. The olfactory tract and bulb have already been described (p. 935). The olfactory tubercle (trigonum olfactorium) is a small triangular mass of gray substance between the diverging roots of the optic tract (p. 935).

Each nerve is surrounded by tubular prolongations from the dura and pia, the former being lost on the periosteum lining the nose, the latter in the neurilemma of the nerve. The nerves, as they enter the nares, are divisible into two groups: an inner group, larger than those on the outer wall, spread out over the upper third of the septum; and an outer set, which is distributed over the superior turbinated bone, and the surface of the ethmoid in front of it. As the filaments descend, they unite in a plexiform network, and are believed by most observers to terminate by becoming continuous with the deep extremities of the olfactory cells.

The olfactory nerves differ in structure from other nerves in being composed exclusively of non-medullated (amyelinic fibres). They are deficient in the white substance of Schwann, and consist of axones with a distinct nucleated sheath, in which there are, however, fewer nuclei than in ordinary amyelinic fibres.

The central olfactory pathways are described on p. 964.
Surgical Anatomy.—Destruction of the olfactory tract of one side causes loss of smell (anosmia) on the side of the injury, because the olfactory tract is practically uncrossed. In severe injuries to the head the olfactory bulb may become separated from the olfactory nerves, thus producing loss of the sense of smell, and with this a considerable loss in the sense of taste, as much of the perfection of the sense of taste is due to the soluble substances, being also odorous and simultaneously exciting the sense of smell. When the sense of smell is lost, an individual cannot distinguish the flavor of food, but he can distinguish that a substance is salt, or sweet, or bitter, or acid. The most usual cause of injury to the olfactory nerve is fracture of the base of the skull the line of fracture passing through the cribriform plate of the ethmoid bone, but a blow upon the face, forehead, or back of the head, which does not produce fracture may injure the nerve.

THE SECOND OR OPTIC NERVE (N. OPTICUS).

The fibres of the optic nerve, the special nerve of the sense of sight, are the central processes of the retinal ganglion cells which, after converging to the optic papilla, leave the eyeball by piercing its fibrous and vascular tunics as a rounded cord. The point of emergence is situated a little mesad (3 to 4 mm.) of the central axis of the globe. Behind the eyeball the nerve passes backward and inward through the orbital fat and optic foramen to enter the middle fossa of the cranium. The total length of the nerve averages 45 to 50 mm. The two nerves converge to decussate partially, forming the chiasm.

The Chiasm (chiasma opticum) (Figs. 681 and 682 and p. 919).—The chiasm is somewhat quadrilateral in form, rests upon the olivary eminence and on the anterior part of the diaphragma sellae, being bounded above by the terma; behind by the tuber; on either side by the preperforatum. Within the commissure, the optic nerves of the two sides undergo a partial decussation (Figs. 594 and 682) described in detail on pp. 918 and 919.

From the chiasm the optic tracts wind as flattened bands obliquely caudo-laterad around the crura to subdivide, each into two bands, one (mesial root) passing to the postgeniculum and not a true continuation of the optic path (see Gudden’s commissure, p. 919), the other (lateral root) passing to the pregeniculm, the pulvinar, and the pregeninum (p. 919).

The optic path has been described on p. 917.

Surgical Anatomy.—The optic nerve is peculiarly liable to become the seat of neuritis or undergo atrophy in affections of the central nerve system, and, as a rule, the pathologic relationship between the two affections is exceedingly difficult to trace. There are, however, certain points in connection with the anatomy of this nerve which tend to throw light upon the frequent association of these affections with intracranial disease: (1) From its mode of development and from its structure the optic nerve must be regarded as a prolongation of the brain-substance, rather than as an ordinary cerebro-spinal nerve. (2) As it passes from the brain it receives sheaths from the three cerebral membranes—a perineurial sheath from the pia, an intermediate sheath from the arachnoid, and an outer sheath from the dura, which is also connected with the periosteum as it passes through the optic foramen. These sheaths are
THE THIRD OR OCULOMOTOR NERVE

Separated from each other by spaces which communicate with the subdural and subarachnoid spaces respectively. The innermost or perineural sheath sends a process around the arteria centralis retinae into the interior of the nerve, and enters intimately into its structure. Thus inflammatory infections of the meninges or of the brain may readily extend themselves along these spaces or along the interstitial connective tissue in the nerve.

The course of the fibres in the optic commissure has an important pathologic bearing, and has been the subject of much controversy. Microscopic examination, experiments; and pathology all seem to point to the fact that there is a partial decussation of the fibres, each tract supplying the corresponding half of each eye, so that the right tract supplies the right half of each eye, and the left tract the left half of each eye. At the same time, Charcot believes—and his view has met with general acceptance—that the fibres which do not decussate at the optic commissure will decussate in the corpora quadrigemina, so that lesion of the cerebral centre of one side causes complete blindness of the opposite eye, because both sets of decussating fibres are destroyed. Whereas should one tract—say the right—be destroyed by disease, there will be blindness of the right half of both retina.

A sagittal section through the commissure would divide the decussating fibres, and would therefore produce blindness of the inner half of each eye; while a section at the margin of the side of the optic commissure would produce blindness of the external half of the retina of the same side.

The optic nerve may also be affected in injuries or diseases involving the orbit, in fractures of the anterior fossa of the base of the skull, in tumors of the orbit itself, or those invading this cavity from neighboring parts.

THE THIRD OR OCULOMOTOR NERVE (N. OCULOMOTORIUS)
(Figs. 683, 684, 687).

The third or oculomotor nerve supplies all the muscles of the orbit except the Superior oblique and External rectus; it also supplies, through its connection with the ciliary ganglion, the Sphincter muscle of the iris and the Ciliary muscle. It is rather a large nerve, of rounded form and firm texture.

Its apparent origin is from the oculomotor groove along the ventro-mesal border of the crus. The deep origin may be traced through the substantia nigra and tegmentum of the crus to a nucleus situated on either side of the median line beneath the floor of the aqueduct. The nucleus of the oculomotor nerve also receives fibres from the abducent nerve of the opposite side. The nucleus of the oculomotor nerve, considered from a physiological standpoint, can be subdivided into several smaller groups of cells, each group controlling a particular muscle (see p. 911). The nerves to the different muscles appear to take their origin from before backward, as follows: Inferior oblique, Inferior rectus, Superior rectus and Levator palpebrae, Internal rectus; while from the cephalic end of the nucleus the fibres for accommodation and for the Sphincter pupillic take their origin.

On emerging from the brain, the nerve is invested with a sheath of pia, and enclosed in a prolongation from the arachnoid. It passes between precerebellar and postcerebral arteries, and then pierces the dura in front of and external to the posterior clinoid process, passing between the two processes from the free and attached borders of the tentorium, which are prolonged forward to be connected with the anterior and posterior clinoid processes of the sphenoid bone. It passes along the outer wall of the cavernous sinus (Figs. 454 and 455); above the other orbital nerves, receiving in its course one or two filaments from the cavernous plexus of the sympathetic, and a communicating branch from the first division of the trigeminal nerve. It then divides into two branches, which enter the orbit through the sphenoidal fissure, between the two heads of the External rectus muscle (Fig. 683). On passing through the fissure, the nerve is placed below the trochlear nerve and the frontal and lacrimal branches of the ophthalmic nerve, and has passing between its two divisions the nasal nerve (Fig. 692).

The Superior Division (ramus superior) (Fig. 684).—The superior division, the smaller, passes inward over the optic nerve, and supplies the Superior rectus and Levator palpebrae.
The Inferior Division (ramus inferior) (Fig. 684).—The inferior division, the larger, divides into three branches. One passes beneath the optic nerve to the Internal rectus; another, to the Inferior rectus; and the third, the longest of the three, passes forward between the Inferior and External recti to the Inferior oblique. From this latter a short, thick branch, radix brevis ganglii ciliaris, is given off to the lower part of the ciliary or lenticular ganglion and forms its short or motor root (Figs. 684 and 687). It also gives off one or two filaments to the Inferior rectus. All these branches enter the muscles on their ocular surface, except that to the Inferior oblique, which enters its posterior border.

Surgical Anatomy.—Paralysis of the oculomotor nerve may be the result of many causes: as cerebral disease; conditions causing pressure on the cavernous sinus; periostitis of the bone entering into the formation of the sphenoidal fissure; fracture of the orbit. It results, when complete, in (1) ptosis, or drooping of the upper eyelid, in consequence of the Levator palpebræ being paralyzed; (2) external strabismus, on account of the unopposed action of the External rectus muscle, which is not supplied by the oculomotor nerve, and is therefore paralyzed; (3) dilatation of the pupil, because the sphincter fibres of the iris are paralyzed; (4) loss of power of accommodation, as the Sphincter pupille, the Ciliary muscle, and the Internal rectus are paralyzed; (5) slight prominence of the eyeball, owing to most of its muscles being relaxed. Occasionally paralysis may affect only a part of the nerve; that is to say, there may be, for example, a dilated and fixed pupil, with ptosis, but no other signs. Irritation of the nerve causes spasm of one or other of the muscles supplied by it; thus, there may be internal strabismus from spasm of the Internal rectus; accommodation for near objects only from spasm of the Ciliary muscle, or contraction of the pupil (myosis), from irritation of the sphincter of the pupil.
THE FOURTH OR TROCHLEAR NERVE (N. TROCHLEARIS) (Figs. 683 and 687).

The fourth or trochlear nerve or patheticus, with the exception of the n. intermedius, the smallest of the cranial nerves, supplies the Superior oblique muscle.

The apparent origin, at the base of the brain, is on the outer side of the crus cerebri, just in front of the pons, but the fibres can be traced backward behind the quadrigemina to the valvula, on the upper surface of which the two nerves decussate, decussatio nervorum trochlearium. Its deep origin may be traced to a nucleus in the floor of the aqueduct immediately below that of the oculomotor nerve, with which it is continuous (Fig. 578).

Emerging from the valvula, the nerve is directed outward across the prepeduncle of the cerebellum, and then winds forward around the outer side of the crus cerebri, immediately above the pons, pierces the dura in the free border of the tentorium, just behind, and external to, the posterior clinoid process, and passes forward in the outer wall of the cavernous sinus, between the oculomotor nerve and the ophthalmic division of the trigeminal nerve (Figs. 454 and 455). It crosses the oculomotor nerve and enters the orbit through the sphenoidal fissure (Fig. 692). It now becomes the highest of all the nerves, lying at the inner extremity of the fissure internal to the frontal nerve. In the orbit it passes inward, above the origin of the Levator palpebrae, and finally enters the orbital surface of the Superior oblique muscle. In the outer wall of the cavernous sinus this nerve is not infrequently blended with the ophthalmic division of the trigeminal nerve.

Branches of Communication.—In the outer wall of the cavernous sinus it receives some filaments from the cavernous plexus of the sympathetic. In the sphenoidal fissure it occasionally gives off a branch to assist in the formation of the lacrimal nerve.

Branches of Distribution.—It gives off a recurrent branch, which passes backward between the layers of the tentorium, dividing into two or three filaments which may be traced as far back as the wall of the lateral sinus.

Surgical Anatomy.—The trochlear nerve when paralyzed causes loss of function in the Superior oblique, so that the patient is unable to turn his eye downward and outward. Should the patient attempt to do this, the eye on the affected side is twisted inward, producing diplopia or double vision. Accordingly, it is said that the first symptom of this disease which presents itself is giddiness when going down hill or in descending stairs, owing to the double vision induced by the patient looking at his steps while descending.

THE FIFTH, TRIGEMINAL OR TRIFACIAL NERVE (N. TRIGEMINUS) (Figs. 683, 685, 686, 687, 688, 689, 690, 691).

The fifth or trigeminal or trifacial nerve is the largest cranial nerve. It resembles a spinal nerve (1) in having two roots; (2) in having a ganglion developed on its dorsal root; and (3) in its function, since it is a compound nerve. It is the great sensor nerve of the head and face and the motor nerve of the muscles of mastication. Its upper two divisions, portio major, are entirely sensor, the third division, portio minor, is partly sensor and partly motor. It arises by two roots: of these the ventral is the smaller, and is the motor root (Fig. 578); the dorsal, the larger and sensor root. Its superficial origin is from the side of the pons nearer to the upper than the lower border (Fig. 578). The smaller root consists of three or four bundles; the larger root consists of numerous bundles of fibres, varying in number from seventy to a hundred. The two roots are separated from one another by a few of the transverse fibres of the pons. The
deep termination of the larger or sensor root is chiefly in a long tract in the oblongata, the lower sensor nucleus, which is continuous below with the glosia or substantia gelatinosa of Rolando. The fibres from this nucleus form the so-called ascending root of the fifth nerve; they pass upward through the pons and join with fibres from the locus cereuleus or upper sensor nucleus (Fig. 578), which is situated to the outer side of the nucleus, from which the lower part of the motor root takes origin. The deep origin of the smaller or motor root is derived partly from a nucleus embedded in the gray substance of the upper part of the floor of the fourth ventricle and partly from a collection of nerve-cells situated at the side of the aqueduct from which the fibres pass caudad under the name of the descending root of the fifth nerve (Fig. 578).

The two roots of the nerve pass forward below the tentorium as it bridges over the notch on the inner part of the superior border of the petrous portion of the temporal bone (Fig. 686); they then run between the bone and the dura to the apex of the petrous portion of the temporal bone, where the fibres of the sensor root appear to enter into the formation of the large semilunar or Gasserian ganglion (Figs. 685 and 686), while the motor root passes beneath the ganglion without having any connection with it, and joins outside the cranium with one of the trunks derived from it (Figs. 685 and 686).

![Diagram of the Nerve System](image_url)

Fig. 685.—The right semilunar or Gasserian ganglion, viewed from the medial side. (Spalteholz.)

The Gasserian or Semilunar Ganglion¹ (ganglion semilunare) (Figs. 685, 686, 687, 688, 689, and 690).—The Gasserian or semilunar ganglion is lodged in an osteo-fibrous space, the cavum Meckelli (Figs. 644 and 686), near the apex of the petrous portion of the temporal bone. The ganglion is of somewhat crescentic form, with its convexity turned forward. Its upper surface is intimately adherent to the dura. Besides the small or motor root, the large superficial petrosal nerve lies underneath the ganglion.

Branches of Communication.—This ganglion receives on its inner side filaments from the carotid plexus of the sympathetic.

Branches of Distribution.—It gives off minute branches to the tentorium and the dura in the middle fossa of the cranium. From its anterior border, which is

¹ A Viennese anatomist, Raimund Balthasar Hirsch (1765), was the first who recognized the ganglionic nature of the swelling on the sensory root of the fifth nerve, and called it, in honor of his otherwise unknown teacher, Jon. Laur. Gasser, the "Ganglion Gasseri." Julius Casserius, whose name is given to the musculocutaneous nerve of the arm, was professor at Padua, 1545-1605. (See Hyrtl, Lehrbuch der Anatomie, p. 805 and p. 85.) Ed. of 16th English edition.
directed forward and outward, three large branches proceed—the ophthalmic, superior maxillary, and inferior maxillary. The ophthalmic and superior maxillary consist exclusively of fibres derived from the larger root and ganglion, and are solely nerves of common sensation. The third division, or inferior maxillary, is joined outside the cranium by the motor root. This, therefore, strictly speaking, is the only portion of the trigeminal nerve which can be said to resemble a spinal nerve.

**Ophthalmic Nerve** (*n. ophthalmicus*) (Figs. 683, 685, 686, 687, 688, 689, and 690).—The ophthalmic or first division of the trigeminal is a sensor nerve. It supplies the eyeball, the lacrimal gland, the mucous lining of the eye and nasal fossæ, and the integument of the eyebrow, forehead, and nose (Fig. 691). It is the smallest of the three divisions of the fifth, arising from the upper part of the Gasserian ganglion. It is a short, flattened band, about 2 cm. in length, which passes forward along the outer wall of the cavernous sinus (Figs. 454 and 455), below the other nerves (Fig. 685), and just before entering the orbit, through the sphenoidal fissure, divides into three branches—lacrimal, frontal, and nasal (Figs. 683, 687, and 688).

**Branches of Communication.**—The ophthalmic nerve gives off in the cavernous sinus a branch to the dura (*n. tentorii*), is joined by filaments from the cavernous plexus of the sympathetic, and gives off minute branches to communicate with the oculomotor and abducens nerves, and not infrequently with the trochlear.

**Branches of Distribution.**—It gives off recurrent filaments which pass between the layers of the tentorium, and then divide into—

- **Lacrimal.**
- **Frontal.**
- **Nasal.**

**The Lacrimal Nerve** (*n. lacrimalis*) (Figs. 683, 687, and 688).—The lacrimal is the smallest of the three branches of the ophthalmic. It sometimes receives a filament from the trochlear nerve, but this is possibly derived from the branch of communication which passes from the ophthalmic to the trochlear. It passes forward in a separate tube of dura, and enters the orbit through the narrowest part of the sphenoidal fissure (Fig. 692). In the orbit it runs along the upper border of the External rectus muscle, with the lacrimal artery, and communicates with the temporomalar branch of the superior maxillary nerve. It enters the lacrimal gland and gives off several filaments, which supply the gland and the conjunctiva. Finally, it pierces the superior palpebral ligament, and terminates in the integument of the upper eyelid, joining with filaments of the facial nerve. The lacrimal nerve is occasionally absent, when its place is taken by the temporal branch of the superior maxillary. Sometimes the latter branch is absent, and a continuation of the lacrimal is substituted for it.

**The Frontal Nerve** (*n. frontalis*) (Figs. 683 and 687).—The frontal is the largest division of the ophthalmic, and may be regarded, both from its size and direction, as the continuation of the nerve. It enters the orbit above the muscles, through the sphenoidal fissure (Fig. 692), and runs forward along the middle line, between the Levator palpebrarum and the periosteum. Midway between the apex and the base of the orbit it divides into two branches, supratrochlear and supraorbital.
The **Supratrochlear Branch** (*n. supratrochlearis*) (Fig. 683), the smaller of the two, passes inward, above the pulley of the superior oblique muscle, and gives off a descending filament, which joins with the infratrochlear branch of the nasal nerve. It then escapes from the orbit between the pulley of the Superior oblique and the supraorbital foramen, curves up on to the forehead close to the bone, ascends beneath the Corrugator supercilii and Occipito-frontalis muscles, and, dividing into branches which pierce these muscles, it supplies the integument of the lower part of the forehead on either side of the middle line and sends filaments to the conjunctiva and skin of the upper lid.

The **Supraorbital Branch** (*n. supraorbitalis*) (Fig. 692) passes forward through the supraorbital foramen, and gives off, in this situation, **palpebral filaments** to the upper eyelid. It then ascends upon the forehead, and terminates in **cutaneous and pericranial branches**.

The **cutaneous branches**, two in number, an inner and an outer, supply the integument of the cranium as far back as the vertex. They are at first situated beneath the Occipito-frontalis, the inner branch perforating the frontal portion of the muscle, the outer branch its tendinous aponeurosis.

The **pericranial branches** are distributed to the pericranium over the frontal and parietal bones.

---

**The Nasal Nerve** (*n. nasociliaris*) (Figs. 683 and 687).—The nasal nerve is intermediate in size between the frontal and lacrimal, and more deeply placed than the other branches of the ophthalmic. It enters the orbit by way of the sphenoidal fissure (Fig. 692) between the two heads of the External rectus, and passes obliquely inward across the optic nerve, beneath the Superior rectus and Superior oblique muscles, to the inner wall of the orbit, where it passes through the anterior ethmoidal foramen, and, entering the cavity of the cranium, traverses a shallow groove on the front of the cribiform plate of the ethmoid bone, and passes down, through the slit by the side of the crista galli, into the nose (Fig. 689), where it divides into two branches, an **internal** and an **external branch**. The **internal branch** (*rami nasales mediales*) supplies the mucous membrane near the forepart of the septum of the nose. The **external branch** (*rami nasales laterales*) descends in a groove on the inner surface of the nasal bone, and supplies a few filaments to the mucous membrane covering the forepart of the outer wall of the nares as far as the inferior turbinate bone; it then leaves the cavity.
of the nose, between the lower border of the nasal bone and the upper lateral cartilage of the nose, and, passing down beneath the Compressor nasi, supplies the integument of the ala and the tip of the nose, joining with the facial nerve.

Branches.—The branches of the nasal nerve are the ganglionic, ciliary, and infra-trochlear.

The Ganglionic Branch or the long root of the ciliary ganglion (radix longa ganglii ciliaris) (Figs. 684 and 687) is a slender branch, about 1 to 2 cm. in length, which usually arises from the nasal nerve, between the two heads of the External rectus muscle. It passes forward on the outer side of the optic nerve, and enters the postero-superior angle of the ciliary ganglion, forming its long root. It is sometimes joined by a filament from the cavernous plexus of the sympathetic or from the superior division of the third nerve.

The Long Ciliary Nerves (nn. ciliares longi), two or three in number, are given off from the nasal as it crosses the optic nerve. They join the short ciliary nerves (Figs. 684 and 687) from the ciliary ganglion, pierce the posterior part of the sclera, and, running forward between it and the choroid, are distributed to the ciliary muscle, iris, and cornea.

The Infra-trochlear Branch (n. infra-trochlearis) (Fig. 683) is given off just before the nasal nerve passes through the anterior ethmoidal foramen. It runs forward along the upper border of the Internal rectus muscle, and is joined, beneath the pulley of the Superior oblique, by a filament from the supratrochlear nerve. It then passes to the inner angle of the eye, and supplies the integument of the eyelids and side of the nose, the conjunctiva, the lacrimal sac, and the caruncula lacrimalis.

Connected with the three divisions of the trigeminal nerve are four small ganglia. With the first division is connected the ophthalmic ganglion; with the second division, the sphenopalatine or Meckel's ganglion; and with the third, the otic and submaxillary ganglia. All the four receive sensor filaments from the trigeminal nerve, and motor and sympathetic filaments from various sources; these filaments are called the roots of the ganglia.

The Ophthalmic, Lenticular or Ciliary Ganglion (ganglion ciliare) (Figs. 684 and 687) is a small, quadrangular, flattened ganglion, of a reddish-gray color, and about the size of a pin's head, situated at the back part of the orbit between the optic nerve and the External rectus muscle, lying generally on the outer side of the ophthalmic artery. It is enclosed in a quantity of loose fat, which makes its exposure by dissection somewhat difficult.

Its branches of communication or roots are three, all of which enter its posterior border. One, the long or sensor root (radix longa ganglii ciliaris), is derived from the nasal branch of the ophthalmic and joins the superior angle of the ganglion. The second, the short or motor root (radix brevis ganglii ciliaris), is a short, thick nerve, occasionally divided into two parts, which is derived from the branch of the oculomotor to the Inferior oblique muscle, and is connected with the inferior angle of the ganglion. The third, the sympathetic root (radix sympathetic ganglii ciliaris), is a slender filament from the cavernous plexus of the sympathetic. This is frequently blended with the long root, although it sometimes passes to the ganglion separately. The ganglion occasionally receives a filament of communication from the sphenopalatine ganglion.

Its branches of distribution are the short ciliary nerves (nn. ciliares breves) (Figs. 684 and 687). These are delicate filaments, from six to ten in number, which arise from the forepart of the ganglion in two bundles, connected with its superior and inferior angles; the lower bundle is the larger. They run forward with the ciliary arteries in a wavy course, one set above and the other below the optic nerve, and are accompanied by the long ciliary branches of the nasal nerve. They pierce the sclera at the back part of the globe, pass forward in delicate
grooves on its inner surface, and are distributed to the Ciliary muscle, iris, and cornea. One small branch is said to penetrate the optic nerve with the arteria centralis retinae.

The circular fibres of the iris are innervated by the oculomotor nerve; the radiating fibres are innervated by the sympathetic.

The Superior Maxillary Nerve (n. maxillaris) (Figs. 685, 686, 687, and 688).
—The superior maxillary or second division of the trigeminal is a sensor nerve. It is intermediate, both in position and size, between the ophthalmic and inferior maxillary. It commences at the middle of the Gasserian ganglion as a flattened plexiform band (Fig. 685), and, passing horizontally forward, it leaves the skull through the foramen rotundum (Fig. 686), where it becomes more cylindrical in form and firmer in texture. It then crosses the sphenoid-maxillary fossa (Fig. 67) enters the orbit through the sphenoid-maxillary fissure, traverses the infraorbital canal in the floor of the orbit, and appears upon the face at the infraorbital foramen. After it enters the infraorbital canal the nerve is usually called the infraorbital (n. infraorbitalis), and is, therefore, the terminal branch of the superior maxillary nerve (Fig. 688). At its termination the nerve lies beneath the Levator labii superioris muscle, and divides into a leash of branches, which spread out upon the side of the nose, the lower eyelid, and upper lip, joining with filaments of the facial nerve.

Branches of Distribution.—The branches of this nerve may be divided into four groups: 1. Those given off in the cranium. 2. Those given off in the sphenomaxillary fossa. 3. Those in the infraorbital canal. 4. Those on the face.

In the cranium . . . Dural.

Sphenomaxillary fossa . . .

Infraorbital canal . . .

On the face . . .

Dural.

Orbital or temporo-malar.

Spheno-palatine.

Posterior superior dental.

Middle superior dental.

Anterior superior dental.

Palpebral.

Nasal.

Labial.

The Dural Branch (n. meningeus medius).—The dural branch is given off by the superior maxillary nerve directly after its origin from the Gasserian ganglion; it accompanies the medidural artery and supplies the dura of the middle fossa of the base of the skull.

The Orbital or Temporo-malar Branch (n. zygomaticus) (Figs. 687 and 688).—The orbital or temporo-malar branch arises in the sphenomaxillary fossa, enters the orbit by the sphenomaxillary fissure, and divides at the back of that cavity into two branches, temporal and malar.

The Temporal Branch (ramus zygomaticotemporalis) runs in a groove along the outer wall of the orbit (in the malar bone), receives a branch of communication from the lacrimal, and, passing through a foramen in the malar bone, enters the temporal fossa. It ascends between the bone and the substance of the Temporal muscle, pierces this muscle and the temporal fascia about an inch above the zygoma, and is distributed to the integument covering the temple and side of the forehead, communicating with the facial and the auriculo-temporal branch of the inferior maxillary nerve. As it pierces the temporal fascia it gives off a slender twig, which runs between the two layers of the fascia to the outer angle of the orbit.

The Malar Branch (ramus zygomaticofacialis) passes along the external inferior angle of the orbit, emerges upon the face through a foramen in the malar bone, and, perforating the Orbicularis palpebrarum muscle, supplies the skin on the
prominence of the cheek, where it is named the subcutaneus malae. It joins with the facial and the palpebral branches of the superior maxillary.

The Spheno-palatine Branches (nn. sphenopalatini) (Fig. 688).—The sphenopalatine branches, two in number, descend to the spheno-palatine ganglion, of which ganglion they are the sensor or short roots.

The Posterior Superior Dental Branches (rami alveolares superiores posteriores) (Fig. 688).—The posterior superior dental branches arise from the trunk of the nerve just as it is about to enter the infraorbital canal; they are generally two in number, but sometimes arise by a single trunk, and immediately divide and pass downward on the tuberosity of the superior maxillary bone. They give off several twigs to the gums and neighboring parts of the mucous membrane of the cheek, superior gingival branches (rami gingivales superiores). They then enter the posterior dental canals on the zygomatic surface of the superior maxil-
enlargement, which is called the **ganglion of Bochdalek**. Neither of these is a true ganglion.

**The Anterior Superior Dental Branch** (*ramus alveolaris superior anteriores*).—The anterior superior dental branch, of large size, is given off from the superior maxillary nerve just before its exit from the infraorbital foramen; it enters a special canal in the anterior wall of the antrum, and divides into a series of branches which supply the incisor and canine teeth. It communicates with the middle dental nerve by a plexus, and gives off a **nasal branch**, which passes through a minute canal into the nasal fossa, and supplies the mucous membrane of the forepart of the inferior meatus and the floor of the cavity, communicating with the nasal branches from the spheno-palatine ganglion.

The **superior dental plexus** (*plexus dentalis superior*) is formed by twigs of the three superior dental nerves. From the plexus come the nerves which supply the teeth of the upper jaw (*rami dentales superiores*) and the gums (*rami gingivales superiores*).

The branches upon the face are known as the **rami n. infraorbitalis** (Fig. 688). There are three sets of them.

**The Palpebral Branches** (*rami palpebrales inferiores*).—The palpebral branches pass upward beneath the Orbicularis palpebrarum muscle. They supply the integument and conjunctiva of the lower eyelid with sensation, joining at the outer angle of the orbit with the facial nerve and the malar branch of the orbital.

**The Nasal Branches** (*rami nasales interni*).—The nasal branches pass inward; they supply the integument of the side of the nose and join with the nasal branch of the ophthalmic.

**The Labial Branches** (*rami labiales superiores*).—The labial branches, the largest and most numerous, descend beneath the Levator labii superioris muscle, and are distributed to the integument of the upper lip, the mucous membrane of the mouth, and the labial glands.

All these branches are joined, immediately beneath the orbit, by filaments from the facial nerve, forming an intricate plexus, the **infraorbital plexus**.

**The Spheno-palatine or Meckel's Ganglion** (*ganglion sphenopalatinum*) (Fig. 689).—The sphenopalatine ganglion, the largest of the cranial ganglia, is deeply placed in the sphenomaxillary fossa, close to the spheno-palatine foramen. It is triangular or heart-shaped, of a reddish-gray color, and is situated just below the superior maxillary nerve as it crosses the fossa.

**Branches of Communication.**—Like the other ganglia of the trigeminal nerve, it possesses a motor, a sensor, and a sympathetic root. Its **sensor root** is derived from the superior maxillary nerve through its two sphenopalatine branches (p. 1047). These branches of the nerve are given off in the sphenomaxillary fossa and descend to the ganglion. Their fibres, for the most part, pass in front of the ganglion, as they proceed to their destination, in the palate and nasal fossa, and are not incorporated in the ganglionic mass; some few of the fibres, however, enter the ganglion, constituting its sensor root. Its **motor root** is derived from the facial nerve through the large superficial petrosal nerve, and its **sympathetic root** from the carotid plexus, through the large deep petrosal nerve. These two nerves join together before their entrance into the ganglion to form a single nerve, the **Vidian**.

The **Large or Great Superficial Petrosal Branch** (*n. petrosus superficialis major*) (Fig. 693) is given off from the **geniculate ganglion** of the facial nerve in the aqueductus Fallopii; it passes through the hiatus Fallopii; enters the cranial cavity, and runs forward, being contained in a groove on the anterior surface of the petrous portion of the temporal bone and lies beneath the dura. It then enters the cartilaginous substance which fills in the foramen lacerum medium basis cranii, and, joining with the large deep petrosal branch, forms the Vidian nerve.
The **Large or Great Deep Petrosal Branch** (*n. petrosus profundus*) (Fig. 694) is given off from the carotid plexus of the sympathetic upon the internal carotid artery, and runs through the carotid canal on the outer side of the internal carotid artery. It then enters the cartilaginous substance which fills in the foramen lacerum medium basis crani, and joins with the large superficial petrosal nerve to form the Vidian.

The **Vidian Nerve** (*n. canalis pterygoidei*) (Fig. 689), formed in the cartilaginous substance which fills in the middle lacerated foramen by the junction of the two preceding nerves, passes forward, through the Vidian canal, with the artery of the same name, and is joined by a small ascending nervous branch, the **sphenoidal branch**, from the otic ganglion. Finally, it enters the spheno-maxillary fossa, and joins the posterior angle of the spheno-palatine ganglion.

**Branches of Distribution of the Spheno-palatine Ganglion.**—Its branches of distribution are divisible into four groups: **ascending**, which pass to the orbit; **descending**, to the palate; **internal**, to the nose; and **posterior branches**, to the pharynx and nasal fossæ.

The **Ascending Branches** (*rami orbitales*) are two or three delicate filaments which enter the orbit by the spheno-maxillary fissure, and supply the peristeum. According to Luschka, some filaments pass through foramina in the suture between the os planum of the ethmoid and frontal bones to supply the mucous membrane of the posterior ethmoidal and sphenoidal sinuses.

The **Descending or Palatine Branches** (*nn. palatini*) (Fig. 689) are distributed to the roof of the mouth, the soft palate, tonsil, and lining membrane of the nose. They are almost a direct continuation of the spheno-palatine branches of the superior maxillary nerve, and are three in number—**anterior**, **middle**, and **posterior**.

The **anterior or large palatine nerve** (*n. palatinus anterior*) descends through the **large posterior palatine canal**, emerges upon the hard palate at the posterior palatine foramen, and passes forward through a groove in the hard palate nearly
as far as the incisor teeth. It supplies the gums, the mucous membrane and glands of the hard palate, and communicates in front with the termination of the naso-palatine nerve (see below). While in the posterior palatine canal it gives off inferior nasal branches (rami nasales posteriores inferiores), which enter the nose through openings in the palate bone, and ramify over the inferior turbinate bone, the middle and the inferior meatus; and at its exit from the canal a palatine branch is distributed to both surfaces of the soft palate.

The middle or external palatine nerve (n. palatinus medius) descends through one of the accessory palatine canals, distributing branches to the uvula, tonsil, and soft palate. It is occasionally wanting.

The posterior or small palatine nerve (n. palatinus posterior) descends with a minute artery through the small posterior palatine canal, emerging by a separate opening behind the posterior palatine foramen. It supplies the Levator palatini and Azygos uvulae muscles, the soft palate, tonsil, and uvula. The middle and posterior palatine join with the tonsillar branches of the glosso-pharyngeal to form the plexus around the tonsil, the circulus tonsillaris.

The Internal Branches are distributed to the septum and outer wall of the nasal fossa. They are the posterior superior nasal and the naso-palatine.

The posterior superior nasal branches (rami nasales posteriores superiores), three in number, enter the back part of the nasal fossa by the sphenopalatine foramen. They supply the mucous membrane covering the superior and middle spongy bones, and that lining the posterior ethmoidal cells, a few being prolonged to the upper and back part of the septum.

The naso-palatine nerve (n. nasopalatinus) has been called the nerve of Scarpa and also the nerve of Cotunnius. It enters the nasal fossa through the sphenopalatine foramen, and passes inward across the roof of the nose, below the orifice of the sphenoidal sinus, to reach the septum; it then runs obliquely downward and forward along the lower part of the septum, to the anterior palatine foramen, lying between the peristeum and mucous membrane. It descends to the roof of the mouth through the anterior palatine canal (Fig. 689). The two nerves are here contained in separate and distinct canals, situated in the intermaxillary suture, and termed the foramina of Scarpa, the left nerve being usually anterior to the right one. In the mouth they become united, supply the mucous membrane behind the incisor teeth, and join with the anterior palatine nerve. The naso-palatine nerve furnishes a few small filaments to the mucous membrane of the septum.

The Posterior Branches are the pharyngeal or pterygo-palatine and the upper posterior nasal branches.

The pharyngeal or pterygo-palatine nerve (Fig. 689) is a small branch arising from the back part of the sphenopalatine ganglion, being generally blended with the Vidian nerve. It passes through the pterygo-palatine canal with the pterygo-palatine artery, and is distributed to the mucous membrane of the upper part of the pharynx, behind the Eustachian tube.

The upper posterior nasal branches are a few twigs given off from the posterior part of the sphenopalatine ganglion, which run backward in the sheath of the Vidian nerve to the mucous membrane at the back part of the roof, septum, and superior meatus of the nose and that covering the end of the Eustachian tube.

The Mandibular or Inferior Maxillary Nerve (n. mandibularis) (Figs. 685, 687, and 688).—The inferior maxillary or third division of the trigeminal nerve distributes branches to the teeth and gums of the lower jaw, the integument of the temple and external ear, the lower part of the face and lower lip, and the muscles of mastication; it also supplies the tongue with a large branch. It is the largest of the three divisions of the trigeminal, and is made up of two roots: a large or sensor

---

1 It is probable that this is not the true motor supply to these muscles, but that they are supplied by the accessory nerve through the pharyngeal plexus.—Ed. of 18th English edition.
root, proceeding from the inferior angle of the Gasserian ganglion; and a small or motor root, which passes beneath the ganglion and unites with the sensor root just after its exit from the skull through the foramen ovale (Figs. 685, 686, and 688). Immediately beneath the base of the skull this nerve divides into two trunks, anterior and posterior. Previous to its division the primary trunk gives off from its inner side a recurrent branch and the nerve to the Internal pterygoid muscle.

The Recurrent or Meningeal Branch (n. spinosus).—The recurrent or meningeal branch is given off directly after the exit of the mandibular nerve from the foramen ovale. It passes backward into the skull through the foramen spinosum with the medidural artery. It divides into two branches, anterior and posterior, which accompany the main divisions of the artery and supply the dura. The posterior branch also supplies the mucous lining of the mastoid cells. The anterior branch communicates with the dural branch of the superior maxillary nerve.

The Internal Pterygoid Nerve (n. pterygoideus internus).—The internal pterygoid nerve, given off from the inferior maxillary previous to its division, is intimately connected at its origin with the otic ganglion. It is a long and slender branch, which passes inward to enter the deep surface of the Internal pterygoid muscle.

The anterior and smaller division of the inferior maxillary nerve, which receives nearly the whole of the motor root of the trigeminal nerve, divides into branches which supply the muscles of mastication. They are the masseteric, deep temporal, buccal, and external pterygoid branches (Fig. 688).

The Masseteric Branch (n. massetericus) passes outward, above the External pterygoid muscle, in front of the temporo-mandibular articulation and behind the tendon of the temporal muscle; it crosses the sigmoid notch with the masseteric artery, to the deep surface of the Masseter muscle, in which it ramifies nearly as far as its anterior border. It occasionally gives a branch to the Temporal muscle, and a filament to the articulation of the jaw.

The Deep Temporal Branches (nn. temporales profundi), two in number, anterior and posterior, supply the deep surface of the Temporal muscle. The posterior branch (n. temporalis profundus posterior), of small size, is placed at the back of the temporal fossa. It is sometimes joined with the masateric branch. The anterior branch (n. temporalis profundus anterior) is frequently given off from the buccal nerve; it is reflected upward, at the pterygoid ridge of the sphenoid, to the front of the temporal fossa. Sometimes there are three deep temporal branches, and if this maintains the third branch, the middle deep temporal, passes outward above the External pterygoid muscle, and runs upward on the bone to enter the deep surface of the Temporal muscle.

The Buccal or Buccinator Branch (n. buccinatorius) passes forward between the two heads of the External pterygoid, and downward beneath the inner surface of the coronoid processes of the lower jaw, or through the fibres of the Temporal muscle, to reach the surface of the Buccinator muscle, upon which it divides into a superior and an inferior branch. It gives a branch to the External pterygoid during its passage through that muscle, and a few ascending filaments to the Temporal muscle, one of which occasionally joins with the anterior branch of the deep temporal nerve. The superior or upper branch supplies the integument and upper part of the Buccinator muscle, joining with the facial nerve around the facial vein. The inferior or lower branch passes forward to the angle of the mouth; it supplies the integument and Buccinator muscle, as well as the mucous membrane lining the inner surface of that muscle, and joins the facial nerve.1

The External Pterygoid Nerve (n. pterygoideus externus) is most frequently derived from the buccal, but it may be given off separately from the anterior trunk of the mandibular nerve. It enters the muscle on its inner surface.

1 There seems to be no reason to doubt that the branch supplying the Buccinator muscle is entirely a nerve of ordinary sensation, and that the true motor supply of this muscle is from the facial.—Eo. of 16th English edition.
The posterior and larger division of the inferior maxillary nerve is for the most part sensor, but receives a few filaments from the motor root. It divides into three branches: auriculotemporal, lingual (gustatory), and inferior dental (Fig. 688).

The Auriculotemporal Nerve (n. auriculotemporalis) (Fig. 690) generally arises by two roots, between which the medidural artery passes. It runs backward beneath the External pterygoid muscle to the inner side of the neck of the lower jaw. It then turns upward with the temporal artery, between the external ear and the condyle of the jaw, under cover of the parotid gland, and, escaping from beneath this structure, ascends over the zygoma and divides into two temporal branches.

The branches of communication are with the facial and with the otic ganglion. The branches of communication with the facial (rami anastomotici cum n. facialis), usually two in number, pass forward from behind the neck of the condyle of the jaw, to join this nerve at the posterior border of the Masseter muscle. They form one of the principal branches of communication between the facial and the trigeminal nerve. The filaments of communication with the otic ganglion are derived from the commencement of the auriculotemporal nerve.

The branches of distribution are—

- Anterior auricular.
- Branches to the meatus auditorius.
- Articular.
- Parotid.
- Superficial temporal.

The anterior auricular branches (rami auriculares anteriores) are usually two in number. They supply the front of the upper part of the pinna, being distributed principally to the skin covering the front of the helix and tragus.

A branch to the external auditory meatus (n. meatus auditorii externi) divides into two. The two nerves enter the canal between the bony and cartilaginous portion of the meatus. They supply the skin lining the meatus; the upper one sending a filament to the membrana tympani (ramus membranae tympani).

A branch to the temporo-mandibular articulation, the articular branch, is usually derived from the auriculotemporal nerve.

The parotid branches (rami parotidei) supply the parotid gland.

The superficial temporal branches (rami temporales superficiales) accompany the temporal artery to the vertex of the skull, and supply the integument of the temporal region, communicating with the facial nerve, and with the temporal branch of the temporo-malar from the superior maxillary.

The Lingual Nerve (n. lingualis) (Fig. 688).—The lingual nerve supplies the papilla and mucous membrane of the anterior two-thirds of the tongue. It is deeply placed throughout the whole of its course. It lies at first beneath the External pterygoid muscle, together with the inferior dental nerve, being placed to the inner side of this nerve, and is occasionally joined to it by a branch which may cross the internal maxillary artery. The chorda tympani nerve also joins it at an acute angle in this situation. The nerve then passes between the Internal pterygoid muscle and the inner side of the ramus of the jaw, and crosses obliquely to the side of the tongue over the Superior constrictor of the pharynx and the Stylo-glossus muscles, and then between the Hyo-glossus muscle and the deep part of the submaxillary gland; the nerve finally runs across Wharton’s duct, and along the side of the tongue to its apex, lying immediately beneath the mucous membrane.

The branches of communication are with the inferior dental and hypoglossal nerves, and the submaxillary ganglion, and, apparently only, with the facial through the chorda. The chorda tympani branch of the facial joins the lingual nerve under the external pterygoid muscle and is distributed with the lingual to the tongue.
The hypoglossal nerve and the lingual nerve lie near together, over the Hyo-glossus muscle, and the two nerves are joined by loops (rami anastomotici cum n. hypoglosso). The branches to the submaxillary ganglion are two or three in number; those connected with the hypoglossal nerve form a plexus at the anterior margin of the Hyo-glossus muscle.

The branches of distribution supply the mucous membrane of the mouth, the gums, the sublingual gland, the filiform and fungiform papillae and mucous membrane of the tongue; the terminal filaments communicate, at the tip of the tongue, with the hypoglossal nerve. The lingual fibres are fibres of common sensation. The chorda tympani fibres which join the lingual nerve are probably taste-fibres and exo-glandular for the submaxillary and sublingual salivary glands.

The Inferior Dental Nerve (n. alveolaris inferior) (Fig. 688).—The inferior dental is the largest of the branches of the inferior maxillary nerve. It passes downward with the inferior dental artery, at first beneath the External pterygoid muscle, and then between the internal lateral ligament and the ramus of the jaw to the dental foramen. It then passes forward in the dental canal of the inferior maxillary bone, lying beneath the teeth, as far as the mental foramen, where it divides into two terminal branches, incisor and mental.

The Branches of the inferior dental are: the mylo-hyoid, dental, incisor, and mental.

The Mylo-hyoid (n. mylohyoideus) is derived from the inferior dental just as that nerve is about to enter the dental foramen. It descends in a groove on the inner surface of the ramus of the jaw, in which it is retained by a process of fibrous membrane. It reaches the under surface of the Mylo-hyoid muscle, and supplies it and the anterior belly of the Digastric.

The Dental Branches supply the molar and bicuspid teeth. They correspond in number to the fangs of those teeth: each nerve entering the orifice at the point of the fang and supplying the pulp of the tooth.

The Incisor Branch is continued onward within the bone to the middle line, and supplies the canine and incisor teeth.

The dental branches and the incisor branch form a plexus (plexus dentalis inferior), and from this plexus come the branches to the teeth (rami dentales inferiores) and to the gums (rami gingivales inferiores).

The Mental Branch (n. mentalis) emerges from the bone at the mental foramen, and divides beneath the Depressor anguli oris muscle into two or three branches; one descends to supply the skin of the chin, and another (sometimes two) ascends to supply the skin and mucous membrane of the lower lip. These branches communicate freely with the facial nerve.

Two small ganglia are connected with the inferior maxillary nerve—the otic with the trunk of the nerve, and the submaxillary with its lingual branch.

Otic or Arnold’s Ganglion (ganglion oticum) (Fig. 690).—The otic or Arnold’s ganglion is a small, oval-shaped, flattened ganglion of a reddish-gray color, situated immediately below the foramen ovale, on the inner surface of the inferior maxillary nerve, and round the origin of the internal pterygoid nerve. It is in relation, externally, with the trunk of the inferior maxillary nerve, at the point where the motor root joins the sensor portion; internally, with the cartilaginous part of the Eustachian tube, and the origin of the Tensor palati muscle; behind, it lies in relation with the medidural artery.

Branches of Communication.—This ganglion is connected with the internal pterygoid branch of the inferior maxillary nerve by two or three short delicate filaments. From this nerve the ganglion may obtain a motor root, and possibly also a sensor root, as these filaments from the nerve to the Internal pterygoid perhaps contain sensor fibres. The otic ganglion communicates with the glossopharyngeal and facial nerves through the small superficial petrosal nerve (Figs. 690
and 603) continued from the tympanic plexus, and through this communication it probably receives its sensor root from the glossopharyngeal and its motor root from the facial; its communication with the sympathetic is effected by a filament from the plexus surrounding the medidural artery. The ganglion also communicates with the auriculo-temporal nerve (ramus anastomoticus cum n. auriculotemporalis). This communicating filament is probably a branch from the glossopharyngeal which passes to the ganglion, and through it and the auriculo-temporal nerve to the parotid gland. A slender filament, the sphenoidal, ascends from it to the Vidian nerve.

**Branches of Distribution.**—Its branches of distribution are a filament to the Tensor tympani (n. tensoris tympani) and one to the Tensor palati (n. tensoris veli palatini). The former passes backward on the outer side of the Eustachian tube; the latter arises from the ganglion, near the origin of the internal pterygoid nerve, and passes forward. The fibres of these nerves are, however, mainly derived from the nerve to the Internal pterygoid muscle. It also gives off a small communicating branch to the chorda tympani (ramus anastomoticus cum n. chorda tympani).

![Fig. 690.—The otic ganglion and its branches.](image)

**The Submaxillary Ganglion** (ganglion submaxillare) (Fig. 688).—The submaxillary ganglion is of small size, fusiform in shape, and situated above the deep portion of the submaxillary gland, near the posterior border of the Mylo-hyoid muscle, being connected by filaments with the lower border of the lingual nerve.

**Branches of Communication.**—This ganglion is connected with the lingual nerve by a few filaments (rami communicantes cum n. lingualis), which join it separately at its fore and back part. It also receives a branch from the chorda tympani, by which it communicates with the facial, and communicates with the sympathetic by filaments from the sympathetic plexus around the facial artery.

**Branches of Distribution.**—These are five or six in number; they arise from the lower part of the ganglion, and supply the mucous membrane of the mouth and Wharton’s duct, some being lost in the submaxillary gland (rami submaxillares). The branch of communication from the lingual nerve to the forepart of the ganglion is by some regarded as a branch of distribution, by which filaments of the chorda tympani pass from the ganglion to the lingual nerve, and by it are conveyed to the sublingual gland and the tongue.
Summary of the Distribution and Connections of the Trigeminal Nerve.—It is the chief sensor nerve of the face, the anterior half of the scalp, the mouth, nasal cavity, lips, teeth, anterior two-thirds of the tongue, orbit, and eyeball. The clearly defined cutaneous distributions of the branches are shown in Fig. 691. The motor portion of the nerve supplies the muscles of mastication, the mylo-hyoid, and the anterior belly of the digastric. By way of branches from the otic ganglion it supplies the Tensor tympani and Tensor palati muscles, and by way of branches from the sphenopalatine ganglion perhaps supplies the Levator palati and Azygos uvulae muscles, although it is more probable that these muscles receive their motor influence by the accessory nerves through the pharyngeal plexus. The ganglia associated with the nerve create communications with the sympathetic, the motor oculi, the facial, and the glosso-pharyngeal, and through these ganglia, as Prof. Cunningham says, “important organs, areas, and muscles” are innervated. The trigeminal communicates many times with the facial, and thus gives sensor fibres to the “muscles of expression supplied by the facial nerve.”

1 Cunningham’s Text-book of Anatomy.
injury to the sensor root there is anaesthesia of the half of the face on the side of the lesion, with the exception of the skin over the parotid gland; insensibility of the conjunctiva, followed, if the eye is not temporarily protected with a watch-glass, by destructive inflammation of the cornea, partly, it is held, from loss of trophic influence, and partly, it is certain, from the irritation produced by the presence of foreign bodies on it, which are not perceived by the patient, and therefore not expelled by the act of winking; dryness of the nose, loss to a considerable extent of the sense of taste, and diminished secretion of the lacrimal and salivary glands. In injury to the motor root there is impaired action of the lower jaw from paralysis of the muscles of mastication on the affected side.

The trigeminal nerve is often the seat of neuralgia, and each of the three divisions has been divided or a portion of the nerve excised for this affection. The supraorbital nerve may be exposed by making an incision an inch and a half in length along the supraorbital margin below the eyebrow, which is to be drawn upward, the centre of the incision corresponding to the supraorbital notch. The skin and Orbicularis palpebrarum having been divided, the nerve can be easily found emerging from the notch and lying in some loose cellular tissue. It should be drawn up by a blunt hook and divided, or, what is better, a portion of it should be removed. The infraorbital nerve has been divided at its exit by an incision on the cheek; or the floor of the orbit has been exposed, the infraorbital canal opened up, and the anterior part of the nerve resected; or the whole nerve, together with Meckel's ganglion as far back as the foramen rotundum, has been removed. This latter operation, though undoubtedly a severe proceeding, appears to have been followed by better results than has nerve resection. The operation is performed as follows: The superior maxillary bone is first exposed by a T-shaped incision, one limb of the incision passing along the lower margin of the orbit, the other from the centre of the first cut vertically down the cheek toward the angle of the mouth. The nerve is then found, is divided, and a piece of silk is tied to it as a guide. A small trephine (one-half inch) is then applied to the bone below, but including the infraorbital foramen, and the antrum opened. The trephine is now applied to the posterior wall of the antrum, and the sphenomaxillary fossa exposed. The infraorbital canal is now opened up from below by fine cutting-pliers or a chisel, and the nerve drawn down into the trephine hole, it being held on the stretch by means of the piece of silk; it is severed with fine curved scissors as near the foramen rotundum as possible, any branches coming off from the ganglion being also divided. The mental branch of the inferior dental nerve may be divided at its exit from the foramen through an incision made through the mucous membrane where it is reflected from the alveolar process on to the lower lip; or a portion of the trunk of the inferior dental nerve may be resected through an incision on the cheek through the Masseter muscle, exposing the outer surface of the ramus of the jaw. A trephine is then applied over the position of the inferior dental foramen and the outer table removed, so as to expose the inferior dental canal. The nerve is dissected out of the portion of the canal exposed, and, having been divided after its exit from the mental foramen, it is by traction on the end exposed in the trephine-hole, drawn out entire, and cut off as high up as possible. The inferior dental nerve has also been divided through an incision within the mouth, the bony point guarding the inferior dental foramen forming the guide to the nerve. The buccal nerve may be divided by an incision through the mucous membrane of the mouth and the Buc- cinator muscle just in front of the anterior border of the ramus of the lower jaw (Stimson).

In invertebral neuralgia of one or two of the branches of the trigeminal nerve a peripheral operation may cure the case, but seldom does. It often gives relief, perhaps for months. In neuralgia of the second division or third division, or of the second division and third division, Abbe, of New York, opens the skull and divides the nerve or nerves by an intracranial operation, removes a piece of nerve so as the foramen of exit is empty, and covers the foramen with rubber tissue, to hinder regrowth of the nerve. Other operators, after removing a piece from each nerve, have plugged the foramina of the exit with dentists' cement or silver-filler.

Rose's method of neurectomy is very valuable for neuralgia of the second division. It is a modification of the Braun-Lossen method. The infraorbital nerve is exposed, a ligature is tied about it, the roof of the infraorbital canal is chiselled open, and the nerve is freed as far back as possible. An incision is made from below the external angular process outward along the zygoma to in front of the lobule of the ear, downward to just above the angle of the jaw, and forward for two inches. The flap is raised and the zygoma is exposed. The root of the zygoma is drilled at two points, and the zygomatic process of the temporal bone is drilled at two points. The bone is sawed in two places between the drill-holes. The freed arch is lifted down and back, the tendon of the temporal muscle is drawn backward, and the pterygo-maxillary fossa is thus exposed. The internal maxillary artery is divided between two ligatures. The External pterygoid muscle is separated from the greater wing of the sphenoid and from the root of the external pterygoid process. The superior maxillary nerve is grasped and twisted off as near the ganglion as possible. The entire nerve is then drawn back from the infraorbital foramen and removed. The wound is then closed. If the third division is also haunted by neuralgia, it too should be removed a few weeks after the performance of Rose's operation.

1 Carnochan, American Journal of the Medical Sciences, 1858, p. 136.
If a peripheral operation fails, or if all the branches of the trigeminal are involved, the Gasserian ganglion must be removed or the sensor root of the trigeminal must be divided, as suggested by Frazier and Spiller.

Removal of the Gasserian ganglion was suggested by J. Ewing Mears in 1884, and was first carried out by Rose in 1890.

The method chiefly in vogue was devised by Hartley, and was first performed by him in 1891. An osteoplastie flap is made in front of the ear, the dura is exposed and lifted. Following Krause’s advice, the third division is exposed and clamped. The second division is exposed and clamped. The nerves are loosened from their beds and then are rolled about the clamps. This twisting pulls out the ganglion intact along with the motor root, and also the sensor root from the pons.

A difficulty in the Hartley operation is the danger of division of the dural artery. If this happens, the surgeon may be able to arrest bleeding and proceed with the operation. If the vessel is torn off at the foramen spinosum, it will be necessary to pack the wound and postpone any further operative manipulation for forty-eight hours.

Dr. Harvey Cushing has modified Hartley’s operation by trephining the wall of the temporal fossa very low down. He opens the skull below the arch of the dural vessels, and thus avoids the medidural at the foramen spinosum, and also the sulcus arteriosus of the parietal bone.

After the removal of the ganglion, Professor Keen, in order to prevent undue inflammation of the eye, sews the eyelids of the affected side together, leaving a space open at each angle, and covers the eye with a watch-crystal. Boric acid solution is flushed into the opening at the external angle at frequent intervals. The stitches are removed from the lid in from eight to ten days.

The lingual nerve is occasionally divided with the view of relieving the pain in cancerous disease of the tongue. This may be done in that part of its course where it lies below and behind the last molar tooth. If a line is drawn from the middle of the crown of the last molar tooth to the angle of the jaw, it will cross the nerve, which lies about half an inch behind the tooth, parallel to the bulging alveolar ridge on the inner side of the body of the bone. If the knife is entered three-quarters of an inch behind and below the last molar tooth and carried down to the bone, the nerve will be divided. Hilton divided it opposite the second molar tooth, where it is covered only by the mucous membrane, and Lucas pulls the tongue forward and over to the opposite side, when the nerve can be seen standing out as a firm cord under the mucous membrane by the side of the tongue and can be easily seized with a sharp hook and divided or a portion excised. This is a simple enough operation on the cadaver, but when the disease is extensive and has extended to the floor of the mouth, as is generally the case when division of the nerve is thought of, the operation is not practicable.

THE SIXTH OR ABDUCENT NERVE (N. ABDUCENS) (Fig. 687).

The sixth or abducens nerve supplies the External rectus muscle. Its superficial origin is by several filaments from the postpontile groove, between pons and pyramid. Its deep origin is from the upper part of the floor of the fourth ventricle, close to the median line, beneath the eminentia abducens (Fig. 578).

From the nucleus of the abducens nerve some fibres are supposed to pass through the medial longitudinal bundle to the oculomotor nucleus of the opposite side and into the oculomotor nerve, along which they are carried to the Internal rectus muscle. The External rectus of one eye and the Internal rectus of the other may therefore be said to receive their nerves from the same nucleus—a factor of great importance in connection with the conjugate movements of the eyeball, and one that may explain certain paralytic phenomena of the Recti muscles, which are often associated with lesions in the pons.

The nerve pierces the dura on the basilar surface of the sphenoid bone, runs through a notch immediately below the posterior clinoid process, and enters the cavernous sinus. It passes forward through the sinus, lying on the outer side of the internal carotid artery (Fig. 454). It enters the orbit through the sphenoid fissure, and lies above the ophthalmic vein, from which it is separated by a lamina of dura (Fig. 692). It then passes between the two heads of the External rectus muscle, and is distributed to that muscle on its ocular surface.

Branches of Communication.—It is joined by several filaments from the carotid and cavernous plexuses, and by one from the ophthalmic nerve.
Relations to Each Other of the Oculomotor, Trochlear, Ophthalmic Division of the Trigeminal and Abducent Nerves as they Pass to the Orbit.—The oculomotor, trochlear, the ophthalmic division of the trigeminal, and the abducent nerves, as they pass to the orbit, bear a certain relation to one another in the cavernous sinus, at the sphenoidal fissure, and in the cavity of the orbit, which will now be described.

In the Cavernous Sinus (Figs. 454 and 455) the oculomotor, trochlear, and ophthalmic division of the trigeminal are placed on the outer wall of the sinus, in their numerical order, both from above downward and from within outward. The abducent nerve lies at the outer side of the internal carotid artery. As these nerves pass forward to the sphenoidal fissure, the oculomotor and trigeminal nerves become divided into branches, and the abducent nerve approaches the rest, so that their relative position becomes considerably changed.

In the Sphenoidal Fissure (Fig. 692) the trochlear nerve and the frontal and lacrimal branches of the ophthalmic division of the trigeminal lie upon the same plane, the former being most internal, the latter external, and they enter the cavity of the orbit above the muscles. The remaining nerves enter the orbit between the two heads of the External rectus muscle. The superior division of the oculomotor nerve is the highest of these; beneath this lies the nasal branch of the ophthalmic nerve; then the inferior division of the oculomotor nerve; and the abducent nerve lowest of all.

In the Orbit (Figs. 683 and 687) the trochlear nerve and the frontal and lacrimal divisions of the ophthalmic nerve lie on the same plane immediately beneath the periosteum, the trochlear nerve being internal and resting on the Superior oblique muscle, the frontal nerve resting on the Levator palpebrae muscle, and the lacrimal nerve on the External rectus muscle. Next in order comes the superior division of the oculomotor nerve, lying immediately beneath the Superior rectus muscle, and then the nasal branch of the ophthalmic nerve, crossing the optic nerve from the outer to the inner side of the orbit. Beneath these is found the optic nerve, surrounded in front by the ciliary nerves, and having the ciliary ganglion on its outer side, between it and the External rectus muscle. Below the optic nerve is the inferior division of the oculomotor nerve and the abducent nerve, which lies on the outer side of the orbit.

Surgical Anatomy.—It is often stated that the abducent nerve is more frequently involved in fractures of the base of the skull than any other of the cranial nerves. As a matter of fact, however, it is injured in only about 2 per cent. of cases of fracture of the skull (Putscher). Cases have been reported in which the nerve was actually ruptured. The nerve may be injured by traction, pressure of a blood clot, of a tumor, or of an arterio-venous aneurism. The result of paralysis of this nerve is internal or convergent squint. When injured so that its function is destroyed, there is, in addition to the paralysis of the External rectus muscle, often a certain amount of contraction of the pupil, because some of the sympathetic fibres to the radiating muscle of the iris pass along with this nerve.
THE SEVENTH OR FACIAL NERVE (N. FACIALIS) (Figs. 693, 694, 695).

The seventh or facial nerve is the motor nerve of all the muscles of expression in the face, and of the Platysma and Buceinator; the muscles of the External ear; the posterior belly of the Digastric, and the Stylo-hyoid. The chorda tympani (or nervus intermedius) is referred to as the sensor portion of the facial.

Its superficial origin is from the upper end of the oblongata, in the groove between the olive and rectis. Its deep origin is from a nucleus situated in the floor of the fourth ventricle, beneath the superior fovea (Fig. 578). The facial nucleus is deeply placed in the reticular formation of the lower part of the preoblongata, a little external and ventral to the nucleus of the abducent nerve. From this origin the fibres pursue a curved course in the substance of the preoblongata. They first pass backward and inward, and then turn upward and forward, forming the fasciculus teres, which with the nucleus abducentis produces an eminence, the eminentia abducentis, on the floor of the fourth ventricle, and finally bend sharply downward and outward around the upper end of the nucleus of origin of the abducent nerve, to reach their superficial origin between the olive and rectis. From the nucleus of the oculomotor nerve some fibres arise which descend in the medial longitudinal bundle and join the facial just before it leaves the preoblongata; these fibres are said to supply the anterior belly of the Occipitofrontalis, the Orbicularis palpebrarum, and the Corrugator supercilii, as these muscles have been observed to escape paralysis in lesions of the nucleus of the facial nerve.

The acoustic or auditory nerve lies to the outer side of the facial nerve; and between the two is a small fasciculus, the nervus intermedius or pars intermedia of Wrisberg, which apparently arises from the oblongata and joins the facial nerve in the internal auditory meatus. The central processes of the ganglion cells, known as the nervus intermedius, end in the upper end of the nucleus of the glosso-pharyngeal nerve.

The nervus intermedius may be regarded as the sensor root of the facial nerve, analogous to the sensor root of the trigeminal, and its real nucleus of origin consists of the geniculate ganglion (see p. 894).

The facial nerve, firmer, rounder, and smaller than the auditory, passes forward and outward upon the medipeduncle of the cerebellum, and enters the internal auditory meatus with the auditory nerve. Within the meatus the facial nerve lies in a groove along the upper and anterior part of the auditory nerve, and the nervus intermedius is placed between the two and joins the inner angle of the geniculate ganglion. Beyond the ganglion its fibres are generally regarded as forming the chorda tympani (see p. 894).

At the bottom of the meatus the facial nerve enters the aqueductus Fallopii and follows the course of that canal through the petrous portion of the temporal bone, from its commencement at the internal meatus to its termination at the stylo mastoid foramen (Figs. 49 and 693). It is at first directed outward between the cochlea and vestibule toward the inner wall of the tympanum; it then bends suddenly backward and arches downward behind the tympanum to the stylo mastoid foramen. At the point in the aqueduct of Fallopii where the nerve changes its direction (geniculum n. facialis), it presents a reddish, gangliform swelling, the geniculate ganglion (ganglion geniculi), which is also called the intumescentia ganglio-
The geniculate ganglion receives a branch from the vestibular division of the auditory nerve. On emerging from the stylo-mastoid foramen the facial nerve runs forward in the substance of the parotid gland, crosses the external carotid artery, and divides behind the ramus of the lower jaw into two primary branches, temporo-facial and cervico-facial, from which numerous offsets are distributed over the side of the head, face, and upper part of the neck, supplying the superficial muscles in these regions. As the primary branches and their offsets diverge from each other, they present somewhat the appearance of a bird's claw; hence the name of pes anserinus is given to the divisions of the facial nerve in and near the parotid gland.

Branches of Communication (Fig. 694).—The communications of the facial nerve may be thus arranged:

In the internal auditory meatus.

From the geniculate ganglion.

In the Fallopian aqueduct.

At its exit from the stylomastoid foramen.

Behind the ear.

On the face.

In the neck.

With the acoustic nerve. The nervus intermedius, which is between the facial and acoustic, is supposed to give branches to both. The branch given to the acoustic accompanies it for a certain distance, and then departs from it to join the geniculate ganglion.

With the acoustic as explained above.

With the sterno-mastoid ganglion by the large superficial petrosal nerve.

With the otic ganglion by the small superficial petrosal nerve.

With the sympathetic on the mediodural artery by the external superficial petrosal nerve.

With the auricular branch of the vagus.

With the glosso-pharyngeal.

With the vagus.

With the auricularis magnus.

With the auriculotemporal.

With the small occipital.

With the superficial cervical.

In the internal auditory meatus some minute filaments pass between the facial and acoustic nerves.

Opposite the hiatus Fallopian the gangliform enlargement on the facial nerve communicates with the sphenopalatine ganglion by means of the large superficial petrosal nerve, which forms its motor root; with the otic ganglion, by the small superficial petrosal nerve; and with the sympathetic filaments accompanying the mediodural artery, by the external petrosal nerve (Bidder). From the gangliform enlargement, according to Arnold, a twig is sent back to the acoustic nerve. Just before the facial nerve emerges from the stylo-mastoid foramen it generally receives a twig of communication from the auricular branch of the vagus.

After its exit from the stylo-mastoid foramen, it sends a twig to the glosso-pharyngeal, another to the vagus nerve, and communicates with the great auricular branch of the cervical plexus, with the auriculo-temporal branch of the inferior maxillary nerve in the parotid gland, with the small occipital nerve behind the ear, on the face with the terminal branches of the three divisions of the trigeminal, and in the neck with the transverse cervical.

Branches of Distribution (Fig. 694).—The branches of distribution of the facial nerves may be thus arranged:
Within the aquaeductus Fallopii.

At its exit from the stylo-mastoid foramen.

On the face.

The branches of the two terminal divisions form the parotid plexus (plexus parotideus).

The Tympanic Branch (n. stapedius) (Fig. 694).—The tympanic branch arises from the nerve opposite the pyramid; it passes through a small canal in the pyramid and supplies the Stapedius muscle.

The Chorda Tympani (Figs. 688, 693, and 694).—The chorda tympani is apparently given off from the facial as it passes vertically downward at the back of the tympanum, about 5 mm. before its exit from the stylo-mastoid foramen. It passes from below upward and forward in a distinct canal, and enters the cavity of the tympanum through an aperture (iter chordae posterius) on its posterior wall between the opening of the mastoid cells and the attachment of the membrana tympani, and becomes invested with mucous membrane. It passes forward through the cavity of the tympanum, between the fibrous and mucous layers of the membrana tympani, and over the handle of the malleus, emerging from that cavity
through a foramen at the inner end of the Glaserian fissure, which is called the canal of Huguen (iter chordae anterius). It then descends between the two Pterygoid muscles, meets the lingual nerve at an acute angle, and accompanies it to the submaxillary gland; part of it then joins the submaxillary ganglion; the rest is continued onward through the muscular substance of the tongue to the mucous membrane covering its anterior two-thirds. A few of its fibres probably pass through the submaxillary ganglion to the sublingual gland. Before joining the lingual nerve it receives a small communicating branch from the otic ganglion. As already stated, the chorda tympani nerve is regarded as the peripheral continuation of the nervus intermedius (see p. 894).

The Posterior Auricular Nerve (n. auricularis posterior) (Figs. 655, 694, and 695).—The posterior auricular nerve arises close to the stylo-mastoid foramen, and passes upward in front of the mastoid process and between the mastoid process and the external ear, where it is joined by a filament from the auricular branch of the vagus, and communicates with the mastoid branch of the great auricular and with the small occipital. As it ascends between the external auditory meatus and the mastoid process it divides into two branches, the auricular and the occipital branches.

The Auricular Branch supplies the Retrahens auriculam and the small muscles on the cranial surface of the pinna.

The Occipital Branch (ramus occipitalis), the larger, passes backward along the superior curved line of the occipital bone, and supplies the occipital portion of the Occipito-frontalis.

The Digastric Branch of the Facial Nerve (ramus digastricus).—The digastric branch usually arises by a common trunk with the Stylo-hyoid branch; it divides into several filaments, which supply the posterior belly of the Digastric; one of these perforates that muscle to join the glossopharyngeal nerve (ramus anastomoticus cum n. glossopharyngeo).

The Stylo-hyoid Branch (ramus stylohyoidus).—The stylo-hyoid branch is a long, slender branch, which passes inward, entering the Stylo-hyoid muscle about its middle.

The Temporo-facial Division (Figs. 694 and 695).—The temporo-facial, the larger of the two terminal branches of the facial, passes upward and forward through the parotid gland, crosses the external carotid artery and temporo-maxillary vein, and passes over the neck of the condyle of the jaw, being connected in this situation with the auriculo-temporal branch of the inferior maxillary nerve, and divides into branches which are distributed over the temple and upper part of the face; these are divided into three sets—temporal, malar, and infraorbital.

The Temporal Branches (rami temporales) cross the zygoma to the temporal region, supplying the Attrahens and Attollens auriculam muscles, and join with the temporal branch of the temporo-malar division of the superior maxillary, and with the auriculo-temporal branch of the inferior maxillary. The more anterior branches supply the frontal portion of the Occipito-frontalis, the Orbicularis palpebrarum, and Corrugator supercilii muscles, joining with the supraorbital and lacrimal branches of the ophthalmic.

The Malar Branches (rami zygomatici) pass across the malar bone to the outer angle of the orbit, where they supply the Orbicularis palpebrarum muscle, joining with filaments from the lacrimal nerve; others supply the lower eyelid, joining with filaments of the malar branch (subcutaneous mala) of the superior maxillary nerve.

The Infraorbital Branches (rami buccales), of larger size than the rest of the malar branches, pass horizontally forward to be distributed between the lower margin of the orbit and the mouth. The superficial branches run beneath the skin and above the superficial muscles of the face, which they supply; some branches are
distributed to the Pyramidalis nasi, joining at the inner angle of the orbit with the infratrochlear and nasal branches of the ophthalmic. The deep branches pass beneath the Zygomatici and the Levator labii superioris, supplying the Levator anguli oris, the Levator labii superioris alaeque nasi and the small muscles of the nose, and form a plexus, infraorbital plexus, by joining with the branches of the infraorbital branch of the superior maxillary nerve and the buccal branches of the cervico-facial.

The Cervico-facial Division.—The cervico-facial division of the facial nerve passes obliquely downward and forward through the parotid gland, crossing the external carotid artery. In this situation it is joined by branches from the great auricular nerve. Opposite the angle of the lower jaw it divides into branches which are distributed on the lower half of the face and upper part of the neck. These may be divided into three sets—buccal, supramaxillary, and inframaxillary.

The Buccal Branches (rami buccales) cross the Masseter muscle. They supply the Buccinator and Orbicularis oris, and join with the infraorbital branches of the temporo-facial division of the nerve, and with filaments of the buccal branch of the inferior maxillary nerve.

The Supramaxillary or Supramandibular Branch (ramus marginalis mandibulae) passes forward beneath the Platysma and Depressor anguli oris, supplying the
muscles of the lower lip and chin, and communicating with the mental branch of the inferior dental nerve.

The **Inframandibular**, **Inframanidibular** or **Cervical Branch** (ramus collis) runs forward beneath the Platysma, and forms a series of arches across the side of the neck over the suprahyoid region. A branch descends vertically to join with the superficial cervical nerve from the cervical plexus; others supply the Platysma.

**Surgical Anatomy.**—The facial nerve is more frequently paralyzed than any of the other of the cranial nerves. The paralysis may depend either upon (1) central causes—i. e., blood-clots or intracranial tumors pressing on the nerve before its entrance into the internal auditory meatus. It is also one of the nerves involved in bulb bar paralysis. Or (2) it may be paralyzed in its passage through the petrous bone by damage due to middle-ear disease or by fractures of the base. Or (3) it may be affected at or after its exit from the stylo-mastoid foramen. This is commonly known as Bell's paralysis. It may be due to exposure to cold or to injury of the nerve, either from accidental wounds of the face or during some surgical operation, as removal of parotid tumors, opening of abscesses, or operations on the lower jaw.

When the cause is central, the a bellent nerve is usually paralyzed as well, and there is also hemiplegia on the opposite side. In these cases the electric reactions are the same as in health; whereas, when the paralysis is due to a lesion in the course of the nerve, the reactions of degeneration develop. When the nerve is paralyzed in the petrous bone, in addition to the paralysis of the muscles of expression, there is loss of taste in the anterior part of the tongue, and the patient is unable to recognize the difference between bitters and sweets, acids and salines, from involvement of the chorda tympani. The mouth is dry, because the salivary glands are not secreting; the sense of hearing is affected from paralysis of the Stapedius, but there is no hemiplegia. When the cause of the paralysis is from fracture of the base of the skull, the acoustic nerve and the petrosal nerves, which are connected with the intumescentia ganglioformis, are also involved. When the injury to the nerve is after its exit from the stylo-mastoid foramen, all the muscles of expression except the Levator palpebrae, together with the posterior belly of the Digastric and Stylo-hyoid, are paralyzed. There is smoothness of the forehead, and the patient is unable to frown; the eyelids cannot be closed, and the lower lid droops, so that the punctum is no longer in contact with the globe, and the tears run down the cheek; there is smoothness of the cheek and loss of the nasolabial furrow; the nostril of the paralyzed side cannot be dilated; the mouth is drawn to the sound side, and there is inability to whistle; food collects between the cheek and gum from paralysis of the Buccinator.

The facial nerve is at fault in cases of so-called histrionic spasm, which consists in an almost constant and uncontrollable twitching of the muscles of the face. This twitching is sometimes so severe as to cause great discomfort and annoyance to the patient and to interfere with sleep, and for its relief the facial nerve has been stretched. The operation is performed by making an incision behind the ear from the root of the mastoid process to the angle of the jaw. The parotid is turned forward, and the dissection carried along the anterior border of the Sterno-mastoid muscle and mastoid process until the upper border of the posterior belly of the Digastric is found. The nerve is parallel to this on about a level with the middle of the mastoid process. When found, the nerve may be stretched by passing a blunt hook beneath it and pulling it forward and outward. Too great force must not be used, for fear of permanent injury to the nerve. In facial palsy of extracerebral origin it may be advisable to expose the nerve, cut it across, and anastomose the distal end of the paralyzed nerve to the accessory nerve or, better, to the hypoglossal nerve (facio-accessory anastomosis or facio-hypoglossal anastomosis). The idea was first proposed by Ballance, and has been put in practice by Ballance and Stewart, Keen, Cushing, Faure, Kennedy, and others.

**The Eighth or Acoustic Nerve** (N. Acusticus) (Fig. 696).

The **eight or acoustic or auditory nerve** comprises two distinct sets of fibres which, although both are devoted to the transmission of afferent impulses, differ in their peripheral distribution and in their central connections. The two divisions appear blended in the interval between the oblongata and the internal auditory meatus, running oblique latero-frontal in company with the facial nerve and internal auditory artery. At the internal auditory meatus the two divisions of the nerve are separable, the vestibular division above, the cochlear below.

**The Cochlear Nerve** (radix cochlearis).—The cochlear nerve is the true nerve of hearing, lacking general sensibility, however, and therefore a nerve of special sense.
The fibres of this division arise from the cells of the spiral ganglion of the cochlear as axones of bipolar cells whose dendrites or peripheral processes terminate about the (auditory) hair-cells of the organ of Corti. The central connections of the cochlear division are described on p. 892.

**The Vestibular Nerve** (radix vestibularis).—The vestibular nerve conducts impulses of equilibratory-sense from the semicircular canals, utricle, and saccule to the vestibular nuclei. The ganglion of origin of this nerve differs from ordinary sensor ganglia in that its cells are of bipolar structure, having retained this embryonic characteristic of the ganglion-cells throughout life. The central processes of the cells of the vestibular ganglion (or ganglion of Scarpa) enter the oblongata with the trunk of the cochlear nerve in the postpontile groove, laterad of the facial nerve, to establish central connections already described on p. 893. The peripheral processes constitute the two main branches of the nerve, viz., (a) the utriculo-ampullar and (b) the sacculo-ampullar.

![Distribution of the acoustic nerve](image)

The upper or **utriculo-ampullar branch** divides into:

(a) The **Utricular Branch**, passing through the superior macula cribrosa of the vestibule to end in the macula acustica of the utricle.

(b) The **Superior Ampullar Branch**, accompanying the utricular branch, to end in the crista acustica of the ampulla of the superior semicircular canal.

(c) The **Lateral Ampullar**, to the ampulla of the lateral semicircular canal. The lower or **sacculo-ampullar branch** is somewhat longer and divides into:

(a) The **Posterior Ampullar**, passing through the foramen singulare and the inferior macula cribrosa to end in the ampulla of the posterior semicircular canal.

(b) The **Saccular Branch**, passing through the middle macula cribrosa to end in the macula acustica of the sacculus.

**Surgical Anatomy.**—The acoustic nerve is frequently injured, together with the facial nerve, in fractures of the middle fossa of the base of the skull implicating the internal auditory meatus. The nerve may be either torn across, producing permanent deafness, it may be bruised or it may be pressed upon by extravasated blood or inflammatory exudation, when the deafness will in all probability be temporary. The nerve may also be injured by violent blows on the head without
Fracture, and deafness may follow loud explosions of dynamite, etc., probably from some lesion of this nerve, which is more liable to be injured than the other cranial nerves on account of its structure. The test that the nerve is destroyed and that the deafness is not due to some lesion of the auditory apparatus is obtained by placing a vibrating tuning-fork on the head. The vibrations will be heard in cases where the auditory apparatus is at fault, but not in cases of destruction of the auditory nerve.

THE NINTH OR GLOSSO-PHARYNGEAL NERVE (N. GLOSSOPHARYNGEUS) (Figs. 697 and 698).

The ninth or glosso-pharyngeal nerve is distributed, as its name implies, to the tongue and pharynx, being the nerve of ordinary sensation to the mucous membrane of the pharynx, fauces, and tonsil; and the nerve of taste to all parts of the tongue to which it is distributed.

Its (apparent) superficial origin is by three or four filaments, closely connected together, from the upper part of the oblongata, in the dorso-lateral groove (Fig. 697). The central connections are described on p. 590. The small motor component arises from cells in the nucleus ambiguous. The real origin of the sensor fibres of the glosso-pharyngeal must be looked for in the jugular and petrosal ganglia which are developed from the neural crest.

From its superficial origin it passes outward across the flocculus, and leaves the skull at the central part of the jugular foramen, in a separate sheath of the dura external to and in front of the vagus and accessory nerves (Fig. 698). In its passage through the jugular foramen it grooves the lower border of the petrous portion of the temporal bone, and at its exit from the skull passes forward between the jugular vein and internal carotid artery, and descends ventrad of the latter vessel, and beneath the styloid process of the temporal bone and the muscles connected with it, to the lower border of the Stylo-pharyngeus muscle. The nerve now curves inward, forming an arch on the side of the neck, and lying upon the Stylo-pharyngeus muscle and the Middle constrictor of the pharynx. It then passes beneath the Hyo-glossus muscle, and is finally distributed to the mucous membrane of the fauces and base of the tongue, and the mucous glands of the mouth and tonsil.

In passing through the jugular foramen the nerve presents, in succession, two gangliform enlargements. The superior and smaller is called the jugular ganglion; the inferior and larger, the petrous ganglion or the ganglion of Andersch.

The Superior or Jugular Ganglion (Ganglion Superius n. Glossopharyngei).

The superior or jugular ganglion is situated in the upper part of the groove in which the nerve is lodged during its passage through the jugular foramen. It is of very small size, and involves only the lower part of the trunk of the nerve. It is usually regarded as a segmentation from the lower ganglion.

The Inferior or Petrous Ganglion (Ganglion Petrosum n. Glossopharyngei) (Fig. 697).

The inferior or petrous ganglion is situated in a depression in the lower border of the petrous portion of the temporal bone; it is larger than the superior ganglion and involves the whole of the fibres of the nerve. From this ganglion arise those filaments which connect the glosso-pharyngeal with the vagus and sympathetic nerves.
Branches of Communication.—The branches of communication are with the vagus, sympathetic, and facial.

The branches to the vagus are two filaments, arising from the petrous ganglion, one of which passes to the auricular branch of the vagus, and one to the upper ganglion of the vagus.

The branch to the sympathetic, also arising from the petrous ganglion, is connected with the superior cervical ganglion.

The branch of communication with the facial perforates the posterior belly of the Digastric muscle. It arises from the trunk of the nerve below the petrous ganglion, and joins the facial just after its exit from the stylo-mastoid foramen.

Branches of Distribution.—The branches of distribution are the tympanic, carotid, pharyngeal, muscular, tonsillar, and lingual.

The Tympanic Branch or Jacobson's Nerve (n. tympanicus).—The tympanic branch or Jacobson's nerve arises from the petrous ganglion, and enters a small bony canal in the lower surface of the petrous portion of the temporal bone, the lower opening of which is situated on the bony ridge which separates the carotid canal from the jugular fossa. It ascends to the tympanum, enters that cavity by an aperture in its floor close to the inner wall, and divides into branches which are contained in grooves upon the surface of the promontory. These branches form a tympanic plexus (plexus tympanicus). This plexus gives off (1) the greater part of the small superficial petrosal nerve (Fig. 694); (2) a branch to join the great superficial petrosal nerve; and (3) branches to the tympanic cavity, all of which will be described in connection with the anatomy of the ear.

The Carotid Branches (n. caroticotympanicus superior and n. caroticotympanicus inferior).—The carotid branches descend along the trunk of the internal carotid artery as far as its commencement, communicating with the pharyngeal branch of the vagus and with branches of the sympathetic.

The Pharyngeal Branches (rami pharynges).—The pharyngeal branches are three or four filaments which unite opposite the Middle constrictor of the pharynx with the pharyngeal branches of the vagus and sympathetic nerves to form the pharyngeal plexus, branches from which perforate the muscular coat of the pharynx to supply the muscles and mucous membrane.

The Muscular Branch (ramus stylopharyngeus).—The muscular branch is distributed to the Stylo-pharyngeus muscle.

The Tonsillar Branches (rami tonsillares).—The tonsillar branches supply the tonsil, forming a plexus (circulus tonsilaris) around this body, from which branches are distributed to the soft palate and fauces, where they communicate with the palatine nerves.

The Lingual Branches (rami linguales).—The lingual branches are two in number: one supplies the circumvallate papillae and the mucous membrane covering the surface of the base of the tongue; the other perforates its substance, and supplies the mucous membrane and follicular glands of the posterior one-third of the tongue and communicates with the lingual nerve.

The Gustatory Path.—The impressions of taste reach the glosso-pharyngeal nucleus in the oblongata in two ways. From the posterior one-third of the tongue and from the palate they reach the nucleus by the glosso-pharyngeal nerve. From the anterior two-thirds of the tongue impulses of taste are conveyed by the chorda tympani and nervus intermedius. From the glosso-pharyngeal nucleus gustatory impressions pass by way of the medial fillet to the thalamus of the opposite side, and from the thalamus through ventral thalamo-cortical radiation to the gyrus hippocampi, where the cortical gustatory centre is situated.

Surgical Anatomy.—Injury may produce hemorrhage about the roots of the nerve. Bergmann reported such a case. The patient died from edema of the glottis after presenting evidences of disorder of speech and difficulty in swallowing.
THE TENTH, VAGUS OR PNEUMOGASTRIC NERVE (N. VAGUS).
(Figs. 697 and 698).

The tenth, vagus or pneumogastric nerve has a more extensive distribution than any of the other cranial nerves, passing through the neck and thorax to the upper part of the abdomen. It is composed of both motor and sensor fibres. It supplies the organs of voice and respiration with motor and sensor fibres, and the pharynx, oesophagus, stomach, and heart with motor fibres. Its superficial origin (Fig. 697) is by eight or ten filaments from the groove between the olive and the restis below the glossopharyngeal; its central connections are described on p. 890.

The real origin of the sensor fibres of the vagus is to be found in the cells of the ganglia on the nerve—viz., the ganglion of the root and the ganglion of the trunk. The filaments become united and form a flat cord, which passes outward beneath the flocculus to the jugular foramen, through which it emerges from the cranium (Fig. 698). In passing through this opening the vagus accompanies the accessory nerve, being contained in the same sheath of dura with it, a membranous septum separating them from the glossopharyngeal, which lies in front (Fig. 698). The nerve in this situation presents a well-marked ganglionic enlargement, which is called the superior ganglion, or jugular ganglion; to it the vagal accessory part of the accessory nerve is connected by one or two filaments. After the exit of the nerve from the jugular foramen the nerve is joined by the accessory portion of the accessory nerve and enlarges into a second gangliform swelling, called the inferior ganglion or the ganglion of the trunk of the nerve, through which the fibres of the accessory nerve pass unchanged, being
principally distributed to the pharyngeal and superior laryngeal branches of the vagus; but some of the filaments from it are continued into the trunk of the vagus below the ganglion to be distributed with the recurrent laryngeal nerve, and probably also with the cardiac nerves. The vagus nerve passes vertically down the neck within the sheath of the carotid vessels lying between the internal carotid artery and the internal jugular vein as far as the thyroid cartilage, and then between the same vein and the common carotid to the root of the neck (Fig. 698). From here the course of the nerve differs on the two sides of the body.

On the right side (Fig. 698) the nerve passes across the subclavian artery between it and the right innominate vein, and descends by the side of the trachea to the back part of the root of the lung, where it spreads out in a plexiform network, the dorsal pulmonary plexus (plexus pulmonalis posterior), from the lower part of which two cords descend upon the oesophagus, on which tube they divide, forming, with branches from the opposite nerve, the esophageal plexus (plexus gulae); below, these branches are collected into a single cord, which runs along the back part of the oesophagus, enters the abdomen, and is distributed to the dorsal surface of the stomach, joining the left side of the solar plexus, and sending filaments to the splenic plexus and a considerable branch to the coeliac plexus.

On the left side the vagus nerve enters the chest between the left carotid and subclavian arteries, behind the left innominate vein. It crosses the arch of the aorta and descends behind the root of the left lung, forming the ventral pulmonary plexus (plexus pulmonalis anterior), and along the ventral surface of the oesophagus, where it unites with the nerve of the right side in forming the esophageal plexus. It passes to the stomach, distributing branches over the ventral surface of that viscus, some extending over the great cul-de-sac, and others along the lesser curvature. Filaments from these branches enter the gastro-hepatic omentum and join the hepatic plexus.

The Ganglion of the Root of the Vagus Nerve (Ganglion Jugulare).

The ganglion of the root or the jugular ganglion is of a grayish color, circular in form, about two lines in diameter, and resembles the ganglion on the larger root of the fifth nerve.

Connecting Branches.—To this ganglion the accessory portion of the accessory nerve is connected by several delicate filaments; it also has a communicating twig with the petrous ganglion of the glosso-pharyngeal, with the facial nerve by means of its (the ganglion’s) auricular branch, and with the sympathetic by means of an ascending filament from the superior cervical ganglion.

The Ganglion of the Trunk of the Vagus Nerve (Ganglion Nodosum).

The ganglion of the trunk or the inferior ganglion is a plexiform cord, cylindrical in form, of a reddish color, and about an inch (2 cm.) in length; it involves the whole of the fibres of the nerve, and passing through it is the accessory portion of the accessory nerve, which blends with the vagus below the ganglion, to be then continued principally into its pharyngeal and superior laryngeal branches.

Connecting Branches.—This ganglion is connected with the hypoglossal, the superior cervical ganglion of the sympathetic, and the loop between the first and second cervical nerves.
The branches of the vagus are—

- In the jugular fossa
  - Dural
  - Auricular
  - Pharyngeal
  - Superior laryngeal
  - Recurrent laryngeal
  - Cervical cardiac
  - Thoracic cardiac
  - Ventral pulmonary
  - Dorsal pulmonary
  - Esophageal
  - Gastric

The Dural Branch (*ramus meningeus*).—The dural branch is a recurrent filament given off from the ganglion of the root in the jugular foramen. It passes backward and is distributed to the dura lining the posterior fossa of the base of the skull.

The Auricular Branch or Arnold's Nerve (*ramus auricularis*) (Fig. 699).—The auricular branch or Arnold's nerve arises from the ganglion of the root, and is joined soon after its origin by a filament from the petrous ganglion of the glosso-pharyngeal; it passes outward behind the jugular vein, and enters a small canal on the outer wall of the jugular fossa. Traversing the substance of the temporal bone, it crosses the aqueductus Fallopii about two lines above its termination at the stylo-mastoid foramen; here it gives off an ascending branch, which joins the facial; the continuation of the nerve reaches the surface by passing through the auricular fissure between the mastoid process and the external auditory meatus, and divides into two branches, one of which communicates with the posterior auricular nerve, while the other supplies the integument at the back part of the pinna and the dorsal part of the external auditory meatus.

The Pharyngeal Branch (*ramus pharyngeus*).

-The pharyngeal branch, the principal motor nerve of the pharynx, arises from the upper part of the ganglion of the trunk of the vagus. It consists principally of filaments from the accessory portion of the accessory nerve; it passes across the internal carotid artery to the upper border of the Middle constrictor of the pharynx, where it divides into numerous filaments which join with those from the glosso-pharyngeal, the superior laryngeal (its external branch), and sympathetic, to form the pharyngeal plexus (*plexus pharyngeus*),
from which branches are distributed to the muscles and mucous membrane of the pharynx and the muscles of the soft palate. From the pharyngeal plexus a minute filament is given off, which descends and joins the hypoglossal nerve as it winds around the occipital artery.

**The Superior Laryngeal Nerve (n. laryngeus superior) (Figs. 697 and 698).**—It is larger than the preceding, and arises partly from the middle of the ganglion of the trunk of the vagus. It consists principally of filaments from the accessory nerve. In its course it receives a branch from the superior cervical ganglion of the sympathetic. It descends by the side of the pharynx behind the internal carotid artery, where it divides into two branches, the external and internal laryngeal. This nerve is the nerve of sensation of the larynx, and also supplies the crico-thyroid muscle. Exner has pointed out that the superior laryngeal nerve innervates to some extent the muscles supplied by the inferior laryngeal, and this fact explains why division of the inferior laryngeal nerve is not of necessity followed by complete paralysis of the muscles it supplies.

The **External Laryngeal Branch of the Superior Laryngeal (ramus externus) (Fig. 698),** the smaller, descends by the side of the larynx, beneath the Sterno-thyroid, to supply the Crico-thyroid muscle. It gives branches to the pharyngeal plexus and the Inferior constrictor, and communicates with the superior cardiac nerve, behind the common carotid.

The **Internal Laryngeal Branch of the Superior Laryngeal (ramus internus)** descends to the opening in the thyro-hyoid membrane, through which it passes with the superior laryngeal artery, and is distributed to the mucous membrane of the larynx. A small branch communicates with the recurrent laryngeal nerve. The branches to the mucous membrane are distributed, some in front to the epiglottis, the base of the tongue, and the epiglottidean glands; while others pass backward, in the aryteno-epiglottidean fold, to supply the mucous membrane surrounding the superior orifice of the larynx, as well as the membrane which lines the cavity of the larynx as low down as the vocal cord. The filament which joins with the recurrent laryngeal descends beneath the mucous membrane on the inner surface of the thyroid cartilage, where the two nerves become united.

The **Inferior or Recurrent Laryngeal Branch of the Vagus (n. laryngeus inferior) (Figs. 698 and 700).**—The inferior or recurrent laryngeal branch, so called from its reflected course, is the motor nerve of the larynx. It arises on the right side, in front of the subclavian-artery; winds from before backward around that vessel, and ascends obliquely to the side of the trachea, behind the common carotid artery and behind or in front of the inferior thyroid artery. On the left side it arises in front of the arch of the aorta, and winds from before backward around the aorta at the point where the remains of the ductus arteriosus are connected with it, and then ascends to the side of the trachea. The nerve on each side ascends in the groove between the trachea and oesophagus, and, passing under the lower border of the Inferior constrictor muscle, enters the larynx behind the articulation of the inferior cornu of the thyroid cartilage with the cricoid, being distributed to all the muscles of the larynx except the Crico-thyroid. It communicates with the superior laryngeal nerve and gives off a few filaments to the mucous membrane of the lower part of the larynx.

The recurrent laryngeal, as it winds around the subclavian artery and aorta, gives off several cardiac filaments, which unite with the cardiac branches from the vagus and sympathetic. As it ascends in the neck it gives off oesophageal branches, more numerous on the left than on the right side, which supply the mucous membrane and muscular coat of the oesophagus; tracheal branches to the mucous membrane and muscular fibres of the trachea; and some pharyngeal filaments to the Inferior constrictor of the pharynx.
The Cervical Cardiac Branches (rami cardiaci superiores).—The cervical cardiac branches, two or three in number, arise from the vagus, at the upper and lower part of the neck.

The Superior Branches are small, and communicate with the cardiac branches of the sympathetic. They can be traced to the great or deep cardiac plexus.

The Inferior Branches, one on each side, arise at the lower part of the neck, just above the first rib. On the right side this branch passes ventral or by the side of the arteria innominata, and communicates with one of the cardiac nerves proceeding to the great or deep cardiac plexus. On the left side it passes ventral of the arch of the aorta and joins the superficial cardiac plexus.

The Thoracic Cardiac Branches (rami cardiaci inferiores).—The thoracic cardiac branches, on the right side, arise from the trunk of the vagus as it lies by the side of the trachea, and from its recurrent laryngeal branch, but on the left side from the recurrent nerve only; passing inward, they terminate in the deep cardiac plexus.

The Ventral Pulmonary Branches.—The ventral pulmonary branches, two or three in number, and of small size, are distributed on the ventral aspect of the root of the lungs. They join with filaments of the sympathetic, and form the ventral pulmonary plexus (plexus pulmonalis anterior).

The Dorsal Pulmonary Branches.—The dorsal pulmonary branches, more numerous and larger than the ventral, are distributed on the dorsal aspect of the root of the lung; they are joined by filaments from the third and fourth (sometimes also from the first and second) thoracic ganglia of the sympathetic, and form the dorsal pulmonary plexus (plexus pulmonalis posterior). Branches from both plexuses accompany the ramification of the air-tubes through the substance of the lungs (rami bronchiae anteriores and rami bronchiae posteriores).

The Oesophageal Branches (rami oesophagei).—The oesophageal branches are given off from the vagus both above and below the pulmonary branches. The lower are more numerous and larger than the upper. They form, together with branches from the opposite nerve, the oesophageal plexus. From this plexus branches are distributed to the back of the pericardium.

The Gastric Branches (rami gastrici) (Fig. 698).—The gastric branches are the terminal filaments of the vagus nerve. The nerve on the right side is distributed to the posterior surface of the stomach. The right vagus sends branches to the coeliac plexus (rami coeliaci), to the splenic plexus (rami lienales), and to the renal plexus (rami renales). The nerve on the left side is distributed over the anterior surface of the stomach, some filaments (rami hepatici) passing across the great cul-de-sac, and others along the lesser curvature. They unite with branches of the right nerve and with the sympathetic, some filaments passing through the lesser omentum to the hepatic plexus.

Surgical Anatomy.—The laryngeal nerves are of considerable importance in considering some of the morbid conditions of the larynx. When the peripheral terminations of the superior laryngeal nerve are irritated by some foreign body passing over them, reflex spasm of the glottis is the result. When the trunk of the same nerve is pressed upon by, for instance, a goitre or an aneurism of the upper part of the carotid, we have a peculiar dry, brassy cough. When the nerve is paralyzed, we have anesthesia of the mucous membrane of the larynx, so that foreign bodies can readily enter the cavity, and, in consequence of its supplying the crico-thyroid muscle, the vocal cords cannot be made tense, and the voice is deep and hoarse. Paralysis of the superior laryngeal nerves may be the result of bulbar paralysis, may be a sequel to diphtheria, when both nerves are usually involved, or it may, though less commonly, be caused by the pressure of tumors or aneurisms, when the paralysis is generally unilateral. Irritation of the inferior laryngeal nerves produces spasm of the muscles of the larynx. When both the recurrent nerves are paralyzed, the vocal cords are motionless in the so-called cadaveric position—that is to say, in the position in which they are found in ordinary tranquil respiration—neither closed as in phonation, nor open as in deep inspiratory effort. When one recurrent nerve is paralyzed, the cord of the same side is motionless, while the opposite cord crosses the middle line to accommodate itself to the affected one; hence phonation is present, but the voice is altered and weak in timbre. The recurrent laryngeal nerves may be paralyzed in bulbar paralysis or after diph-
therapy, when the paralysis usually affects both sides; or they may be affected by the pressure of aneurisms of the aorta, innominate or subclavian arteries; by mediastinal tumors; by bronchocle; or by cancer of the upper part of the oesophagus, when the paralysis is often unilateral. The nerve may be accidentally divided during the operation for goitre.

It is a well-recognized fact that disease or injury of the vagus may induce serious symptoms. Bruising may cause such symptoms; so may injury of the nerve by a stab, a bullet, or during surgical operations. Either accidental ligation or crushing with clamp forceps is particularly dangerous. Michaux accidentally ligated the vagus, and the patient became comatose and ceased to breathe, but was restored on removing the ligature. Tillmanns, while removing a cancer, accidentally caught and crushed a portion of the nerve in a clamp, and both pulse and respiration ceased. The clamp was removed, the patient was restored with difficulty, and the nerve was sutured. Recovery followed. It thus becomes evident that division of the vagus on one side is not, as was so long taught, a necessarily fatal accident; in fact, it is sometimes undertaken deliberately in removing tumors adherent to the nerve. Division of a nerve which has been long compressed is probably not so dangerous as division of a healthy nerve, as in the former case the opposite vagus has probably assumed some of its colleague’s duties. A number of cases of deliberate division have been reported. Twenty-three cases are referred to in the system of surgery by von Bergmann and Mikulicz, and twelve of them died, but in none of the deaths was the removal of the vagus the apparent cause of the fatality. The editor of this American edition of “Gray” has seen three cases: One was operated upon by Dr. W. Joseph Hearn, one by Dr. Melvin Franklin, and one by the editor. All three recovered, and not one presented any serious disturbance, although each had hoarseness and weakness of voice.

One would assume that after division of the vagus below the superior laryngeal nerve and above the recurrent laryngeal nerve (the region usually attacked) that there would be paralysis of all the muscles of one side of the larynx, except the crico-thyroid, and widespread aberration evinced by disturbances of the heart, stomach, and lungs. As a matter of fact, this has not been the case. It might be and probably would be the case, were a healthy nerve divided; but the surgeon who deliberately divides the nerve does so during the removal of a tumor which has long made pressure. In most cases there is no change in the pulse or respiration. In some cases dysphagia and pneumonia arise, but they may be due to other causes than vagus-nerve injury (the formidable nature and the duration of the operation—the ligation of vessels of large size—the age of the subject).

Laryngeal symptoms, to a greater or less degree, are always noted. The difference in the degree of the palsy is explainable when we recall Exner’s statement that the muscles supplied by the recurrent laryngeal also receive some innervation from the superior laryngeal. In fact, Mills points out that a portion of the recurrent laryngeal has been resected without completely paralyzing the muscles supposed to be supplied solely by the recurrent laryngeal. The laryngeal symptoms result from unilateral laryngeal paralysis, in which there is paralysis of the muscles which open the glottis. The voice may be lost or may be hoarse. Usually, after a time, this is, to a great extent, compensated for by the opposite vocal cord, although the voice may always remain weak, and the patient will tire easily on talking. If both vagi were to be divided death would ensue.

THE ELEVENTH OR ACCESSORY NERVE (N. ACCESSORIUS)
(Figs. 697 and 698).

The eleventh, accessory, or spinal accessory nerve consists of two parts: one the accessory part to the vagus, and the other the spinal portion.

The Bulbar or Vagal Accessory Part of the Accessory Nerve (Ramus Internus).

The bulbar or vagal accessory part is the smaller of the two. It is accessory to the vagus. Its superficial origin (Fig. 697) is by four or five delicate filaments from the side of the oblongata, below the roots of the vagus. Its deep origin is described in detail on page 890. It passes outward to the jugular foramen, where it interchanges fibres with the spinal portion or becomes united to it for a short distance; it is also connected, in the foramen, with the upper ganglion of the vagus by one or two filaments. It then passes through the foramen (Fig. 698), and becoming again separated from the spinal portion it is continued over the surface.
of the ganglion of the trunk of the vagus, being adherent to its surface, and is
distributed principally to the pharyngeal and superior laryngeal branches of the
vagus. Through the pharyngeal branch it probably supplies the muscles of the soft
palate. Some few filaments from it are continued into the trunk of the vagus below
the ganglion, to be distributed with the recurrent laryngeal nerve to supply most
of the laryngeal muscle, and probably also with the cardiac nerves.

The Spinal Portion of the Accessory Nerve (Ramus Externus).

The spinal portion is firm in texture. Its superficial origin (Fig. 697) is by
several filaments or rootlets from the lateral tract of the cord, as low down as
the sixth cervical nerve. Its deep origin (Fig 578) may be traced to the inter-
medio-lateral tract of the gray substance of the cord. The rootlets of origin join and
form a trunk which ascends in the subdural space between the ligamentum den-
ticulatum and the ventral roots of the spinal nerves, enters the skull through the
foramen magnum, and is then directed outward to the jugular foramen, through
which it passes, lying in the same sheath as the vagus, but separated from it by a
fold of the arachnoid. In the jugular foramen it receives one or two filaments
from the vagal accessory portion. At its exit from the jugular foramen it passes
into the neck and becomes the external branch (Figs. 655 and 698). It passes
backward, either in front of or behind the internal jugular vein, and descends
obliquely behind the Digastric and Stylo-hyoid muscles to the upper part of the
Sterno-mastoid muscle. It pierces that muscle, and passes obliquely across the
posterior triangle, to terminate in the deep surface of the Trapezius muscle.
This nerve gives several branches to the Sterno-mastoid muscle during its passage
through it, and joins in its substance with branches from the second cervical, which
supply the muscle. In the posterior triangle it joins with the second and
third cervical nerves, while beneath the Trapezius it forms a sort of plexus with
the third and fourth cervical nerves, and from this plexus fibres are distributed
to the muscle.

Surgical Anatomy.—Division of the external branch of the accessory nerve causes paralysis
of the Sterno-clido-mastoid and Trapezius muscles; not absolute paralysis, for these muscles
also receive nerves from the cervical plexus. In cases of spasmodic torticollis in which all
palliative treatment has failed division or excision of a portion of the external branch of the
accessory nerve has been suggested by Keen. This may be done either along the anterior or
posterior border of the Sterno-mastoid muscle. The former operation is performed by making
an incision from the apex of the mastoid process, three inches in length, along the anterior border of
the Sterno-mastoid muscle. The anterior border of the muscle is defined and pulled back-
ward, so as to stretch the nerve, which is then to be sought for beneath the Digastric muscle,
about two inches below the apex of the mastoid process. The other operation consists in
making an incision along the posterior border of the muscle, so that the centre of the incision
corresponds to the middle of this border of the muscle. The superficial structures having been
divided and the border of the muscle defined, the nerve is to be sought for as it emerges from
the muscle to cross the occipital triangle. When found, it is to be traced upward through the
muscle, and a portion of it is excised above the point where it gives off its branches to the Sterno-
mastoid. In this operation one of the descending branches of the superficial cervical plexus is
liable to be mistaken for the nerve.

THE TWELFTH OR HYPOGLOSSAL NERVE (N. HYPOGLOSSUS)
(Figs. 701 and 702).

The twelfth or hypoglossal nerve is the motor nerve of the tongue. Its superficial origin is by several filaments, from ten to fifteen in number, from the groove
between the pyramidal and olivary bodies of the oblongata, in a continuous line
with the ventral roots of the spinal nerves. Its deep origin can be traced to a
nucleus of gray substance (nucleus hypoglossi) in the floor of the fourth ventricle described on p. 890.

The filaments of this nerve are collected into two bundles, which perforate the dura separately, opposite the anterior condyloid foramen, and unite together after their passage through it. In those cases in which the anterior condyloid

or hypoglossal foramen in the occipital bone is double, these two portions of the nerve are separated by the small piece of bone which divides the foramen. The nerve descends almost vertically to a point corresponding with the angle of the jaw. It is at first deeply seated beneath the internal carotid artery and internal jugular vein, and is intimately connected with the vagus nerve (Fig. 702); it then passes forward between the vein and artery, and lower down in the neck becomes superficial below the Digastric muscle. The nerve then loops around the occipital artery, and crosses the external carotid and its lingual branch below the tendon of the Digastric muscle. It passes beneath the tendon of the Digastric, the Stylohyoid, and the Mylo-hyoid muscles, lying between the last-named muscle and the Hyoglossus (Fig. 702), and communicates at the anterior border of the Hyoglossus with the lingual nerve (Fig. 701); it is then continued forward in the fibres of the Genio-hyglossus muscle as far as the tip of the tongue, distributing branches to its muscular substance.

Branches of Communication (Fig. 701).—The branches of communication are with the

Vagus. First and Second Cervical Nerves.
Sympathetic. Lingual (gustatory).
The first mentioned takes place close to the exit of the nerve from the skull, numerous filaments passing between the hypoglossal and the ganglion of the trunk of the vagus through the mass of connective tissue which here unites the two nerves. It also communicates with the pharyngeal plexus by a minute filament as it winds around the occipital artery.

The communication with the sympathetic takes place opposite the atlas vertebra by branches derived from the superior cervical ganglion, and in the same situation the nerve is joined by filaments derived from the loop connecting the first two cervical nerves.

The communication with the lingual nerve takes place near the anterior border of the Hypoglossus muscle by numerous filaments which ascend upon it.

**Fig. 702.**—Hypoglossal nerve, cervical plexus, and their branches.

**Branches of Distribution** (Fig. 701).—The branches of distribution are—the

<td>Muscular</td>
</tr>
</tbody>
</table>

**Dural Branches** (Fig. 701).—As the hypoglossal nerve passes through the anterior condyloid foramen it gives off, according to Luschka, several filaments to the dura in the posterior fossa of the base of the skull; these filaments are probably derived from a branch which passes from the first cervical nerve to the hypoglossal nerve.

**The Descendens Hypoglossi** (ramus descendens) (Figs. 701 and 702).—The descendens hypoglossi, long called the descendens noni, is a long slender branch,
which quits the hypo-glossal where it turns around the occipital artery. It consists mainly of fibres which pass to the hypo-glossal from the first and second cervical nerves in the above-mentioned communication. It descends in front of or within the sheath of the common carotid artery, giving off a branch to the anterior belly of the Omo-hyoid, and then joins the communicating branches from the second and third cervical nerves, just below the middle of the neck, to form a loop, the **ansa hypo-glossi**. From the convexity of this loop branches pass to supply the Sterno-hyoid, Sterno-thyroid, and the posterior belly of the Omo-hyoid. According to Arnold, another filament descends in front of the vessels into the chest, and joins the cardiac and phrenic nerves.

The **Thyro-hyoid Branch** (*ramus thyreohyoidens*) (Fig. 701).—The thyro-hyoid is a small branch arising from the hypoglossal near the posterior border of the Hyo-glossus; it passes obliquely across the great cornu of the hyoid bone and supplies the Thyro-hyoid muscle.

The **Muscular Branches** (Fig. 701).—The muscular branches are distributed to the Stylo-glossus, Hyo-glossus, Genio-hyoid, and Genio-hyo-glossus muscles. At the under surface of the tongue numerous slender branches (*rami linguales*) pass upward into the substance of the organ to supply its intrinsic muscles.

**Surgical Anatomy.**—A wound in the submaxillary region may injure the hypoglossal nerve and result in motor paralysis of the corresponding half of the tongue. The hypo-glossal nerve is an important guide in the operation of ligation of the lingual artery (see page 606). It runs forward on the Hyo-glossus muscle just above the great cornu of the hyoid bone, and forms the upper boundary of the triangular space in which the artery is to be sought for by cutting through the fibres of the Hyo-glossus muscle.

THE SYMPATHETIC NERVE SYSTEM (*SYMPATHICUS*) (Fig. 703).

The sympathetic nerve system consists of (1) a series of **ganglia** (*ganglia trunci sympathici*) connected together by a great **ganglionic cord**, the **gangliated cord** (*trunci sympathicus*), extending from the base of the skull to the coccyx, one gangliated cord on each side of the middle line of the body, partly in front and partly on each side of the vertebral column; (2) of three **great gangliated plexuses** (*plexus sympathici*) or aggregations of nerves and ganglia, situated in front of the spine in the thoracic, abdominal, and pelvic cavities respectively; (3) of **smaller or terminal ganglia**, situated in relation with the abdominal viscera; and (4) of numerous **nerve-fibres**. These latter are of two kinds: **communicating**, by which the ganglia communicate with each other and with the cerebro-spinal nerves; and **distributory**, supplying the internal viscera and the coats of the blood-vessels.

Each gangliated cord may be traced upward from the base of the skull into the cranial cavity by an ascending branch, which passes through the carotid canal, forms a plexus on the internal carotid artery and in the cavernous sinus (Fig. 707), and communicates with certain cranial nerves (p. 1084). According to some anatomists, the two cords are joined, at their cephalic extremities, by these ascending branches communicating in a small ganglion, the **ganglion of Ribes**, situated upon the anterior communicating artery. Upon the gangliated cord are ganglia distinguished as **cervical**, **thoracic**, **lumbar**, and **sacral**, and except in the neck they correspond pretty nearly in number to the vertebrae against which they lie. They may be thus arranged:

<table>
<thead>
<tr>

</tr>
</tbody>
</table>
In the neck they are situated in front of the transverse processes of the vertebrae; in the thoracic region, in front of the heads of the ribs; in the lumbar region, on the sides of the bodies of the vertebrae; and in the sacral region, in front of the sacrum. As the two cords pass into the pelvis they converge and unite together in a single ganglion, the coccygeal ganglion or ganglion impar (ganglion coccygeum impar) placed in front of the coccyx. Each ganglion may be regarded as a distinct centre, and, in addition to its branches of distribution, possesses also branches of communication which communicate with other ganglia and with the cerebro-spinal nerves.

The branches of communication between the ganglia (Figs. 704 and 705) are composed of gray nerve-fibres (gray rami communicantes) and white nerve-fibres (white rami communicantes), the latter being continuous with those fibres of the spinal nerves which pass to the ganglia.

The three great gangliated plexuses (collateral ganglia) are situated in front of the spine in the thoracic, abdominal, and pelvic regions, and are named, respectively, the cardiac, the solar or epigastric, and the hypogastric plexus. They consist of collections of nerves and ganglia, the nerves being derived from the gangliated cords and from the cerebro-spinal nerves. They distribute branches to the viscer.

Smaller or Terminal ganglia are also found lying amidst the nerves, some of them of microscopic size, in certain viscer—as, for instance, in the heart, the stomach, and the uterus. They serve as additional centres for the origin of nerve-fibres. There are numerous special ganglia connected with the cranial nerves.

These ganglia have been described in a previous section (see ophthalmic ganglion, otic ganglion, sphenopalatine ganglion, and submaxillary ganglion).

The branches of distribution derived from the gangliated cords, from the prevertebral plexuses, and also from the smaller ganglia, are principally destined...
for the blood-vessels and thoracic and abdominal viscera, supplying the involuntary muscular fibre of the coats of the vessels and the hollow viscera, and the secreting cells, as well as the muscular coats of the vessels in the glandular viscera.

**Structure of the Sympathetic System.**—The sympathetic system is not, as was so long taught, an independent system. It receives fibres from the cerebro-spinal system and arranges them for distribution to the splanchnic blood-vessels and the viscera. It receives fibres from the viscera and transmits them to the cerebro-spinal system, and it transmits fibres by way of the spinal nerves to unstripped muscles, to vessels, and to glands. It is simply an arrangement of spinal nerves to permit of the re-arrangement and transmission of impulses. In order to effect this, the spinal nerves are connected with a series of ganglia, which possess a certain power of government or automatic action. In the sympathetic system amyelinic fibres predominate. The individual nerve-fibres are smaller in diameter than those of the cerebro-spinal system, and the fibres are interrupted by nerve-cells contained in a ganglia chain, known as the gangliated cord, and are also sometimes interrupted in gangliated plexuses and in terminal ganglia. The sympathetic nerves have a notable disposition to form plexuses. It is important to note that not all of the visceral branches of the spinal nerves join the gangliated cord—for instance, the visceral branches of the third and fourth sacral do not. The majority, but not all, of the sympathetic fibres are amyelinic (fibres of Remak), but in the adult true amyelinic fibres are found only in the sympathetic system. These fibres are of smaller diameter than spinal nerve-fibres, and are prolongations of axones of sympathetic ganglia cells. Each fibre is surrounded by connective-tissue structure which resembles the neurilemma, which contains numerous nuclei, and which is a prolongation of the capsule of a sympathetic cell capsule.

A sympathetic nerve consists of numerous amyelinic and some myelinic fibres. The connective tissue which separates the nerve-bundles carries blood-vessels and nervi nervorum, but no lymph vessels.

The **sympathetic ganglia** contain multipolar cells which are smaller than those of the spinal ganglia. Each cell contains two nuclei, and is surrounded by a delicate capsule of connective tissue. The cell gives off one axone and several short dendrites. The axone is amyelinic when it begins and may remain so or may become myelinic. Fibres which take origin from sympathetic axones, the **commissural fibre**, may pass to an adjacent ganglion cell, may pass toward the centre, **central fibre** or **gray ramus communicans**, or may pass toward the periphery, **peripheral fibre**, and reach certain glands, or to unstripped muscle of blood-vessels, intestines, iris, etc. The fibres passing to glands are called **secreter fibres**.

The dendrites of a ganglion cell form arborizations about other ganglion cells. The sympathetic ganglia contains fibres as well as cells. Some of the fibres are myelinic and some are amyelinic, the latter taking origin from the sympathetic ganglion cells, the former being motor and sensor cerebro-spinal fibres which have reached the sympathetic by the rami communicantes.

The **amyelinic fibres**, the **white rami communicantes** or the **visceral branches** of the **spinal nerves** (Figs. 704 and 705), originate from the ventral divisions of certain accessory nerves. Two groups of them can be recognized, one group coming from the nerves from the first or second thoracic to the second or third lumbar nerves; another group from the second or third lumbar to the third or fourth sacral. The visceral branches of the third and fourth sacral do not join the gangliated cord; the other visceral branches do join it. The fibres of the visceral branches of the spinal nerves are derived from both the ventral and the dorsal nerve-roots, but more largely from the ventral than from the dorsal. The visceral fibres of the ventral roots are axones of nerve-cells of the spinal cord, and by way of the white

---

1 Histology and Microscopic Anatomy, by Szymonowicz. Translated and edited by John Bruce MacCallum.
rami enter into the sympathetic ganglia. Some of them end and form networks about the ganglia cells. Others pass up or down and end in an adjacent ganglion. Others pass through a ganglion of the gangliated cord and end in a peripheral ganglion with amyelinic fibres, which take origin from ganglia of the gangliated cord. The fibres of the white rami which pass through the ganglion and go to the periphery are known as the splanchnic efferent fibres, and constitute the secretor fibres of the splanchnic glands and the motor fibres of the muscular tissue of splanchnic blood-vessels and viscera. The visceral fibres of the dorsal nerve-roots aid in the formation of the white rami and arise as axones of nerve-cells in the spinal ganglia on the dorsal roots; they then pass through the ganglia of the sympathetic cord, but do not terminate in them, and leave the ganglion directly to pass through a peripheral ganglion to be distributed to the periphery, or ascend, or descend to an adjacent ganglion and pass through this to a collateral ganglion, and thence to the periphery. They constitute the splanchnic afferent fibres, the sensor fibres of the viscera.

The amyelinic fibres take origin from the cells of the sympathetic ganglia and are axones of these cells. Some help to form the commissure, which joins a ganglion to adjacent ganglia and end as networks about the cells of an adjacent ganglion. Others run to the periphery and help to form the splanchnic efferent branches. Some pass from the ganglia to the spinal nerve-roots and to the ventral and dorsal divisions of the nerves. The latter are the gray rami communicantes (Fig. 705), largely composed of amyelinic but containing some myelinic fibres. They give branches to the somatic part of the nerves but not the visceral, and furnish secretor fibres and fibres to unstriated muscle and minute branches to the membranes which enwrap the nerve-roots. The commissures of the gangliated cord are composed of white and gray fibres. The former consist of both splanchnic efferent and splanchnic afferent fibres. The latter are axones from sympathetic ganglion cells, and some of these are truly commissural, but
others pass up or down the cord and through a ganglion and become branches which go to the periphery.

From the above it becomes evident that the peripheral branches of the sympathetic contain white fibres, which are composed of splanchnic efferent and splanchnic afferent branches and also contain splanchnic efferent gray fibres.

These connections will be better understood by examining the plan drawn out in Fig. 704. There a represents a myelinic nerve-fibre from a ventral nerve-root, passing by a white ramus communicans through the ganglion directly connected with that spinal nerve to a ganglion higher up, where it will form an arborization round a nerve-cell, like e; b, a myelinic nerve-fibre forming an arborization round a cell of the ganglion of its own segment; c, a fibre passing through the ganglion without interruption and leaving it by one of its efferent branches to a prevertebral plexus or directly to some viscera; d, a fibre passing through the ganglion to some lower ganglion, there to end round some nerve-cell, or pass out through an efferent ramus; e, a myelinic nerve from a lower ganglion, behaving as a.

The dotted lines are amyelinic nerves. The fibre, f, arises as the axis-cylinder process of a ganglion cell, and passes by a gray ramus communicans along the sheath of the posterior nerve-root to the spinal meninges; g passes by the posterior division to supply sympathetic fibres to its area of distribution; h enters the anterior division and is similarly distributed; k joins the spinal recurrent branch to supply the interior of the vertebral canal, and l passes for a little way along the gray ramus communicans, but leaves it to be distributed to the sides of the vertebral and intercostal or lumbar vessels. Gray fibres to the prevertebral plexuses, vessels, or viscera, are represented by m, m; and n, n are amyelinic fibres joining neighboring ganglia. In addition to these, sensor fibres from the ganglia of the posterior spinal nerve-roots pass through the sympathetic ganglia to viscera without interruption.

THE GANGLIATED CORD (TRUNCUS SYMPATHICUS).

The Cervical Portion (Pars Cervicalis) of the Gangliated Cord.

The cervical portion of the gangliated cord is to be regarded as a prolongation upward of the primitive sympathetic along the great vessels of the neck (Cunningham). It is not connected to the cervical spinal nerves by white rami communicantes. It obtains its spinal fibres from the upper thoracic nerves. These fibres ascend in the commissure of the gangliated cord and join the cells of the cervical ganglia. From the cervical ganglia come fibres to the unstriped muscle (veins and arteries of the head, neck, and limbs, and to the skin of the head and neck, secretor fibres to the salivary glands and fibres to the heart). The fibres to the vessels are called vasomotor nerves, and the fibres to the heart are called cardio-motor nerves. In the neck the gangliated cord is situated behind the carotid vessels and upon the muscles in front of the vertebrae, and runs from the root of the neck to the base of the skull, being continuous below with the thoracic gangliated cord and ending above in the carotid plexus. There are usually three ganglia on each side, each of which is distinguished, according to its position, as the superior, middle, and inferior cervical ganglion.

The Superior Cervical Ganglion (ganglion cervicale superior) (Figs. 705 and 706).—The superior cervical ganglion, the largest of the three, is about three-quarters of an inch in length. It is placed opposite the second and third cervical vertebrae. It is of a reddish-gray color, is usually fusiform in shape, is sometimes broad and flattened, and is occasionally constricted at intervals, so as to give rise to
the opinion that it consists of the coalescence of several smaller ganglia; and it is usually believed that it is formed by the coalescence of the four ganglia correspond-
ing to the four upper cervical nerves. It is in relation, in front, with the sheath of the internal carotid artery and internal jugular vein; behind, it lies on the Rectus capitis anticus major muscle. It is connected to the middle cervical gan-
glion by the commissure of the gangliated cord.  

Branches.—The branches of the superior cervical ganglion are central and peripheral.  

Central or Communicating Branches.—1. Gray rami communicantes arise in the ganglion and pass to the first, second, third, and fourth cervical nerves. 2. Branches are given off to certain cranial nerves in the neck (Fig. 706). What is known as the jugular nerve (n. jugularis) passes to the ganglion on the trunk of the vagus, a branch from the ganglion passes to the ganglia on the root of the vagus and to the petrosal ganglion of the glosso-pharyngeal, and a branch goes to the hypo-glossal.  

Peripheral Branches.—These branches may be divided into superior, internal, and anterior.  

The Superior Branch of the Superior Cervical Ganglion or the Internal Carotid Branch (n. caroticus internus) (Fig. 706) appears to be a direct prolongation of the ganglion. It is soft in texture and of a reddish color. It ascends by the side of the internal carotid artery, and, entering the carotid canal in the temporal bone, divides into two branches, which lie, one on the outer, and the other on the inner, side of that vessel.  

The outer branch, the larger of the two, distributes filaments to the internal carotid artery and forms the internal carotid plexus.  

The inner branch also distributes filaments to the internal carotid, and, continu-
ing onward, forms the cavernous plexus.  

The Internal Carotid Plexus (plexus caroticus internus) (Figs. 705 and 706).—The carotid plexus is situated on the outer side of the internal carotid artery. Filaments from this plexus occasionally form a small gangliform swelling on the under surface of the artery, which is called the carotid ganglion. The internal carotid plexus communicates with the Gassarian ganglion, with the abducent nerve, and the sphenopalatine ganglion, and distributes filaments to the wall of the carotid artery and to the dura (Valentin), while in the carotid canal it communicates with Jacobson's nerve, which is the tympanic branch of the glosso-
pharyngeal.  

The communicating branches to the abducent nerve consist of one or two filaments which join that nerve as it lies upon the outer side of the internal carotid. Other filaments are also connected with the Gasserian ganglion. The communication with the sphenopalatine ganglion is effected by a branch, the large deep petrosal nerve (Fig. 694), which is given off from the plexus on the outer side of the artery, and which passes through the cartilage filling up the foramen lacerum medium, and joins the large superficial petrosal from the facial to form the Vidian nerve (Figs. 689 and 694). The Vidian nerve then proceeds along the pterygoid or Vidian canal to the sphenopalatine ganglion. The com-

munication with Jacobson's nerve is effected by two branches, one of which is called the deep petrosal nerve, and the other the carotico-typanic nerve; the latter may consist of two or three delicate filaments.  

The Cavernous Plexus (plexus cavernosus) (Fig. 706).—The cavernous plexus is situated below and internal to that part of the internal carotid which is placed by the side of the sella cavernous sinus, and is formed chiefly by the internal division of the ascending branch from the superior cervical ganglion. It communicates with the oculomotor, the trochlear, the ophthalmic division of the trigeminal, and the abducent nerves, and with the ophthalmic ganglion, and distributes filaments to the wall of the internal carotid and to the hypophysis.  

The branch of communication with the oculomotor nerve joins it at its point of
division; the branch to the trochlear nerve joins it as it lies on the outer wall of the cavernous sinus; other filaments are connected with the under surface of the trunk of the ophthalmic nerve; and a second filament of communication joins the abducent nerve.

The filament of connection with the ophthalmic ganglion (Fig. 684) arises from the anterior part of the cavernous plexus; it accompanies the nasal nerve or continues forward as a separate branch.

Terminal Branches of the Carotid and Cavernous Plexuses.—The terminal filaments from the carotid and cavernous plexuses are prolonged along the internal carotid, forming plexuses which entwine around the cerebral and ophthalmic arteries; along the former vessels they may be traced on to the pia; along the latter, into the orbit, where they accompany each of the subdivisions of the vessel, a separate plexus passing, with the arteria centralis retinae, into the interior of the eyeball. The filaments prolonged on to the anterior communicating artery form a small ganglion, the ganglion of Ribes,¹ which serves, as mentioned above, to connect the sympathetic nerves of the right and left sides.

The so-called Inferior or Descending Branch of the Superior Cervical Ganglion communicates with the middle cervical ganglion. It is the commissure of the gangliated cord.

The Internal Branches of the Superior Cervical Ganglion are three in number—the pharyngeal, laryngeal, and superior cardiac nerve.

The pharyngeal branches (rami pharyngei) (Fig. 705) pass inward to the side of the pharynx, where they join with branches from the glossopharyngeal, vagus, and external laryngeal nerves to form the pharyngeal plexus.

¹ The existence of this ganglion is doubted by some observers.—En. of 15th English edition.
The laryngeal branches unite with the superior laryngeal nerve and its branches. The superior cardiac nerve or the nervus superficialis cordis (n. cardiacus superior) (Fig. 705) arises by two or more branches from the superior cervical ganglion, and occasionally receives a filament from the cord of communication between the first and second cervical ganglia. It runs down the neck behind the common carotid artery, lying upon the Longus colli muscle, and crosses in front of the inferior thyroid artery and recurrent laryngeal nerve. The right superior cardiac nerve, at the root of the neck, passes either in front of or behind the subclavian artery, and along the arteria innominata, to the back part of the arch of the aorta, where it joins the deep cardiac plexus. This nerve, in its course, is connected with other branches of the sympathetic; about the middle of the neck it receives filaments from the external laryngeal nerve; lower down it obtains one or two twigs from the vagus, and as it enters the thorax it is joined by a filament from the recurrent laryngeal. Filaments from this nerve communicate with the thyroid branches from the middle cervical ganglion. The left superior cardiac nerve, in the chest, runs by the side of the left common carotid artery and in front of the arch of the aorta to the superficial cardiac plexus, but occasionally it passes behind the aorta and terminates in the deep cardiac plexus.

The Anterior Branches of the Superior Cervical Ganglion (nn. carotici externi) (Fig. 707) ramify upon the external carotid artery and its branches, forming around each a delicate plexus, on the nerves composing which small ganglia are occasionally found. The plexuses accompanying some of these arteries have important communications with other nerves. That surrounding the external carotid artery (plexus caroticus externus) is connected with the branch of the facial nerve to the Stylohyoid muscle; that surrounding the facial artery communicates with the submaxillary ganglion by one or two filaments; and that accompanying the medidural artery sends offsets which pass to the otic ganglion and to the genulate ganglion of the facial nerve and constitute the external superficial petrosal nerve (Fig. 694).

The Middle Cervical or Thyroid Ganglion (ganglion cervical medium) (Figs. 705 and 707).—The middle cervical or thyroid ganglion is the smallest of the three cervical ganglia, and is occasionally altogether wanting. It varies somewhat in position, but in most individuals is placed opposite the sixth cervical vertebra, usually upon, or close to, the inferior thyroid artery; hence the name, thyroid ganglion, assigned to it by Haller. It is probably formed by the coalescence of two ganglia corresponding to the fifth and sixth cervical nerves.
It communicates above with the superior cervical ganglion and below with the inferior cervical ganglion by means of the commissure of the gangliated cord.

The Central Communicating Branches.—The central communicating branches are: 1. Gray rami communicantes passing from the ganglion to the anterior divisions of the fifth and sixth cervical nerves. 2. The subclavian loop or the ansa of Vieussens (ansa subclavia) (Fig. 708) arises from the ganglion, passes down over the front and under the subclavian artery and runs back to join the inferior cervical ganglion. It gives branches to the artery. In some cases this nerve takes origin from the sympathetic trunk below the ganglion.

The Peripheral Branches.—The peripheral branches are the thyroid and the middle cardiac nerve.

The Thyroid Branches are small filaments which accompany the inferior thyroid artery to the thyroid gland, forming the inferior thyroid plexus (plexus thyreoideus inferior); they communicate, on the artery, with the superior cardiac nerve, and, in the gland, with branches from the recurrent and external laryngeal nerves.

The Middle or Great Cardiac Nerve (n. cardiacus medius) (Fig. 705), the largest of the three cardiac nerves, arises from the middle cervical ganglion or from the cord between the middle and inferior ganglia. On the right side it descends behind the common carotid artery, and at the root of the neck passes either in front of or behind the subclavian artery; it then descends on the trachea, receives a few filaments from the recurrent laryngeal nerve, and joins the right side of the deep cardiac plexus. In the neck it communicates with the superior cardiac and recurrent laryngeal nerves. On the left side the middle cardiac nerve enters the chest between the left carotid and subclavian arteries, and joins the left side of the deep cardiac plexus. If the middle cervical ganglion is absent, the above-named branches arise from the gangliated cord.

The Inferior Cervical Ganglion (ganglion cervicale inferius) (Figs. 705 and 707).—The inferior cervical ganglion is situated between the base of the transverse process of the last cervical vertebra and the neck of the first rib on the inner side of the superior intercostal artery. Its form is irregular; it is larger in size than the preceding, and is frequently joined to the first thoracic ganglion. It is probably formed by the coalescence of two ganglia which correspond to the two last cervical nerves. It joins the middle ganglion above and the first thoracic ganglion below by means of the commissural cord, and is usually also joined to the middle ganglion by the subclavian loop.

The Central Communicating Branches.—Its central communicating branches are:
1. Gray rami communicantes passing to the anterior divisions of the seventh and eighth cervical nerves (Fig. 707). 2. The subclavian loop (Fig. 708), which has been previously described and which passes under and in front of the subclavian artery to reach the middle cervical ganglion or the commissural cord.

The Peripheral Branches.—The peripheral branches are: 1. Vascular. The vertebral plexus (plexus vertebralis) lies upon the vertebral artery and its branches in the neck and in the cranial cavity. The subclavian plexus (plexus subclavius) arises from the subclavian loop, which may be regarded as a branch of the inferior or of the middle ganglion. 2. Cardiac. The inferior or minor cardiac nerve (n. cardiacus inferior) arises from the inferior cervical or first thoracic ganglion. It passes down behind the subclavian artery and along the front of the trachea to join the deep cardiac plexus. It communicates freely behind the subclavian artery with the recurrent laryngeal and middle cardiac nerves.
Surgical Anatomy. — The situation of the cervical sympathetic makes wounds of it rare. Thirteen cases of sympathetic traumatic injury were collected by Seeligmüller. In ten cases paralysis existed; in three, irritation. Tumors of the neck may cause irritation or paralysis. In irritation of the sympathetic the corresponding side of the face becomes pale, the pupil dilates, the palpebral fissure widens, and the eyeball protrudes. In many cases there is acceleration of the heart beats. In paralysis of the sympathetic the pupil contracts, the palpebral fissure is narrowed by partial ptosis, the corresponding side of the face reddens, there is an increase in the flow of tears, and recession of the eyeball.

The surgeon occasionally resects the sympathetic. Jonnesco recommends bilateral removal of the superior cervical ganglia for glaucoma, and bilateral removal of all the cervical sympathetic ganglia for epilepsy and for exophthalmic goitre.

The Thoracic Portión (Pars Thoracalis) of the Gangliated Cord (Fig. 709).

The thoracic portion of the gangliated cord consists of a series of ganglia which usually correspond in number to that of the vertebrae, but, from the occasional coalescence of two, their number is uncertain. These ganglia are placed on each side of the spine, resting against the heads of the ribs, and are covered by the pleura costalis; the last two ganglia are, however, ventral to the rest, being placed on the side of the bodies of the eleventh and twelfth thoracic vertebrae. The ganglia are small in size and of a grayish color. The first ganglion, larger than the rest, is of an elongated form and is frequently blended with the last cervical ganglion. They are connected together by cord-like prolongations from their substance. In the thorax each thoracic spinal nerve, with occasionally the exception of the first, sends a visceral branch or white ramus communicans to the thoracic gangliated cord (Fig. 709). As Prof. Cunningham points out, the white rami “separate into two main streams in relation to the sympathetic cord. Those of the upper five nerves are, for the most part, directed upward in the gangliated cord to be distributed through the cervical part of the sympathetic in the manner already described. The white rami of the lower thoracic nerves are, for the most part, directed downward in the lower part of the sympathetic cord and its branches, to be distributed to the abdomen; at the same time some of their fibres are directly associated with the supply of certain thoracic viscera—lungs, aorta, œsophagus.” The white rami are composed of splanchnic afferent fibres and somatic and splanchnic efferent fibres.

Central Communicating Branches.—1. White rami communicantes (see above). 2. Gray rami communicantes arise from each one of the thoracic ganglia, pass backward with the white rami, and enter into the ventral divisions of the thoracic nerves.

Peripheral Branches.—1. Aortic Branches come off from the first five or six upper ganglia. They send filaments to the aorta and its branches, to the vertebral bodies, and to the vertebral ligaments. The aortic branches help to form the thoracic aortic plexus (plexus aorticus thoracalis). This plexus is completed by branches from the cardiac plexus.

2. Pulmonary Branches come off from the third and fourth and sometimes from the first and second ganglia.

3. The Splanchnic Nerves (Figs. 705 and 709).—From the six or seven lower ganglia and from the commissural cord a number of large white branches arise. They give filaments to the aorta and unite to form the three splanchnic nerves on each side. These are named the great, the lesser, and the smallest or renal splanchnic.

The superior or great splanchnic nerve (n. splanchnicus major) is of a white color, firm in texture, and presents a marked contrast to the ganglionic nerves. It is formed by branches from the thoracic ganglia between the fifth or sixth and the ninth or tenth, but the fibres in the higher roots may be traced upward in the sympathetic cord as far as the first or second thoracic ganglion. These roots unite to form a large round cord of considerable size. It descends obliquely
inward in front of the bodies of the vertebrae along the posterior mediastinum, perforates the crus of the Diaphragm, and terminates in the **semilunar ganglion of the solar plexus** (Fig. 709), distributing filaments to the **renal and adrenal plexuses**.

The **middle, lesser, or small splanchnic nerve** (*n. splanchnicus minor*) is formed by filaments from the tenth and eleventh ganglia, and from the cord between them. It pierces the Diaphragm with the preceding nerve, and joins the **solar plexus** (Fig. 709). It communicates in the chest with the great splanchnic nerve, and occasionally sends filaments to the renal plexus.

The **inferior, smallest, least, or renal splanchnic nerve** (*n. splanchnicus imus*) arises from the last thoracic ganglion, and, piercing the Diaphragm, terminates in the **renal plexus** and lower part of the **solar plexus**. It occasionally communicates with the preceding nerve.

A striking analogy appears to exist between the splanchnic and the cardiac nerves. The cardiac nerves are three in number; they *arise* from the three **cervical ganglia**, and are distributed to a large and important organ in the thoracic
cavity. The splanchnic nerves, also three in number, are connected probably with all the thoracic ganglia, and are distributed to important organs in the abdominal cavity

The Lumbar Portion (Pars Lumbalis) of the Gangliated Cord (Fig. 705).

The lumbar portion of the gangliated cord is situated in front of the vertebral column along the inner margin of the Psoas muscle. It consists usually of four ganglia, but there may be as many as eight, connected together by interganglionic cords. The ganglia are of small size, of a grayish color, shaped like a barleycorn, and placed much nearer the median line than the thoracic ganglia. Sometimes several ganglia are fused together.

It is connected with the thoracic portion by a thin commissure, which passes back of or through the Diaphragm. It is connected with the sacral portion by a commissure which is under the common iliac artery.

The upper lumbar ganglia or the upper portion of the gangliated cord receives white rami communicantes from the first two or three lumbar spinal nerves.

Central Communicating Branches.—Gray rami communicantes pass irregularly from the gangliated cord to the ventral divisions of the lumbar spinal nerves, the gray rami accompanying the white rami.

From the situation of the lumbar ganglia these branches are longer than in the other regions. They are usually two in number from each ganglion, but their connection with the spinal nerves is not so uniform as in other regions. They accompany the lumbar arteries around the sides of the bodies of the vertebrae, passing beneath the fibrous arches from which some of the fibres of the Psoas muscle arise.

Peripheral Branches.—Some branches pass inward, in front of the aorta, and help to form the abdominal aortic plexus (plexus aorticus abdominalis) (Fig. 705) which plexus is, however, developed chiefly by filaments from the celiac plexus. Other branches descend in front of the common iliac arteries, and join over the promontory of the sacrum, helping to form the hypogastric plexus (plexus hypogastricus) (Fig. 705). Numerous delicate filaments are also distributed to the bodies of the vertebrae and the ligaments connecting them.

Pelvic or Sacral Portion (Pars Sacralis) of the Gangliated Cord (Fig. 705).

The pelvic portion of the gangliated cord is situated in front of the sacrum along the inner side of the ventral sacral foramina. It consists of four or five small ganglia on each side, connected together by interganglionic cords. Below these cords converge and unite on the front of the coccyx by means of a small ganglion, the coccygeal ganglion or ganglion impar (ganglion coccygeum impar (Fig. 705). The commissural cord joins the pelvic portion to the lumbar portion of the gangliated cord. Like the cervical and the lower lumbar divisions the sacral portion receives no white rami communicantes.

The visceral branches of the third sacral, and usually of the second and fourth sacral spinal nerves, are not connected with the ganglionic cord.

Central Communicating Branches.—Gray rami communicantes, which arise in the sacral ganglia and pass to the anterior divisions of the sacral and coccygeal nerves.

Peripheral Branches.—1. Visceral branches arise from the upper portion of the gangliated cord and pass to the pelvic plexus.

2. Parietal branches communicate, on the front of the sacrum, with the corresponding branches from the opposite side; some, from the first two ganglia, pass to
join the pelvic plexus, and others form a plexus which accompanies the middle sacral artery and sends filaments to the coccygeal gland.

THE GREAT PLEXUSES OF THE SYMPATHETIC SYSTEM.

The great plexuses of the sympathetic are the large aggregations of nerves and ganglia, previously alluded to, situated in the thoracic, abdominal, and pelvic cavities respectively. From them are derived the branches which supply the viscera.

The Cardiac Plexus (Plexus Cardiacus) (Fig. 705).

The cardiac plexus is situated at the base of the heart, and is divided into a superficial part, which lies in the concavity of the arch of the aorta, and a deep part, which lies between the trachea and aorta. The two plexuses are, however, closely connected.

The Great or Deep Cardiac Plexus.—The great or deep cardiac plexus, the plexus magnus profundus of Scarpa, is situated in front of the trachea at its bifurcation, above the point of division of the pulmonary artery and behind the arch of the aorta. It is formed by the cardiac nerves derived from the cervical ganglia of the sympathetic and the cardiac branches of the recurrent laryngeal and vagus. The only cardiac nerves which do not enter into the formation of this plexus are the left superior cardiac nerve and the inferior cervical cardiac branch from the left vagus.

The branches from the right side of this plexus pass, some in front of, and others behind, the right pulmonary artery; the former, the more numerous, transmit a few filaments to the ventral pulmonary plexus, and are then continued onward to form part of the left or ventral coronary plexus; those behind the pulmonary artery distribute a few filaments to the right auricle, and are then continued onward to form a part of the right or dorsal coronary plexus.

The branches from the left side of the deep cardiac plexus distribute a few filaments to the superficial cardiac plexus, to the left auricle of the heart, and to the ventral pulmonary plexus, and then pass on to form the greater part of the dorsal coronary plexus.

The Ventral or Left Coronary Plexus (plexus coronarius cordis anterior).—The ventral or left coronary plexus is formed chiefly from the superficial cardiac plexus, but receives filaments from the deep cardiac plexus. Passing forward between the aorta and pulmonary artery, it accompanies the left coronary artery on the ventral surface of the heart.

The Dorsal or Right Coronary Plexus (plexus coronarius cordis posterior).—The dorsal or right coronary plexus is chiefly formed by filaments prolonged from the left side of the deep cardiac plexus, and by a few from the right side. It surrounds the branches of the coronary artery at the back of the heart, and its filaments are distributed with those vessels to the muscular substance of the ventricles.

The Superficial or Ventral Cardiac Plexus.—The superficial or ventral cardiac plexus lies beneath the arch of the aorta, in front of the right pulmonary artery. It is formed by the left superior cardiac nerve, the left (and occasionally also the right) inferior cervical cardiac branches of the vagus, and filaments from the deep cardiac plexus. A small ganglion, the cardiac ganglion of Wrisberg (ganglion cardiaeum [Wrisbergi]) is occasionally found connected with these nerves at their point of junction. This ganglion, when present, is situated immediately beneath the arch of the aorta, on the right side of the ductus arteriosus. The superficial
cardiac plexus forms the chief part of the ventral coronary plexus, and several filaments pass along the pulmonary artery to the left ventral pulmonary plexus.

Valentin has described nerve filaments ramifying under the endocardium; and Remak has found, in several mammalia, numerous small ganglia on the cardiac nerves, both on the surface of the heart and in its muscular substance.

The Pulmonary Plexus (Plexus Pulmonalis).

The larger dorsal pulmonary plexus is situated back of the root of the lung. It is formed by the vagus nerve and branches from the second, third, and fourth thoracic sympathetic ganglia. It sends branches along the bronchi and blood-vessels into the lung and some fibres pass to the front of the root of the lung to form the ventral pulmonary plexus. The smaller ventral pulmonary plexus is in front of and above the root of the lung. It is formed on each side by the fibres from the dorsal pulmonary plexus. The left plexus receives branches from the superficial cardiac plexus. The ventral plexus supplies the structures of the root of the lung.

The Æsophageal Plexus (Plexus Oesophageus).

The Æsophageal plexus is in the dorsal mediastinum and surrounds the Æsophagus. It is formed by the vagus nerves which have come from the dorsal pulmonary plexuses, and by fibres from the great splanchnic nerve and ganglion. The Æsophageal plexus is usually considered as a portion of the vagus nerve (p. 1072).

The Epigastric or Solar Plexus (Plexus Coeliacum) (Figs. 705, 710, 711).

The epigastric or solar plexus supplies all the viscera in the abdominal cavity. It consists of a great network of nerves and ganglia, situated behind the pancreas and the lesser peritoneal cavity and in front of the aorta and crura of the Diaphragm. It surrounds the coeliac axis and root of the superior mesenteric artery, extending downward as low as the pancreas and outward to the suprarenal capsules. This plexus, and the ganglia connected with it, receive the great, the small, and the least splanchnic nerves of both sides, and some filaments from the right vagus nerve. It distributes filaments which accompany, under the name ofplexuses, all the branches from the front of the abdominal aorta.

Of the ganglia of which the solar plexus is partly composed the principal are the two semilunar ganglia (ganglia coeliaca) (Figs. 710 and 711), which are situated one on each side of the plexus, and are the largest ganglia in the body. They are large, irregular, gangliiform masses formed by the aggregation of smaller ganglia, having interspaces between them. They are situated in front of the crura of the diaphragm, close to the suprarenal capsules: the one on the right side lies beneath the postcava; the upper part of each ganglion is joined by the greater splanchnic nerve, and to the inner side of each the branches of the solar plexus are connected.

From the epigastric or solar plexus are derived the following:

- Phrenic or Diaphragmatic plexus.
- Adrenal plexus.
- Renal plexus.
- Spermatic plexus.

Coeliac plexus

{ Gastric plexus.
{ Splenic plexus.
{ Hepatic plexus.

Superior mesenteric plexus.

Aortic plexus.
The Phrenic Plexus (*plexus phrenicus*) (Fig. 710).—The phrenic plexus accompanies the phrenic artery to the Diaphragm, which it supplies, some filaments passing to the adrenal. It arises from the upper part of the semilunar ganglion, and is larger on the right than on the left side. It receives one or two branches from the phrenic nerve. In connection with this plexus, on the right side, at its point of junction with the phrenic nerve, is a small ganglion, the diaphragmatic or phrenic ganglion (*ganglion phrenicum*) (Fig. 711). This ganglion is placed on the under surface of the Diaphragm, near the right adrenal.

Its branches are distributed to the postcava, adrenal, and hepatic plexus. There is no ganglion on the left side.

The Adrenal Plexus (*plexus suprarenalis*) (Fig. 710).—The adrenal plexus is formed by branches from the solar plexus, from the semilunar ganglion, and from the phrenic and great splanchnic nerves, a ganglion being formed at the point of junction of the latter nerve. It supplies the adrenal. The branches of this plexus are remarkable for their large size in comparison with the size of the organ they supply.
The Renal Plexus (*plexus renalis*) (Figs. 710 and 711).—The renal plexus is formed by filaments from the solar plexus, the outer part of the semilunar ganglion, and the aortic plexus. It is also joined by filaments from the lesser and smallest splanchnic nerves. The nerves from these sources, fifteen or twenty in number,
have numerous ganglia developed upon them. They accompany the branches of the renal artery into the kidney, some filaments on the right side being distributed to the postcava, and others, on both sides, to the spermatic plexuses.

**The Spermatic Plexus** (plexus spermaticus) (Fig. 710).—The spermatic plexus is derived from the renal plexus, receiving branches from the aortic plexus. It accompanies the spermatic vessels to the testes.

**The Ovarian Plexus** (plexus arteriae ovariae).—In the female the ovarian plexus is distributed to the ovaries and fundus of the uterus.

**The Cœliac Plexus** (plexus coeliacus).—The coeliac plexus, of large size, is a direct continuation from the solar plexus; it surrounds the celiac axis and subdivides into the gastric, hepatic, and splenic plexuses. It receives branches from the lesser splanchnic nerves, and, on the left side, a filament from the right vagus.

**The Gastric or Coronary Plexus** (plexus gastricus superior) (Fig. 710) accompanies the gastric artery along the lesser curvature of the stomach, and joins with branches from the left vagus nerve. It is distributed to the stomach.

**The Splenic Plexus** (plexus lienalis) (Fig. 710) is formed by branches from the coeliac plexus, the left semilunar ganglion, and from the right vagus nerve. It accompanies the splenic artery and its branches to the substance of the spleen, giving off, in its course, filaments to the pancreas, the pancreatic plexus, and the left gastro-epiploic plexus, which accompanies the gastro-epiploica sinistra artery along the convex border of the stomach.

**The Hepatic Plexus** (plexus hepaticus) (Fig. 710), the largest offset from the coeliac plexus, receives filaments from the left vagus and right phrenic nerves. It accompanies the hepatic artery, ramifying in the substance of the liver upon its branches and upon those of the vena portae.

Branches from this plexus accompany all the divisions of the hepatic artery. Thus there is a pyloric plexus accompanying the pyloric branch of the hepatic, which joins with the gastric plexus and vagus nerves. There is also a gastro-duodenal plexus, which subdivides into the pancreatico-duodenal plexus, which accompanies the pancreatico-duodenal artery, to supply the pancreas and duodenum, joining with branches from the mesenteric plexus. The gastro-epiploic plexus, which accompanies the right gastro-epiploic artery along the greater curvature of the stomach, and which is said to anastomose with branches from the splenicplexus, is in reality derived from the splenic plexus. A cystic plexus, which supplies the gall-bladder, also arises from the hepatic plexus near the liver.

**The Superior Mesenteric Plexus** (plexus mesentericus superior) (Fig. 710).—The superior mesenteric plexus is a continuation of the lower part of the great solar plexus, receiving a branch from the junction of the right vagus nerve with the coeliac plexus. It surrounds the superior mesenteric artery, which it accompanies into the mesentery, and divides into a number of secondary plexuses, which are distributed to all the parts supplied by the artery—viz., pancreatic branches to the pancreas; intestinal branches, which supply the whole of the small intestine; and ileo-colic, right colic, and middle colic branches, which supply the corresponding parts of the large intestine. The nerves composing this plexus are white in color and firm in texture, and have numerous ganglia developed upon them near their origin.

**The Abdominal Aortic Plexus** (plexus aorticus abdominalis) (Figs. 705, 710, and 711).—The abdominal aortic plexus is formed by branches derived, on each side, from the solar plexus and the semilunar ganglia, receiving filaments from some of the lumbar ganglia. It is situated upon the sides and front of the aorta, between the origins of the superior and inferior mesenteric arteries. From this plexus arise part of the spermatic, the inferior mesenteric, and the hypogastric plexuses; and it distributes filaments to the postcava.

**The Inferior Mesenteric Plexus** (plexus mesentericus inferior) (Fig. 710) is derived chiefly from the left side of the aortic plexus. It surrounds the inferior mesenteric
artery, and divides into a number of secondary plexuses, which are distributed to all the parts supplied by the artery—viz., the left colic and sigmoid plexuses, which supply the descending and sigmoid flexure of the colon; and the superior hemorrhoidal plexus (plexus haemorrhoidalis superior), which supplies the upper part of the rectum and joins in the pelvis with branches from the pelvic plexus.

The Hypogastric Plexus (Plexus Hypogastricus) (Figs. 705 and 711).

The hypogastric plexus supplies the viscera of the pelvic cavity. It is situated in front of the promontory of the sacrum, between the two common iliac arteries, and is formed by the union of numerous filaments, which descend on each side from the abdominal aortic plexus and from the lumbar ganglia. This plexus contains no evident ganglia; it bifurcates, below, into two lateral portions, right and left, which form the pelvic plexuses.

The Pelvic or Sacral Plexus (Plexus Sacralis).

Each pelvic plexus, sometimes called the inferior hypogastric, supplies the viscera of the pelvic cavity, is situated at the side of the rectum in the male, while in the female it lies in the base of the broad ligament near the ureters. It is formed by a continuation of the hypogastric plexus, by branches from the second, third, and fourth sacral nerves, and by a few filaments from the first two sacral ganglia. At the points of junction of these nerves small ganglia are found. From this plexus numerous branches are distributed to the rectum and bladder in the male and to the rectum, bladder, uterus, and vagina in the female. They accompany the branches of the internal iliac artery. These secondary plexuses are (1) the inferior hemorrhoidal, (2) vesical, (3) prostatic, (4) vaginal, and (5) uterine plexus.

The Inferior Hemorrhoidal Plexus (plexus haemorrhoidalis inferior).—The inferior hemorrhoidal plexus arises from the back part of the pelvic plexus. It supplies the rectum, joining with branches of the superior hemorrhoidal plexus.

The Vesical Plexus (plexus vesicalis).—The vesical plexus arises from the forepart of the pelvic plexus. The nerves composing it are numerous, and contain a large proportion of spinal nerve-fibres. They accompany the vesical arteries, and are distributed at the side and base of the bladder. Numerous filaments also pass to the vesicule seminales and vasa deferentia; those accompanying the vasa deferens join, on the spermatic cord, with branches from the spermatic plexus.

The Prostatic Plexus (plexus prostaticus).—The prostatic plexus is continued from the lower part of the pelvic plexus. The nerves composing it are of large size. They are distributed to the prostate gland, vesiculae seminales, and erectile structure of the penis. The nerves supplying the erectile structure of the penis consist of two sets, the small and large cavernous nerves. They are slender filaments, which arise from the forepart of the prostatic plexus, and, after joining with branches from the internal pubic nerve, pass forward beneath the pubic arch.

The Small Cavernous Nerve (n. cavernosus penis minor) perforates the fibrous covering of the penis—near its roots.

The Large Cavernous Nerve (n. cavernosus penis major) passes forward along the dorsum of the penis, joins with the dorsal branch of the pudic nerve, and is distributed to the corpora cavernosa and corpus spongiosum.

The uterine and vaginal plexuses in reality constitute one plexus, the uterovaginal plexus (plexus uterovaginalis).

The Vaginal Plexus arises from the lower part of the pelvic plexus. It is lost on the walls of the vagina, being distributed to the erectile tissue at its ventral
part and to the mucous membrane. The nerves composing this plexus contain, like the vesical nerves, a large proportion of spinal nerve-fibres.

The *Uterine Plexus* arises from the upper part of the pelvic plexus above the point where the branches from the sacral nerves join the plexus. Its branches accompany the uterine arteries to the sides of the organ between the layers of the broad ligaments, and are distributed to the cervix and lower part of the body of the uterus, penetrating its substance.

Other filaments pass separately to the body of the uterus and the oviduct.

Branches from the plexus accompany the uterine arteries into the substance of the uterus. Upon these filaments ganglionic enlargements are found.
THE ORGANS OF SPECIAL SENSE.

The Organs of the Senses are five in number—viz., those of Taste, of Smell, of Sight, of Hearing, and of Touch.

THE TONGUE (LINGUA) (Fig. 712).

The tongue is a very mobile muscular organ, undergoing changes in length and width at every contraction of its muscle. It is the organ of the special sense of taste, and is also an organ of speech, mastication, and deglutition. It is situated in the floor of the mouth, in the interval between the two lateral portions of the body of the lower jaw, and when at rest is about three and one-half inches in length. We describe the body, base, apex, dorsum, margin, and inferior surface.

The Body (corpus linguae).—The body forms the great bulk of the organ and is composed of striated muscle.

The Base or Root (radix linguae).—The base or root is directed backward, and connected with the os hyoideum by the Hyo-glossi and Genio-hyo-glossi muscles and the hyo-glossal membrane; with the epiglottis by three folds of mucous membrane, the glosso-epiglottic folds; with the soft palate by means of the anterior pillars of the fauces; and with the pharynx by the Superior constrictors and the mucous membrane.

The Apex or Tip (apex linguae).—The apex or tip is thin and narrow, and is directed forward against the inner surface of the lower incisor teeth.

The Dorsum of the Tongue (dorsum linguae).—The dorsum when the tongue of a living person is at rest is markedly arched from before backward. On the dorsum is a median longitudinal raphe (sulcus medianus linguae). This slight depression terminates posteriorly in the depression known as the foramen caecum (foramen caecum linguae [Morgagnii]), from which a shallow-shaped groove, the sulcus terminalis of His, runs outward and forward on each side to the lateral margin of the tongue. The part of the dorsum of the tongue in front of this groove, known as the anterior or oral part, forming about two-thirds of its upper surface, is rough and covered with papillae; the posterior third of the dorsum is back of the sulcus terminalis, is known as the posterior or pharyngeal portion, is smoother, and contains numerous muciparous glands and lymphoid follicles.

The Margin of the Tongue (margo lateralis linguae).—The margin of the tongue is free in front of the anterior arch of the palate. Just in front of the arch are several vertical folds, the folia linguae.

The Under or Inferior Surface (facies inferior linguae).—The under or inferior surface of the tongue is connected with the lower jaw by the Genio-hyoglossi muscles, from its sides the mucous membrane is reflected to the inner surface of the gums; and from its under surface on to the floor of the mouth, where, in the middle line, it is elevated into a distinct vertical fold, the fraenum linguae (frenulum linguae). To each side of the fraenum is a slight fold of the mucous membrane, the plica fimbriata, the free edge of which exhibits a series of fringe-like processes.

The tip of the tongue, part of the under surface, its sides, and dorsum are free.
Structure of the Tongue.—The tongue is partly invested by mucous membrane and a submucous fibrous layer. It consists of symmetrical halves, separated from each other, in the middle line, by a fibrous septum. Each half is composed of muscular fibres arranged in various directions (page 400), containing much interposed fat, and supplied by vessels and nerves.

The Mucous Membrane (tunica mucosa linguae).—The mucous membrane invests the entire extent of the free surface of the tongue. On the dorsum it is thicker behind than in front, and is continuous with the sheath of the muscles attached to it, through the submucous fibrous layer. On the under surface of the organ, where it is thin and smooth, it can be traced on each side of the fraenum through the ducts of the submaxillary and the sublingual glands. As it passes over the borders of the organ it gradually assumes a papillary character.

Structure.—The structure of the mucous membrane of the tongue differs in different parts. That covering the under surface of the organ is thin, smooth, and identical in structure with that lining the rest of the oral cavity. The mucous membrane covering the tongue behind the foramen caecum and sulcus terminalis is thick and freely movable over the subjacent parts. It contains a large number of lymphoid follicles (folliculi linguales), which together constitute what is sometimes termed the lingual tonsil (tonsilla lingualis). Each follicle forms a rounded eminence, the centre of which is perforated by a minute orifice leading into a
funnel-shaped cavity or recess; around this recess are grouped numerous oval or rounded nodules of lymphoid tissue, each enveloped by a capsule derived from the submucosa, while opening into the bottom of the recesses are also seen the ducts of mucous glands (glandulae linguales). The mucous membrane on the anterior part of the dorsum of the tongue is thin and intimately adherent to the muscular tissue, and covered with minute eminences, the papillae of the tongue. It consists of a layer of connective tissue, the corium or mucosa, supporting numerous papillae, and covered, as well as the papillae, with epithelium.

The epithelium is of the scaly variety, like that of the epidermis. It covers the free surface of the tongue, as may be readily demonstrated by maceration or boiling, when it can be easily detached entire; it is much thinner than that of the skin; the intervals between the large papillae are not filled up by it, but each papilla has a separate investment from root to summit. The deepest cells may sometimes be detached as a separate layer, corresponding to the rete mucosum, but they never contain coloring matter.

The Corium.—The corium consists of a dense feltwork of fibrous connective tissue, with numerous elastic fibres, firmly connected with the fibrous tissue forming the septa between the muscular bundles of the tongue. It contains the ramifications of the numerous vessels (Fig. 713) and nerves from which the papillae are supplied, large plexuses of lymphatic vessels, and the glands of the tongue.

The Papillae of the Tongue (papillae linguales) (Figs. 712, 713, 714, and 715).—These are papillary projections of the corium. They are thickly distributed over the anterior two-thirds of the upper surface of the tongue, giving to it its characteristic roughness. The varieties of papillae met with are—the papillae maximae or circumvallate papillae, papillae mediae or fungiforme papillae, papillae minimae, conical or filiforme papillae, and papillae simplices or simple papillae.

The Papillae Maximae or Circumvallate Papillae (papillae vallatae) (Figs. 712, 713, and 714) are of large size, and vary from eight to twelve in number. They are situated at the back part of the dorsum of the tongue, near its base, in front of the foramen caecum and sulcus terminalis, forming a row on each side, which, running backward and inward, meet in the middle line, like the two lines of the letter V inverted A. Each papilla consists of a projection of mucous membrane from $\frac{1}{20}$ to $\frac{1}{12}$ of an inch wide, attached to the bottom of a cup-shaped depression of the mucous membrane; the papilla is in shape like a truncated cone, the smaller end being directed downward and attached to the tongue, the broader part or base projecting on the surface and being studded with numerous small secondary papillae (Fig. 713), which, however, are covered by a smooth layer of the epithelium. The cup-shaped depression forms a kind of fossa around the papilla, having a circular margin of about the same elevation covered with smaller papillae.
Immediately behind the apex of the V is the foramen cecum, mentioned above. This foramen, according to His, represents the remains of the invagination which forms the median rudiment of the thyroid body, and which for a time opens by a duct, the thyroglossal duct (ductus thyreoglossus), on to the dorsum of the tongue. It may extend downward toward the hyoid bone. Kanthack, however, disputes this view.  

The *Fungiforme Papillae* or *Papillae Mediae* (papillae fungiformes et papillae lenticales) (Fig. 713), more numerous than the preceding, are scattered irregularly and sparingly over the dorsum of the tongue, but are found chiefly at its sides and apex. They are easily recognized among the other papillae, by their large size, rounded eminences, and deep-red color. They are narrow at their attachment to the tongue, but broad and rounded at their free extremities, and are covered with secondary papillae. Their epithelial investment is very thin.

The *Conical* or *Filiform Papillae* or *Papillae Minimae* (papillae conicae et papillae filiformes) (Fig. 713) cover the anterior two-thirds of the dorsum of the tongue. They are very minute, more or less conical or filiform in shape, and arranged in lines corresponding in direction with the two rows of the papillae circumvallatae, excepting at the apex of the organ, where their direction is transverse. Projecting from their apices are numerous filiform processes or secondary papillae; these are of a whitish tint, owing to the thickness and density of the epithelium of which they are composed, and which has here undergone a peculiar modification, the cells having become cornified and elongated into dense, imbricated, brush-like processes. They contain also a number of elastic fibres, which render them firmer and more elastic than the papillae of mucous membrane generally.

*Simple Papillae*, similar to those of the skin, cover the whole of the mucous membrane of the tongue, as well as the larger papillae. They consist of closely set, microscopic elevations of the corium, containing a capillary loop, covered by a layer of epithelium.

*Structure of the Papillae* (Figs. 713 and 714).

The papillae apparently resemble in structure the papillae of the cutis, consisting of a cone-shaped projection of connective tissue, covered with a thick layer of squamous epithelium, and contain one or more capillary loops, amongst which nerves are distributed in great abundance. If the epithelium is removed, it will be found, however, that they are not simple elevations like the papillae of the skin, for the surface of each is studded with minute conical processes of the mucous membrane, which form secondary papillae (Todd and Bowman). In the papillae circumvallatae the nerves are numerous and of large size; in the papillae fungiformes they are also numerous, and terminate in a plexiform network, from which brush-like branches proceed; in the papillae filiformes their mode of termination is uncertain. Buried in the epidermis of the papillae circumvallatae, and in some of the fungiformes, are certain peculiar bodies, called *taste-buds* (Fig. 715). Each is flask-like in shape, the broad base resting on the corium, and the neck opening by an orifice, the *gustatory pore*, between the cells of the epithelium.

---

1 Journal of Anatomy and Physiology, 1891.
2 These bodies are also found in considerable numbers at the side of the base of the tongue, just in front of the anterior pillars of the fauces, and also on the posterior surface of the epiglottis and anterior surface of the soft palate.—En. of 16th English edition.
They are formed by two kinds of cells, supporting cells and gustatory cells. The supporting cells are mostly arranged like the staves of a cask, and form an outer envelope for the bud. Some, however, are found in the interior of the bud between the gustatory cells. The gustatory cells occupy the central portion of the bud; they are spindle-shaped, and each possesses a large spherical nucleus near the middle of the cell. Until recently the teaching was as follows: The peripheral end of the cell terminates as the gustatory pore in a fine, hair-like filament, the gustatory hair. The central process passes toward the deep extremity of the bud, and there ends in a single or bifurcated varicose filament, which was formerly supposed to be continuous with the terminal fibril of a nerve; the investigations of Lenhossék and others would seem to prove, however, that this is not so, but that the nerve-fibrils after losing their medullary sheaths enter the taste-bud, and terminate in a fine extremity between the gustatory cells. Other nerve-fibrils may be seen ramifying between the cortical cells and terminating in fine extremities; these, however, are believed to be nerves of ordinary sensation, and not gustatory. It is now not believed that the epithelia of the taste-buds are directly connected with the nerve-fibres by long processes. "The latest researches have shown that dendrites of sensor neurones (sensor nerves) enter the taste-buds and end free in telodendria. The latter surround the neuro-epithelial, and, to some extent, the sustentacular cells, their relations depending on contact."

Glands of the Tongue.—The tongue is provided with mucous and serous glands. The mucous glands are similar in structure to the labial and buccal glands. They are found especially at the back part, behind the circumvallate papillae, but are also present at the apex and marginal parts. In connection with these glands special ones have been described by Blandin and Nuhn. They are known as the glands of Nuhn and Blandin or apical glands (glandulae linguales anteriores of Nuhn and Blandin) (Fig. 716). They are situated near the apex of the tongue on either side of the fraenum, and each is covered over by a fasciculus of muscular fibre derived from the Stylo-glossus and Inferior lingualis muscles. Each gland is from half an inch to nearly an inch long and about the third of an inch broad. It has from four to six ducts, which open on the under surface of the apex.

The Serous Glands or Glands of v. Ebner occur only at the back of the tongue in the neighborhood of the taste-buds, their ducts opening for the most part into the

---

fossae of the papillae circumvallatae. These glands are racemose, the duct branching into several minute ducts, which terminate in alveoli lined by a single layer of more or less columnar epithelium. Their secretion is of a watery nature, and probably assists in the distribution of the substance to be tasted over the taste-area (Ebner).

The Hyo-glossal membrane is a strong fibrous lamina which is derived from the septum of the tongue and which connects the under surface of the base of the tongue to the body of the hyoid bone. This membrane receives, in front, some of the posterior fibres of the Genio-hyo-glossi muscles.

The Vessels of the Tongue.—The arteries of the tongue are derived from the lingual, the facial, and ascending pharyngeal. The veins of the tongue open into the internal jugular.

The lingual artery (Fig. 718) on each side passes forward beneath the Hyo-glossus muscle and courses to the apex of the tongue, between the Genio-glossus and the Inferior lingual muscles, about one-eighth of an inch from the surface. It divides into the ranine (Fig. 716) and sublingual (Fig. 718). Near the apex a branch is given off from the ranine artery, which penetrates the septum and joins a like branch from the other side. The dorsalis linguae is a branch of the lingual

supplying the posterior part of the tongue, and rami from the tonsillar branch of the facial go to the same region. A network of capillary vessels is placed beneath the epithelium.

The ranine veins lie to the sides of the fraenum underneath the mucous membrane. Each ranine vein runs backward, superficial to and upon the Hyo-glossus muscle and near to the hypo-glossal nerve. The venae comites of the lingual artery usually join the ranine vein, and the trunk opens into the internal jugular vein, but the vessels may open separately into the jugular (Fig. 445).

The Muscles of the Tongue.—The muscular fibres of the tongue run in various directions. These fibres are divided into two sets, Extrinsic and Intrinsic, which have already been described (pp. 398, 399, 400, 401, and 402).
The Extrinsic come from the Stylo-glossus, Hyo-glossus, Genio-glossus, Palato-glossus, and Chondro-glossus. The Intrinsic muscles are the Superior lingualis (m. longitudinalis superior), the Inferior lingualis (m. longitudinalis inferior), the Transverse lingual (m. transversus linguae), and the Vertical lingual (m. verticalis linguae). The outer or cortical portion of the tongue is composed chiefly of longitudinal fibres. The central or medullary portion is composed chiefly of vertical and transverse fibres and is divided into two parts by a vertical septum (septum linguae), which is a fibrous structure, beginning at the apex and passing back. As it approaches the back it becomes narrower vertically and broadens out transversely to form the hyo-glossal membrane. The fibrous septum is well displayed by making a vertical section of the tongue.

The Lymphatic Vessels of the Tongue (Fig. 490).—The lymphatic vessels from the anterior half of the tongue pass to the submaxillary lymph glands.

Lymph vessels from the posterior half of the tongue are connected with satellite glands on the Hyo-glossus muscle and terminate in the deep cervical glands. The last-named lymph-vessel accompanies the ranine vein. The lingual lymphatics arise from a network beneath the epithelium. Across the anterior two-thirds of the tongue there is little or no lymphatic connection between the two sides; in the posterior one-third there is free connection.

![Diagram of the tongue](image)

**The Nerves of the Tongue** (Fig. 718).—The nerves of the tongue are five in number in each half: the lingual branch of the inferior maxillary division of the trigeminal, which is distributed to the papillae at the forepart and sides of the tongue, and forms the nerve of ordinary sensibility for its anterior two-thirds; the chorda tympani, which runs in the sheath of the lingual, is generally regarded as the nerve of taste for the same area (p. 898); the lingual branch of the glosso-pharyngeal, which is distributed to the mucous membrane at the base and sides of the tongue, and to the papillae circumvallatae, and which supplies both sensory and gustatory filaments to this region; the hypo-glossal nerve, which is the motor nerve to the muscular substance of the tongue; and the internal laryngeal branch of the superior laryngeal, which sends some fine branches to the root near to the epiglottis. Sympathetic filaments also pass to the tongue from the nervi molles on the lingual and other arteries supplying it. Some of the nerves end free between the cells of epithelium; others terminate as end organs (Meissner's corpuscles and the end-bulbs of Krause), and in taste-buds as sensory dendrites (p. 833).

**Surgical Anatomy.**—The diseases to which the tongue is liable are numerous, and its surgical anatomy is of importance, since any or all the structures of which it is composed—muscles, connective tissue, mucous membrane, glands, vessels, nerves, and lymphatics—may be the seat of morbid changes. It is not often the seat of congenital defects, though a few cases of vertical...
cleft have been recorded, and it is occasionally, though much more rarely than is commonly sup-
pposed, the seat of tongue-tie, from shortness of the frenum.

There is, however, one condition which must be regarded as congenital, though not uncom-
monly it does not exhibit the significant changes until a year or two after birth. This is an
enlargement of the tongue which is due primarily to a dilatation of the lymph-channels and a
greatly increased development of the lymphatic tissue throughout the tongue (macroglossia). This
is often aggravated by inflammatory changes induced by injury or exposure, and the tongue may
assume enormous dimensions and hang out of the mouth, giving the child an imbecile expression.
The treatment consists in excising a V-shaped portion and bringing the cut surfaces together
with deeply placed silver sutures. Compression has been resorted to in some cases with occa-
sional success, but it is difficult to apply. Acute inflammation of the tongue (acute glossitis),
which may be caused by injury or the introduction of some septic or irritating matter, and it
is attended by great swelling from infiltration of the connective tissue of the tongue; this con-
nective tissue is present in considerable quantity. The great swelling renders the patient
incapable of swallowing or speaking, and may seriously impede respiration. The condition may
eventuate in suppuration and the formation of an acute abscess. Chronic abscess, which has
been mistaken for cancer, may also occur in the substance of the tongue.

The mucous membrane of the tongue may become chronically inflamed, and presents different
appearances in different stages of the disease, to which the terms leucoplakia, psoriasis, and
ichthyosis have been given.

The tongue, being very vascular, is often the seat of naevoid growths, and these have a tendency
to grow rapidly.

The tongue is frequently the seat of ulceration, which may arise from many causes, as from
the irritation of jagged teeth, dyspepsia, tuberculosis, syphilis, and cancer. Of these the cancerous
ulcer is the most important, and probably also the most common. The variety is the squamous
epithelioma, which soon develops into an ulcer with an indurated base. It produces great pain
which speedily extends to all parts supplied with sensation by the trigeminal nerve, especially to the
The pain in these cases is conducted to the ear and temporal region by the lingual nerve, and from this nerve pain radiates to the other branches of the inferior maxillary nerve, especially the auriculo-temporal. Possibly pain in the ear itself may be due to implication of the fibres of the glosso-pharyngeal nerve, which by its tympanic branch reaches the tympanic plexus. Cancer of the tongue spreads through the organ very rapidly because of the almost constant muscular movements.

Cancer of the tongue may necessitate removal of a part or the whole of the organ, and many different methods have been adopted for its excision. It may be removed from the mouth by the ecraseur or the scissors. The better method is by the scissors, usually known as Whitehead's method. The mouth is widely opened with a gag, the tongue is transfixed with a stout silk ligature, by which to hold and make traction on it and the reflection of mucous membrane from the tongue to the jaw, and the insertion of the Genio-hyo-glossi first divided with a pair of curved blunt scissors. The Palato-glossi are also divided. The tongue can now be pulled well out of the mouth. The base of the tongue is cut through by a series of short snips, each bleeding vessel being dealt with as soon as divided, until the situation of the ranine artery is reached. The remaining undivided portion of tissue is to be seized with a pair of Wells's forceps, the tongue removed, and the vessel secured. In the event of the ranine artery being accidentally injured early in the operation, hemorrhage can be at once controlled by passing two fingers over the dorsum of the tongue as far as the epiglottis and dragging the root of the tongue forcibly forward.

In cases where the disease is confined to one side of the anterior portion of the tongue this operation may be modified by splitting the tongue down the centre and removing only the affected half. If the posterior portion of the tongue is attacked by cancer the entire tongue must be removed, even if but one side of the organ is apparently involved. The exchange of lymph between the halves of the posterior portion of the tongue makes it certain that the opposite half becomes involved soon after the origin of the disease. Whatever operation is performed for cancer of the tongue, the glands must be removed from both sides of the neck. This is to be done, even if but one side of the tongue is removed. Kocher, after performing a preliminary tracheotomy, removes the tongue from the neck; by an incision taken from near the lobe of the ear, down the anterior border of the Sermo-mastoid to the level of the great cornu of the hyoid bone, then forward to the body of the hyoid bone, and upward to near the symphysis of the jaw. The lingual artery is now secured and by a careful dissection the submaxillary lymphatic glands and the tongue removed. Regnoli advocated the removal of the tongue by a semilunar incision in the submaxillary triangle along the line of the lower jaw, and a vertical incision from the centre of the semilunar one backward to the hyoid bone. Care must be taken not to carry the first incision too far backward, so as to wound the facial arteries. The tongue is thus reached through the floor of the mouth pulled out through the external incision, and removed with the knife. The great objection to this operation is that all the muscles which raise the hyoid bone and larynx are divided, and that therefore the movements of deglutition and respiration are interfered with.

Finally, where both sides of the floor of the mouth are involved in the disease, or where very free access is required on account of the extension backward of the disease to the pillars of the fauces and the tonsil, or where the lower jaw is involved, the operation recommended by Syme must be performed. This is done by an incision through the central line of the lip, across the chin, and down as far as the hyoid bone. The lower jaw is sawed through at the symphysis, and the two halves of the bone forcibly separated from each other. The mucous membrane is separated from the bone, and the Genio-hyo-glossi detached from the bone, and the Hyo-glossi divided. The tongue is then drawn forward and removed close to its attachment to the hyoid bone. Adjacent lymph glands can be removed and if the bone is implicated in the disease, it can also be removed by freeing it from the soft parts externally and internally, and making a second section with the saw beyond the diseased part.

Formerly many surgeons before removing the tongue performed a preliminary tracheotomy: (1) to prevent blood entering the air-passages; and (2) to allow the patient to breathe through the tube and not inspire air which had passed over a sloughy wound, and which was loaded with septic organisms and likely to induce septic pneumonia. By operating with the patient in the Trendelenburg position, the blood is caused to flow away from the air-passages. By the judicious use of iodoform the evil mentioned secondly may be obviated, and the preliminary tracheotomy is now usually dispensed with.

THE NOSE.

The nose is the peripheral portion of the organ of smell (organum olfactorius): by means of the peculiar properties of its nerves it protects the lungs from the inhalation of deleterious gases and assists the organ of taste in discriminating the properties of food. The organ of smell consists of two parts; one external, the outer nose; the other internal, the nasal fossae.
THE OUTER NOSE (NASUS EXTERNUS).

The outer nose is the more anterior and prominent part of the organ of smell. Of a triangular form, it is directed downward, and projects from the centre of the face, immediately above the upper lip. Its summit or root (radix nasi) is connected directly with the forehead. Its inferior part or base (basis nasi) presents two elliptical orifices, the nostrils or anterior nares (nares), separated from each other by an antero-posterior septum, the mobile septum or columna nasi (septum mobile nasi). The margins of the nostrils are provided with a number of stiff hairs or vibrissae, which arrest the passage of foreign substances carried with the current of air intended for respiration. The point (apex nasi) is the free extremity of the nose. The lateral surfaces of the nose form, by their union in the middle line, the dorsum (dorsum nasi), the direction of which varies considerably in different individuals. The portion of the dorsum over the nasal bones is the bridge. Each lateral surface terminates below in a rounded eminence, the wing or ala nasi, which, by its lower margin (margo nasi), forms the outer boundary of the corresponding nostril. Above the ala is a depression, the alar sulcus.

Structure.—The nose is composed of a framework of bones and cartilages, the latter being slightly acted upon by certain muscles. It is covered externally by the integument, internally by mucous membrane, and is supplied with vessels and nerves.

The Bony Framework.—The bony framework occupies the upper part of the organ; it consists of the nasal bones and the nasal processes of the superior maxillary bones (pp. 104 and 109).

The Cartilaginous Framework (cartilagines nasi) (Figs. 719 and 720).—The cartilaginous framework consists of five pieces, the two upper and the two lower lateral cartilages and the cartilage of the septum.

The Upper Lateral Cartilage (cartilago nasi lateralis) of each side is situated below the free margin of the nasal bone. It is flattened and triangular in shape. Its anterior margin is thicker than the posterior, and continuous with the cartilage of the septum. Its posterior margin is attached to the nasal process of the superior maxillary and nasal bones. Its inferior margin is connected by fibrous tissue with the lower lateral cartilage; one surface is turned outward, the other inward toward the nasal cavity.
The Lower Lateral Cartilage, the Cartilage of the Aperture or the Greater Alar Cartilage (cartilago alaris major) of each side consists of two thin, flexible plates situated immediately below the preceding, and bent upon themselves in such a manner as to form the inner and outer walls of the orifice of the nostril. The portion which forms the inner wall (crus mediale), thicker than the rest, is loosely connected with the corresponding portion of the opposite cartilage, and forms a small part of the column. Its inferior border, free, rounded, and projecting, forms, with the thickened integument and subjacent tissue and the corresponding parts of the opposite side, the mobile septum. The part of the cartilage which forms the outer wall (crus laterale) is curved to correspond with the ala of the nose; it is oval and flattened, narrow behind, where it is connected with the nasal process of the superior maxilla by a tough fibrous membrane, in which are found three or four small cartilaginous plates, the sesamoid, accessory quadrate or lesser alar cartilages (cartilagines alares minores). Above, it is connected by fibrous tissue to the upper lateral cartilage and front part of the cartilage of the septum; below, it falls short of the margin of the nostril; the ala being formed by dense cellular tissue covered by skin. In front the lower lateral cartilages are separated by a notch which corresponds with the point of the nose.

The Triangular Cartilage of the Septum (cartilago septi nasi) (Figs. 719 and 721) is somewhat quadrilateral in form, thicker at its margins than at its centre, and completes the separation between the nasal fossae in front. Its anterior margin, thickest above, is connected with the nasal bones, and is continuous with the anterior margins of the two upper lateral cartilages. Below, it is connected to the inner portions of the lower lateral cartilages by fibrous tissue. Its posterior margin is connected with the perpendicular lamella of the ethmoid; its inferior margin with the vomer and the palate processes of the superior maxillary bones (Fig. 103).

It may be prolonged backward (especially in children) for some distance between the vomer and perpendicular plate of the ethmoid, forming what is termed the sphenoidal process (processus sphenoidalis septi cartilaginis). The septal cartilage does not reach as far as the lowest part of the nasal septum. This is formed by the inner portions of the lower lateral cartilages and by the skin; it is freely movable, and hence is termed the mobile septum.

Along the lower margin of the anterior half of the cartilage of the septum is another cartilage which is attached to the vomer and is known as the vomerine cartilage or cartilage of Jacobson (cartilago vomeronasalis).

These various cartilages are connected to each other and to the bones by a tough fibrous membrane, which allows the utmost facility of movement between them.

The Muscles of the Nose.—The muscles of the nose are situated beneath the integument; they are (on each side) the Pyramidalis nasi, the Levator labii superiores alacque nasi, the Dilatator naris, anterior and posterior, the Compressor nasi, the Compressor narium minor, and the Depressor alac nasi. They have been previously described (p. 378).

The Integument covering the dorsum and sides of the nose is thin, and loosely connected with the subjacent parts; but the integument of the tip and the alae of
the nose is thicker and more firmly adherent, and is furnished with a large number of sebaceous follicles, the orifices of which are usually very distinct.

The **Mucous Membrane** lining the interior of the nose is continuous with the skin externally and with the mucous membrane which lines the nasal fossae within.

The **Arteries of the Outer Nose**.—The arteries of the nose are the *lateralis nasi from the facial*, and the *inferior artery of the septum from the superior coronary*, which supply the alae and septum, the sides and dorsum being supplied from the *nasal branch of the ophthalmic* and the *infraorbital*.

The **Veins of the Outer Nose**.—The veins of the nose terminate in the *facial* and *ophthalmic*.

The **Lymphatics of the Outer Nose**.—These vessels are shown in Figs. 486, 488, and 489. They empty chiefly into the *submaxillary lymph glands*.

The **Nerves of the Outer Nose**.—The nerves for the muscles of the nose are derived from the *facial*, while the skin receives its branches from the *infraorbital, infra-trochlear*, and nasal branches of the *ophthalmic*.

**THE NASAL FOSSAE (CAVUM NASI).**

The nasal fossae are two irregular cavities situated in the middle of the face, one on each side of the middle line, and extending from before backward. They open in front, when the soft parts are in place, by the two *nostrils* or anterior nares, and terminate, behind, in the naso-pharynx by the *posterior nares*.

![Diagram of the nasal fossae](image)

The **Anterior Nares** (*nares*).—The anterior nares are somewhat pear-shaped apertures, each measuring about one inch antero-posteriorly and half an inch transversely at their widest part. The nasal fossae in the dry skull open in front by the anterior nasal aperture (*apertura pyriformis*).

The **Posterior Nares** (*choanae*).—The posterior nares are two oval openings, which are smaller in the living or recent subject than in the skeleton, because they
are narrowed by the mucous membrane. Each measures an inch in the vertical and half an inch in the transverse direction in a well-developed adult skull.

For the description of the bony boundaries of the nasal fossae see section on Osteology (p. 143).

Inside the aperture of the nostril is a slight dilatation, the vestibule (vestibulum nasi), which extends as a small pouch, the ventricle, toward the point of the nose. Above and behind the vestibule is surrounded by a prominence (limen nasi). Below the prominence the vestibule is lined with skin; above and behind it the fossa is lined with mucous membrane. The fossa, above and behind the vestibule, has been divided into two parts: an olfactory portion (regio olfactoria), a slit-like cavity, comprising the upper and central part of the septum and probably the superior turbinated bone, and a respiratory portion (regio respiratoria), which comprises the rest of the fossa.

Outer Wall (Figs. 722 and 723).—The superior, middle, and inferior meatus (meatus nasi superior, medius, and inferior) are described on pages 144 and 145. The sphenoidal air sinus opens into the sphenoethmoidal recess (recessus sphenoethmoidalis), a narrow recess above the superior turbinated bone (Fig. 722). The posterior ethmoidal cells (cellula ethmoidalis posterior) open into the front and upper part of the superior meatus (Fig. 722). On raising or cutting away the middle turbinated bone the outer wall of the middle meatus is fully exposed (Figs. 722 and 723) and presents: (1) a rounded elevation, termed the bulla ethmoidalis, opening on or immediately above which are the orifices of the middle ethmoidal cells; (2) a
deep, narrow, curved groove, in front of the bulla ethmoidalis, termed the **hiatus semilunaris**, into which the **anterior ethmoidal cells** (*cellula ethmoidalis anterior*) and the **antrum of Highmore** (*sinus maxillaris*) open, the orifice of the latter being placed near the level of its roof. The middle meatus is prolonged, above and in front, into the **infundibulum** (*infundibulum ethmoidale*), which leads into the **frontal sinus** (*sinus frontalis*). The anterior extremity of the meatus is continued into a depressed area which lies above the vestibule and is named the **atrium** (*atrium meatus medii nasi*). The **nasal duct** (*ductus nasalis*) opens into the anterior part of the inferior meatus, the opening being frequently overlapped by a fold of mucous membrane, and from the orifice of the duct a groove leads downward and forward.

**The Inner Wall** (Fig. 723).—The inner wall or septum is frequently more or less deflected from the mesal plane (Figs. 101 and 723), thus limiting the size of one fossa and increasing that of the other. **Ridges** or **spurs of bone** growing outward from the septum are also sometimes present. Immediately over the incisive foramen at the lower edge of the cartilage of the septum a depression, the **nasopalatine recess** (*recessus nasopalatinus*), may be seen. In the septum close to this recess a minute orifice may be discerned; it leads into a blind pouch, the **rudimentary organ of Jacobson** (*organum vomeronasale*), which is well developed in some of the lower animals, but is rudimentary in man. The organ is supported by a plate of cartilage, distinct from the cartilage of the septum, the **cartilage of Jacobson** (p. 1107). The cartilage of Jacobson is to the outer side of the lower edge of the cartilage of the septum. The diverticulum opens anteriorly near the floor of the nose and close by Stenson’s foramen. Just below the opening of the blind pouch is an elevation, the **eminence of Jacobson**.

**The Mucous Membrane** (*membrana mucosa nasi*).—The mucous membrane lining the nasal fossae is called the **pituitary**, from the nature of its secretion; or **Schneiderian**, from Schneider, the first anatomist who showed that the secretion proceeded from the mucous membrane, and not, as was formerly imagined, from the brain. It is intimately adherent to the periosteum or perichondrium, over which it lies. It is continuous externally with the skin through the anterior nares, and with the mucous membrane of the naso-pharynx through the posterior nares. From the nasal fossae its continuity may be traced with the conjunctiva through the nasal duct and lachrymal canals; with the lining membrane of the tympanum and mastoid cells through the Eustachian tube; and with the frontal, ethmoidal, and sphenoidal sinuses, and the antrum of Highmore through the several openings in the meatuses. The mucous membrane is thickest and most vascular over the turbinated bones. It is also thick over the septum, but in the intervals between the spongy bones and on the floor of the nasal fossae it is very thin. Where it lines the various sinuses and the antrum of Highmore it is thin and pale.

Owing to the great thickness of this membrane, the nasal fossae are much narrower, and the turbinated bones, especially the lower ones, appear larger and more prominent than in the skeleton. From the same circumstances also the various apertures communicating with the meatuses are considerably narrowed or completely closed. The vestibule is lined by modified skin, and contains hairs (**vibrissae**) which guard the entrance of the nostril.

**Structure of the Mucous Membrane** (Fig. 724).—The epithelium covering the mucous membrane differs in its character according to the functions of the part of the nose in which it is found. In the respiratory portion of the nasal cavity the epithelium is columnar and ciliated. Interspersed among the columnar ciliated cells are goblet or mucin cells, while between their bases are found smaller pyramidal cells. In this region, beneath the epithelium and its basement membrane, is a fibrous layer infiltrated with lymph-corpuscles, so as to form in many parts
a diffuse adenoid tissue, which is particularly plentiful in children, and beneath this a nearly continuous layer of smaller and larger glands, some mucous and some serous, the ducts of which open upon the surface. In the respiratory portion of the mucous membrane there is an extensive anastomosing plexus of veins, which in some regions forms a distinct cavernous tissue (plexus cavernosus concharium). The cavernous tissue is particularly distinct over the inferior turbinated bones. In the olfactory region the mucous membrane is yellowish in color and the epithelial cells are columnar and non-ciliated; they are of two kinds, supporting cells and olfactory cells.

The Supporting Cells contain oval nuclei, situated in the deeper parts of the cells; the free surface of each cell presents a sharp outline, and its deep extremity is prolonged into a process which runs inward, branching to communicate with similar processes from neighboring cells, so as to form a network in the deep part of the mucous membrane. Lying between these central processes of the supporting cells are a large number of spindle-shaped cells, the olfactory cells, which consist of a large spherical nucleus surrounded by a small amount of granular protoplasm, and possessing two processes, of which one runs outward between the columnar epithelial cells, and projects on the surface of the mucous membrane as a fine, hair-like process, the olfactory hair; the other or deep process runs inward, is frequently beaded like a nerve-fibre, and is believed by most observers to be in connection with one of the terminal filament of the olfactory nerve. Beneath the epithelium, extending through the thickness of the mucous membrane, is a layer of tubular, often branched, glands, the glands of Bowman (glandulae olfactoriae), identical in structure with serous glands.

The Arteries of the Nasal Fossae.—The arteries of the nasal fossae are the anterior and posterior ethmoidal, from the ophthalmic, which supply the ethmoidal cells, frontal sinuses, and roof of the nose; the sphenopalatine, from the internal maxillary, which supplies the mucous membrane covering the spongy bones, the meatuses, and septum; the inferior artery of the septum, from the superior coronary of the facial; and the infraorbital and alveolar branches of the internal maxillary, which supply the lining membrane of the antrum. The ramifications of these vessels form a close, plexiform network, beneath and in the substance of the mucous membrane.

The Veins of the Nasal Fossae.—The veins of the nasal fossae form a close, cavernous-like network beneath the mucous membrane. This cavernous appearance

![Diagram of the olfactory mucous membrane](image-url)
is especially well marked over the lower part of the septum and over the middle and inferior turbinated bones. Some of the veins pass, with those accompanying the sphenopalatine artery, through the sphenopalatine foramen; and others, through the alveolar branch, to join the facial vein; some accompany the ethmoidal arteries, and terminate in the ophthalmic vein; and, lastly, a few communicate with the veins in the interior of the skull, through the foramina in the cribiform plate of the ethmoid bone, and the foramen caecum.

The Lymphatics of the Nasal Fossae.—The lymphatics can be injected from the subdural and subarachnoid spaces, and form a plexus in the superficial portion of the mucous membrane. The lymph is drained partly into one or two glands which lie near the great cornu of the hyoid bone and partly into a gland situated in front of the axis.

The Nerves of the Nasal Fossae.—The nerves are: the olfactory, the nasal branch of the ophthalmic, filaments from the anterior dental branch of the superior maxillary, the Vidian, the naso-palatine, descending anterior palatine, and nasal branches of Meckel's ganglion. The olfactory, the special nerve of the sense of smell, is distributed to the olfactory region, and has been already referred to (p. 1019). The nasal branch of the ophthalmic division of the trigeminal nerve distributes filaments to the floor of the septum and outer wall of the nasal fossae. Filaments from the anterior dental branch of the superior maxillary supply the inferior meatus and inferior turbinated bone. The Vidian nerve supplies the upper and back part of the septum and superior spongy bone, and the upper anterior nasal branches from the sphenopalatine ganglion have a similar distribution. The naso-palatine nerve supplies the middle of the septum. The larger or anterior palatine nerve supplies the lower nasal branches to the middle and lower spongy bones.

Surgical Anatomy.—Instances of congenital deformity of the nose are occasionally met with, such as complete absence of the nose, an aperture only being present; or perfect development on one side, and suppression or malformation on the other; or there may be imperfect apposition of the nasal bones, so that the nose presents a median cleft or furrow. Deformities which have been acquired are much more common, such as flattening of the nose (saddle nose), the result of syphilitic necrosis, imperfect development of the nasal bones in cases of congenital syphilis, or a lateral deviation of the nose the result of fracture.

The skin over the alae and tip of the nose is thick and closely adherent to subjacent parts. Inflammation of this part is therefore very painful, on account of the tension. The skin is largely supplied with blood, and, the circulation here being terminal, vascular engorgement is liable to occur, especially in women at the menopause and in both sexes from disorders of digestion, exposure to cold, etc. The skin of the nose also contains a large number of sebaceous follices, and these, as a result of intemperance, are apt to become affected, and the nose becomes reddened, congested, and irregularly swollen. To this condition the term gorg-blossom is popularly applied. In some of these cases there is enormous hypertrophy of the skin and subcutaneous tissues, producing pendulous masses, termed lipomata nasi. Ordinary epithelioma and rodent ulcer may attack the nose, the latter being the more common of the two. Lupus and syphilitic ulceration frequently attack the nose, and may destroy the whole of the cartilaginous portion. In fact, lupus vulgaris begins more frequently on the ala of the nose than in any other situation.

Cases of congenital occlusion of one or both nostrils, or adhesion between the ala and septum may occur, and may require immediate operation, since the obstruction much interferes with sucking. Bone closure of the posterior nares may also occur.

To examine the nasal cavities, the head should be thrown back and the nose drawn upward, the parts being dilated by some form of speculum. They can also be examined with the little finger or a probe, and in this way foreign bodies detected. A still more extensive examination can be made by Roux's operation, which was introduced for the cure of osseum. This operation enables the surgeon to remove any dead bone which may be present in this disease. The cartilaginous framework of the nose is lifted up by an incision made inside the mouth, through the junction of the upper lip with the bone; the septum nasi and the lateral cartilages are divided with strong scissors till the anterior nares are completely exposed. The posterior nares can be explored by the aid of reflected light from the mouth, by which the posterior nares can be illuminated. The examination is very difficult to carry out, and, as a rule, sufficient information regarding the
presence of foreign bodies or tumors in the naso-pharynx can be obtained by the introduction of the finger behind the soft palate through the mouth. The septum of the nose may be displaced or deviate from the middle line; this may be the result of an injury or from some congenital defect in its development; in the latter case the deviation usually occurs along the line of union of the vomer and mesethmoid, and rarely occurs before the seventh year. Sometimes the deviation may be so great that the septum may come in contact with the outer wall of the naso fossa, and may even become adherent to it, thus producing complete obstruction. Perforation of the septum is not an uncommon affection and may arise from several causes; syphilitic or tuberculous ulceration, blood-tumor or abscess of the septum, and especially in workmen exposed to the vapor of bichromate of potash, from the irritating and corrosive action of fumes. When small, the perforation may cause a peculiar whistling sound during respiration. When large, it may lead to the falling in of the bridge of the nose.

Epistaxis is a very common affection in children. It is rarely of much consequence, and will almost always subside, but in the more violent hemorrhages of later life it may be necessary to plug the posterior nares. In performing this operation it is desirable to remember the size of the posterior nares. A ready method of regulating the size of the plug to fit the opening is to make it of the same size as the terminal phalanx of the thumb of the patient to be operated on.

Nasal polypus is a very common disease, and presents itself in three forms: the gelatinous, the fibrous, and the malignant. The first is by far the most common. It grows from the mucous membrane of the outer wall of the naso fossa, where there is an abundant layer of highly vascular submucous tissue; rarely from the septum, where the mucous membrane is closely adherent to the cartilage and bone, without the intervention of much, if any, submucous tissue. The most common seat of gelatinous polyps is probably the middle turbinate bone. The fibrous polypus generally grows from the base of the skull behind the posterior nares or from the roof of the naso fossae. The malignant polypi, both sarcomatous and carcinomatous, may arise in the nasal cavities and the naso-pharynx; or they may originate in the antrum, and protrude through its inner wall into the naso fossa.

Rhinoliths or nose-stones may sometimes be found in the nasal cavities. They arise from the deposition of phosphate of lime upon either a foreign body or a piece of inspissated secretion. The nasal passages furnish a secretion of their own and receive secretion from other parts (tears and secretions of the accessory sinuses). The nasal cavities contain the ethmoidal labyrinth, the lateral masses of the ethmoid (which form the superior and middle turbinate bones), and the inferior turbinate bones. The nasal cavity is surrounded by three pairs of pneumatic spaces, the accessory sinuses, which are the maxillary sinuses, the frontal sinuses, and the cells of the ethmoidal labyrinth. The lachrymal duct opens into the inferior meatus. Inflammation of the air-cells may follow inflammation of the nasal mucous membrane or bone disease. One set of cells or many may suffer. Suppuration may occur. Pus may be blocked up and retained. Dead bone may form. The most serious conditions may follow (abscess of brain, sinus thrombosis, septicaemia), and an operation is necessary to obtain relief.

THE EYE.

The eyeball or globe (bulbus oculi) (Figs. 725 and 729) is contained in the anterior part of the cavity of the orbit. In this situation it is securely protected from injury, whilst its position is such as to ensure the most extensive range of sight. It is acted upon by numerous muscles, by which it is capable of being directed to different parts; it is supplied by vessels and nerves, and is additionally protected in front by the orbital margins, eyelids, etc.

The eyeball is embedded in the fat of the orbit, but is partly surrounded by a thin membranous sac, the capsule of Ténon, which isolates it, so as to allow of free movement.

The Fascia or Capsule of Ténon (fascia bulbi [Tenoni]) (Figs. 725 and 726).—The fascia or capsule of Ténon consists of a thin membrane which envelopes the eyeball from the optic nerve to the ciliary region, separating it from the orbital fat and forming a socket in which it plays. Its inner surface is smooth, and is in contact with the outer surface of the sclerotic, the perisclerotic or suprasceral lymph-space only intervening. This lymph-space is continuous with the subdural and subarachnoid spaces, and is traversed by delicate bands of con-
The right eye in sagittal section, showing the capsule of Ténon (semidiagrammatic). (Testut.)

The capsule of Ténon forms a flexible pocket, in which the globe rotates. The capsule is perforated behind by the ciliary vessels and nerves and by the optic nerve, being continuous with the sheath of the latter. In front it blends with the ocular conjunctiva, and with it is attached to the ciliary region of the eyeball. It is perforated by the muscles which move the eyeball and on to each muscle it sends a tubular sheath. The sheath of the Superior oblique is carried as far as the fibrous pulley of that muscle; that on the inferior oblique reaches as far as the floor of the orbit, to which it gives off a slip. The sheaths on the recti are gradually lost in the perimysium, but they give off important expansions. The expansion from the Superior rectus blends with the tendon of the Levator palpebrae; that of the Inferior rectus is attached to the inferior tarsal plate. These two recti, therefore, will exercise some influence on the movements of the eyelids. The expansions
from the sheaths of the Internal and External recti are strong, especially the one from the latter muscle, and are attached to the lachrymal and malar bones respectively. As they probably check the action of these two recti, they have been named the internal and external check ligaments.

Lockwood has also described a thickening of the lower part of the capsule of Ténon, which he has named the suspensory ligament of the eye. It is slung like a hammock below the eyeball, being expanded in the centre and narrow at its extremities, which are attached to the malar and lachrymal bones respectively.¹

The anterior one-third of the globe is covered by the conjunctiva, or mucous membrane, reflected from the inner surfaces of the lids (Fig. 728). A lateral view of the globe shows that it is composed of segments of two spheres of different sizes (Figs. 725, 727, 728, and 729). The anterior segment is one of a small sphere, and forms about one-sixth of the eyeball. It is more prominent than the posterior segment, which is one of a much larger sphere, and forms about five-sixths of the globe. The segment of the larger sphere is opaque, and formed by the sclerotic, the tunic of protection to the eyeball; the smaller sphere is transparent, and formed by the cornea. Between the small, anterior or corneal segment, and the large, posterior or scleral segment, is a shallow and narrow groove, the scleral sulcus (sulcus sclerae). The anterior pole is the centre of the anterior portion of the cornea. The posterior pole is the centre of the posterior portion of the sclerotic. A straight line joining these two poles is the sagittal or optic axis (axis optica) (Fig. 727). A line drawn around the eyeball equally distant at all points from the two poles is called the

equatorial diameter or the equator (Fig. 727). The plane of the equator divides the globe in an anterior and a posterior hemisphere. Meridians may be drawn from one pole to the other at right angles to the equator. The visual axis (linea visus) (Fig. 727) passes in a straight line from the first nodal point on the cornea to the fovea centralis of the yellow spot on the retina. A nodal point is the point of intersection of convergent rays with the visual axis. The first nodal point is 6.9685 mm.

Fig. 728.—Diagram of a horizontal section of the right eye, showing the upper surface of the lower segment. (Testut.)

behind the summit of the cornea. The axes of the eyeballs are nearly parallel, and therefore do not correspond to the axes of the orbits, which are directed outward. The optic nerves follow the direction of the axes of the orbits, and are therefore not parallel; each nerve enters its eyeball about 1 mm. below and 3 mm. to the inner or nasal side of the posterior pole (Fig. 727). The eyeball measures rather more in its transverse and antero-posterior diameters than in its vertical diameter, the former amounting to nearly an inch, the latter to about nine-tenths of an inch. The diameters in the female are somewhat less than in the male.

The eyeball is composed of three investing tunics and of three refracting media.
THE TUNICS OF THE EYE.

From without inward the three tunics are:

I. Sclerotic Coat and Cornea.
II. Choroid, Ciliary Body, and Iris.
III. Retina.

I. The Fibrous or External Coat: The Sclerotic and Cornea
(Tunica Fibrosa Oculi).

The sclerotic and cornea (Figs. 727, 728, and 729) form the external tunic of the eyeball; they are essentially fibrous in structure, the sclerotic being opaque, and forming the posterior five-sixths of the globe; the cornea, which forms the remaining sixth, being transparent.

The Sclera or Sclerotic Coat (σκλέρος, hard).—The sclera or sclerotic coat has received its name from its extreme density and hardness; it is a firm, unyielding, opaque, fibrous membrane, forming the posterior five-sixths of the outer coat and serving to maintain the form of the globe. It is much thicker behind than in front. Its external surface is of a white color, and is in contact with the inner surface of the capsule of Ténon, a lymph-space intervening; it is quite smooth, except one-quarter of an inch back of the sclero-corneal junction, at the points where the Recti and Obliqui muscles are inserted into it, and its anterior part is covered by the conjunctival membrane (Fig. 757); hence the whiteness and brilliancy of the front of the eyeball. Its inner surface is stained a brown color, marked by grooves, in which are lodged the ciliary nerves and vessels (Figs. 732, 737, and 738); the inner surface of the sclera is loosely connected by three layers of exceed-
ingly fine cellular pigmented tissue (lamina fusca) with the outer surface of the choroid, an extensive lymph-space, the perichoroidal space (spatium perichorioideale) (Figs. 740 and 757) intervening between the sclerotic and choroid. Behind, the sclera is pierced by the optic nerve (n. opticus), and is continuous with the fibrous sheath of the nerve, which is derived from the dura (Fig. 734). At the point where the optic nerve passes through the sclerotic, the lamina fusca is represented by an arrangement of the fibrous tissue which forms a thin network, the cribiform lamina (lamina cribrosa sclerae) (Fig. 744); the minute orifices in this network serve for the transmission of separate bundles of nervous filaments, and the fibrous septa dividing them from one another are continuous with the membranous processes which separate the bundles of nerve-fibres. One of these openings (porus opticus), larger than the rest, occupies the centre of the lamella; it transmits the arteria centralis retinæ to the interior of the eyeball (Fig. 744). Around the cribiform lamella are numerous small apertures for the transmission of the ciliary nerves and the short ciliary arteries, and about midway between the margin of the cornea and the entrance of the optic nerve are four or five large apertures, for the transmission of veins (venae vorticosae) (Fig. 757). In front, the fibrous tissue of the sclerotic is continuous with the substantia propria of the cornea by direct continuity of tissue (Fig. 757), but the opaque sclerotic slightly overlaps the outer surface of the transparent cornea. In the depths of the line of junction between the cornea and the sclera there is a circular canal, the canal of Schlemm (sinus venosus sclerae) (Figs. 729, 736, 740, and 757). This canal receives the sclera veins (Fig. 736) and communicates internally by numerous minute openings in the pectineal ligament of the iris (Fig. 757) with the anterior chamber of the eyeball. These openings are the spaces of Fontana (Fig. 740).

Structure.—The sclerotic is formed of white fibrous tissue intermixed with fine elastic fibres, and of flattened connective-tissue corpuscles, some of which are pigmented, contained in cell-spaces between the fibres (Figs. 733 and 744). These fibres are aggregated into bundles, some of which are arranged in layers having an equatorial direction, but most of which are arranged in layers lying in meridian lines. The sclera is joined to the choroid by three thin layers of loose connective tissue containing pigment cells, the lamina fusca (lamina fasciae sclerae) (Fig. 737). Where the optic nerve passes through the sclera there is a very thin network to represent the lamina fusca. This network is the lamina cribrosa (Fig. 744). The muscles of the eyeball are attached to the sclera (Figs. 728, 729, and 757), and their tendons enter among the bundles of fibrous connective tissue. The conjunctiva covers the anterior portion of the sclera and is attached to it by submucous tissue (Figs. 728 and 740). The sclera yields gelatin on boiling. Its vessels (Figs. 734 and 736) are not numerous, the capillaries being of small size and uniting at long and wide intervals. It obtains arterial blood from the short posterior ciliary and the anterior ciliary arteries. The venous blood is removed by the venae vorticosae and the anterior ciliary veins. There are lymph-spaces between the cells which empty into the periscleral (Fig. 725 and p. 1114) and perichoroidal lymph-spaces (Fig. 740). Its nerves are derived from the ciliary nerves (Fig. 732). They lose their medullary sheaths and enter among the bundles of fibrous tissue, but it is not known how they terminate.

The Cornea (Figs. 725, 728, and 734).—The cornea is the projecting transparent part of the external tunic of the eyeball, and forms the anterior sixth of the globe. It is almost, but not quite, circular in shape, occasionally a little broader in the transverse than in the vertical direction. It is convex anteriorly, and projects forward from the sclerotic in the same manner that a watch-glass does from the case. Its degree of curvature varies in different individuals, and in the same individual at different periods of life, it being more prominent in youth than in advanced life, when it becomes flattened. Usually the curvature is slightly greater in the vertical plane than in the horizontal plane; at its centre than at its periphery, and at its temporal than at its nasal side. The cornea is dense and of uniform thickness throughout;
its posterior surface is perfectly circular in outline, and exceeds the anterior surface slightly in extent, from the latter being overlapped by the sclerotic. The antérieur surface is covered with conjunctiva (Fig. 740).

**Structure** (Fig. 730).—The cornea consists of five layers—namely: (1) the anterior or epithelial layer; (2) the anterior elastic layer; (3) the substantia propria; (4) the posterior elastic layer; (5) the posterior or endothelial layer.

(1) The **Anterior Layer** (*epithelium corneae*) is composed of stratified epithelium and is continuous with the cells of the conjunctiva at the borders of the cornea. There are from five to eight strata of nucleated cells in the anterior layer. The deepest cells are columnar. Above the columnar cells are several layers of polygonal cells, most of which have finger-like processes and are called **prickle cells**. At the surface the cells and nuclei become flat. The anterior epithelial layer prevents the absorption of the fluid of the tears.

(2) The **Anterior Elastic** or **Anterior Limiting Layer** or **Bowman's Membrane** (*lamina elastica anterior*) is less than half the thickness of the layer of stratified epithelium.
It differs in some essential respects from true elastic tissue. It shows evidences of fibrillar structure, and does not have a tendency to curl inward or to undergo fracture when detached from the other layers of the cornea. It consists of extremely close interwoven fibrils, similar to those found in the rest of the cornea proper, but contains no corneal corpuscles. It ought, therefore, to be regarded as a part of the proper tissue of the cornea.

(3) The Substantia Propria or proper substance of the cornea forms the main thickness of that structure. It is fibrous, tough, unyielding, perfectly transparent, and continuous with the sclerotic. It is composed of about sixty flattened lamellae, superimposed one on another. These lamellae are made up of bundles of modified connective tissue, the fibres of which are directly continuous with the fibres of the sclerotic. The fibres of each lamella are for the most part parallel with each other; those of alternating lamellae at right angles to each other. Fibres, however, frequently pass obliquely from one lamella to the next (fibrae arcuatae).

The lamellae are connected with each other by an interstitial cement-substance, in which are spaces, the corneal spaces, cell spaces or lacunae (Fig. 731). The spaces are stellate in shape, and have numerous offsets or canaliculi (Fig. 731), by which they communicate with each other. Each space contains a cell, the corneal corpuscle (Fig. 731), which resembles in form the space in which it is lodged, but it does not entirely fill it, the remainder of the space containing lymph. In the aged the margin of the cornea becomes opaque gray. This rim is called the arcus senilis, and is due to fat deposit in the lamellae and corneal corpuscles.

(4) The Posterior Elastic Lamina, the Membrane of Descemet, or the Membrane of Demours (lamina elastica posterior), which covers the proper structure of the cornea behind, presents no structure recognizable under the microscope. It consists of an elastic, and perfectly transparent homogeneous membrane, of extreme thinness, which is not rendered opaque by either water, alcohol, or acids. It is very brittle, but its most remarkable property is its extreme elasticity, and the tendency which it presents to curl up, or roll upon itself, with the attached surface innermost, when separated from the proper substance of the cornea. Its use appears to be (as suggested by Dr. Jacob) "to preserve the requisite permanent correct curvature of the flaccid cornea proper."

At the margin of the cornea this posterior elastic membrane breaks up into fibres to form a reticular structure at the outer angle of the anterior chamber, the intervals between the fibres forming small cavernous spaces, the spaces of Fontana (spatia

---

Fig. 731.—From a horizontal section of an ox's cornea. Positive picture of the canal system demonstrated by the gold chloride method. X 450. (Szymonowicz.)
anguli iridis) (Fig. 740). These little recesses communicate with a circular canal in the deeper parts of the corneo-scleral junction. This is the canal of Schlemm (Figs. 729, 736, and 740); it communicates internally with the anterior chamber through the spaces of Fontana, and externally with the scleral veins. Some of the fibres of this reticulated structure are continued into the front of the iris, forming the ligamentum pectinatum iridis; while others are connected with the forepart of the sclerotic and choroid.

(5) The Posterior Layer or the Corneal Endothelium (endothelium camerae anterioris) lines the aqueous chamber and prevents the absorption of the aqueous humor. It covers the posterior surface of the elastic lamina, is reflected on to the front of the iris, and also lines the spaces of Fontana. It consists of a single layer of polygonal flattened transparent nucleated cells, similar to those lining other serous cavities.

Arteries and Nerves.—The foetal cornea contains blood-vessels which pass from the margin almost to the centre. The adult cornea contains no blood-vessels, except at its margin. The capillaries from the sclera and conjunctiva form loops at the corneal margin, and many of these loops enter the cornea for a distance of 1 mm. (Fig. 736). The balance of the cornea is non-vascular and obtains its nourishment from the lymph in the lacunae and canaliculi. Lymphatic vessels have not as yet been demonstrated in it, but are represented by the channels in which the bundles of nerves run; these channels are lined by endothelium and are continuous with the cell-spaces. The nerves are numerous, twenty-four to thirty-six in number (Köllicker), forty to forty-five (Waldeyer and Stümisch); they are derived from the ciliary nerves; they form the annular plexus (plexus annularis), at the corneal margin, and enter the laminated tissue of the cornea, lose their medullary sheaths, and ramify throughout the substantia propria as the fundamental plexus or the plexus of the stroma. From this deep plexus come perforating fibres (fibræ perforantes), which pass through the anterior elastic lamina and form the subepithelial plexus, and from it fibrils are given off which ramify between the epithelial cells, forming a network which is termed the intra-epithelial plexus. Nerve-fibres from the annular plexus and from the plexus of the stroma come into close relation with the corneal corpuscles.

Dissection.—In order to separate the sclerotic and cornea, so as to expose the second tunic, the eyeball should be immersed in a small vessel of water and held between the finger and thumb. The sclerotic is then carefully incised, in the equator of the globe, till the choroid is exposed. One blade of a pair of probe-pointed scissors is now introduced through the opening thus made, and the sclerotic divided around its entire circumference, and removed in separate portions. The front segment being then drawn forward, the handle of the scalpel should be pressed gently against it at its connection with the iris, and, these being separated, a quantity of perfectly transparent fluid will escape; this is the aqueous humor. In the course of the dissection the ciliary nerves (Fig. 732) may be seen lying in the loose cellular tissue between the choroid and sclerotic or continued in delicate grooves on the inner surface of the latter membrane.

II. The Choroid, Ciliary Body, and Iris, the Tunica Media, the Uveal Tract (Tunica Vasculosa Oculi) (Figs. 727, 729, 732, 737, 757).

The second or middle tunic of the eye is formed from behind forward by the choroid, the ciliary body, and the iris.

The choroid is the vascular and pigmentary tunic of the eyeball, investing the posterior five-sixths of the globe, and extending as far forward as the ora serrata of the retina; the ciliary body connects the choroid to the circumference of the iris. The iris is the circular muscular septum, which hangs vertically behind the cornea, presenting in its centre a large rounded aperture, the pupil.

The Choroid (chorioides).—The choroid is a thin, highly vascular membrane, of a dark-brown or chocolate color, which invests the posterior five-sixths of the
THE ORGANS OF SPECIAL SENSE

globe, and is pierced behind by the optic nerve, and in this situation is firmly adherent to the sclerotic. It is thicker behind than in front. Externally, it is loosely connected by the lamina fusca with the inner surface of the sclerotic (p. 1118). Its inner surface is attached to the retina.

**Structure** (Fig. 733).—The choroid consists of a dense capillary plexus and of small arteries and veins, carrying the blood to and returning it from this plexus (Fig. 736), and of branched and pigmented cells which lie in connective tissue. There are three layers in the choroid. Named from without inward, they are the lamina suprachorioidea, the choroid proper, and lamina basalis (Fig. 733).

1. The Lamina Suprachorioidea is on the external surface, that is, the surface next to the sclerotic. It resembles the lamina fusca of the sclerotic. It is composed of delicate non-vascular lamellae, each lamella consisting of a network of fine elastic fibres, among which are branched pigment-cells. The spaces between the lamellae are lined by endothelium, and open freely into the perichoroidal lymph-space, which, in its turn, communicates with the periscleral space by the perforations in the sclerotic through which the vessels and nerves are transmitted.

2. The Choroid Proper is internal to the lamina suprachorioidea. In consequence of the small arteries and veins of the choroid proper being arranged on the outer surface of the capillary network, it is customary to describe this as consisting of two layers: the outermost (lamina vasculosa), composed of small arteries and veins, with pigment-cells interspersed between them, and the inner (lamina choriocapillaris), consisting of a capillary plexus. The external layer of the choroid proper or the lamina vasculosa consists, in part, of the larger branches of the short
posterior ciliary arteries (Figs. 734, 736, and 738). which run forward between the veins, before they bend inward to terminate in the capillaries; but this layer is formed principally of veins, which have a whirl-like arrangement and empty into four or five large equidistant trunks, the venae vorticosae (Figs. 734, 735, and 736), which pierce the sclerotic midway between the margin of the cornea and the entrance of the optic nerve. Around the veins are lymph-spaces. Interspersed between the vessels are dark star-shaped pigment-cells, the offsets from which, communicating with similar branchings from neighboring cells, form a delicate network or stroma, which toward the inner surface of the choroid loses its pigmentary character. The internal layer of the choroid proper consists of an exceedingly fine capillary plexus, formed by the short ciliary vessels (Fig. 736), and is known as the tunic of Ruysch (lamina choriocapillaris). The network is close, and finer at the hinder part of the choroid than in front. About half an inch behind the cornea its meshes become larger, and are continuous
with those of the ciliary processes. These two laminae are connected by an intermediate stratum, which is destitute of pigment-cells and consists of fine elastic fibres.

On the inner surface of the lamina choriocapillaris is a very thin, structureless, or, according to Kölliker, faintly fibrous membrane, called the lamina basalis or membrane of Bruch; it is closely connected with the stroma of the choroid, and separates it from the pigmentary layer of the retina.

---

**Tapetum (lucidum).—** This name is applied to the iridescent appearance which is seen in the outer and posterior parts of the choroid of many animals, but not in man.

The ciliary body should now be examined. It may be exposed, either by detaching the iris from its connection with the Ciliary muscle, or by making a transverse section of the globe, and examining it from behind.
The Ciliary Body (corpus ciliare) (Fig. 729).—The ciliary body or cyclon joins the choroid to the margin of the iris. It is in reality a process of the choroid or uveal tract and comprises the orbiculus ciliaris, the ciliary processes, and the Ciliary muscle.

The Orbiculus Ciliaris or Annulus Ciliaris (Figs. 737, 739, and 755).—The orbiculus ciliaris is a zone of about one-sixth of an inch in width, directly continuous with the anterior part of the choroid. The lamina basalis presents numerous ridges arranged in a radial manner. The depressions between the ridges are filled with retinal pigment epithelium (Szymonowicz). The orbiculus contains no lamina choriocapillaris.

The Ciliary Processes (processus ciliares) (Figs. 727, 729, 739, and 757).—The ciliary processes are formed by the plaeting and folding inward of the various layers of the choroid—i.e., the choroid proper and the lamina basalis—at its anterior margin, and are received between corresponding foldings of the suspensory ligament of the lens, thus establishing a connection between the choroid and inner tunic of the eye. They are arranged in a circle, and form a sort of plaited frill, the corona ciliaris, behind the iris, round the margin of the lens (Figs. 739 and 757). They vary between sixty and eighty in number, lie side by side, and may be divided into large and small; the latter, consisting of about one-third of the entire number, are situated in the spaces between the former, but without regular alternation. The larger processes are each about one-tenth of an inch in length, and are attached by their periphery to three or four of the ridges of the orbiculus ciliaris, and are continuous with the layers of the choroid; the opposite margin is free, and rests upon the circumference of the lens. Their anterior surface is turned toward the back of the iris, with the circumference of which they are continuous. The posterior surface is connected with the suspensory ligament of the lens.

Structure.—The ciliary processes are similar in structure to the choroid, but the vessels are larger, and have chiefly a longitudinal direction. They are the most vascular portion of the eyeball. The processes are covered on their inner surface by two strata of black pigment-cells, which are continued forward from the retina, and are named the pars ciliaris retinae (Figs. 733 and 740). In the stroma of the ciliary processes there are also stellate pigment-cells, which, however, are not so numerous as in the choroid itself.

The Ciliary Muscle or Bowman's Muscle (m. ciliaris) (Figs. 732, 734, 738, 740, 741, and 742).—The ciliary muscle consists of unstriped fibres; it forms a grayish, semitransparent, circular band, about one-eighth of an inch broad, on the outer surface of the forepart of the choroid, between the choroid and the iris and back of the sclero-corneal junction. It is thickest in front and gradually becomes thinner behind. It consists of two sets of fibres, radiating and circular.

The Radiating Fibres (fibrae meridianales [Bruckei]) (Figs. 740 and 757), much the more numerous, arise at the point of junction of the cornea and sclerotic, and partly also from the ligamentum pectinatum iridis, and, passing backward, are attached to the choroid opposite to the ciliary processes. One bundle, according to Waldeyer, is continued backward to be inserted into the sclerotic.
The **Circular Fibres** (fibrae circulares [Mulleri]) (Figs. 740 and 757) are internal to the radiating ones and to some extent unconnected with them, and have a circular course around the attachment of the iris. They are sometimes called the "ring muscle" of Muller, and were formerly described as the ciliary ligament. They are well developed in hypermetropic, but are rudimentary or absent in myopic eyes.

The **Ciliary muscle** is admitted to be the chief agent in accommodation—i.e., in adjusting the eye to the vision of near objects. Bowman believed that this was effected by its compressing the vitreous body, and so causing the lens to advance. At the present time all agree that the chief element in accommodation is altered curvature of the lens, but there is diversity of opinion as to the manner in which this is accomplished. The view which now prevails is that of Helmholtz. He maintained that in an unaccommodated eye the capsule and suspensory ligament of the lens are tense, and their pressure flattens the anterior surface of the lens, and parallel rays (and rays from objects far off are practically parallel) "are focused on the retina without any sense of effort."

"In accommodation for a near object the meridional or antero-posterior fibres

---

1 Stewart, Manual of Physiology.
of the ciliary muscle by their contraction pull forward the choroid and relax the suspensory ligament. The elasticity of the lens at once causes it to bulge forward till it is again checked by the tension of the capsule. The pupil is at the same time slightly contracted.

**The Iris (iris, a rainbow)** (Figs 729, 732, 734, 736, 737, 740, 741, 742, 743, and 757).—The iris has received its name from its various colors in different individuals. It is a thin, circular-shaped, contractile curtain, suspended in the aqueous humor behind the cornea, and in front of the lens, being perforated a little to the nasal side of its centre by a circular aperture, the pupil (pupilla) (Fig. 743), for the transmission of light. The pupil of a living person varies in size under the influence of light and in efforts at accommodation. In looking at a near object the pupil is small; in looking at a distant object it is large. In light the pupil contracts, in darkness it dilates; hence the pupil is a window which permits light to pass into the interior of the eye. The size of this window depends on the contraction or relaxation of the iris. The iris divides the *aqueous chamber* (the space between

---

1 Stewart, Manual of Physiology.
look forward and backward, the anterior toward the cornea, the posterior toward the ciliary processes and lens. The iris is pigmented and the color of an individual's eyes depends upon this pigment. The anterior surface (facies anterior) (Figs. 741 and 757) of the iris is variously colored in different individuals, and is marked by lines which converge toward the pupil. The posterior surface (facies posterior) (Figs. 739 and 757) is of a deep-purple tint, from being covered by two layers of pigmented, columnar epithelium, which layers are continuous posteriorly with the pars ciliaris retinae. This pigmented epithelium is termed the pars iridica retinae, though it is sometimes named uvea, from its resemblance in color to a ripe grape.

**Structure.**—The iris is composed of the following structures:

1. In front is a layer of flattened endothelial cells placed on a delicate hyaline basement-membrane. This layer is continuous with the endothelial layer covering the membrane of Descemet, and in men with dark-colored irides the cells contain pigment-granules.

2. **Stroma** (stroma iridis).—The stroma consists of fibres and cells. The former are made of fine, delicate bundles of fibrous tissue, of which some few fibres have a circular direction at the circumference of the iris, but the chief mass consists of fibres radiating toward the pupil. They form, by their interlacement, a delicate mesh, in which the vessels and nerves are contained. Interspersed between the bundles of connective tissue are numerous branched cells with fine processes. Many of them in dark eyes contain pigment-granules, but in blue eyes and the pink eyes of albinos they are unpigmented.

3. The **Muscular Fibre** is involuntary and consists of circular and radiating fibres. The circular fibres (m. sphincter pupillae) surround the margin of the pupil on the posterior surface of the iris, like a sphincter, forming a narrow band about one-thirtieth of an inch in width, those near the free margin being closely aggregated; those more external somewhat separated, and forming less complete circles. The radiating fibres (m. dilator pupillae) converge from the circumference toward the centre, and blend with the circular fibres near the margin of the pupil. These fibres are regarded by some as elastic, not muscular, but Grunert positively demonstrated them. The fibres are very small and are placed between the stroma and the posterior layer of endothelium.

---

1 Von Graefe's Arch. f. Ophthal., Bd. xlvii.
4. **Pigment.**—The situation of the pigment-cells differs in different irides. In the various shades of blue eyes the only pigment-cells are several layers of small round or polyhedral cells filled with dark pigment, situated on the posterior surface of the iris and continuous with the pigmentary lining of the ciliary processes. The color of the eye in these individuals is due to this coloring-matter showing more or less through the texture of the iris. In the albino even this pigment is absent.

In the gray, brown, and black eye there are, as mentioned above, pigment-granules to be found in the cells of the stroma and in the endothelial layers on the front of the iris; to these the dark color of the eye is due.
The Arteries of the Iris (Figs. 736, 738, 740, and 743).—The arteries of the iris are derived from the long posterior ciliary and anterior ciliary and from the vessels of the ciliary processes (see p. 1125). The long posterior ciliary arteries (Figs. 734 and 736), two in number, pass through the sclera, one on the inner and one on the outer side of the optic nerve, and pass forward between the sclera and choroid, and, having reached the attached margin of the iris (Figs. 734 and 743), divide into an upper and a lower branch, and, encircling the iris, anastomose with corresponding branches from the opposite side; into this vascular zone (circulus arteriosus major) (Fig. 757) the anterior ciliary arteries (Fig. 757), from the lachrymal and anterior ciliary from the muscular branches of the ophthalmic, pour their blood. From this zone vessels converge to the free margin of the iris, and these communicate by branches from one to another and thus form a second zone (circulus arteriosus minor) in this situation. The veins pass toward the ciliary margin and communicate with the veins of the ciliary processes and of the canal of Schlemm (Figs. 734 and 736).

The Nerves of the Choroid and Iris (Fig. 732).—The nerves of the choroid and iris are the short ciliary, the ciliary branches of the lenticular ganglion, and the long ciliary from the nasal branch of the ophthalmic division of the trigeminal. They pierce the sclerotic around the entrance of the optic nerve, and run forward in the perichoroidal lymph-space in which they form a plexus, from which plexus filaments pass to supply the blood-vessels of the choroid. After reaching the iris they form a plexus around its attached margin; from this are derived myelinated fibres which terminate in the circular and radiating muscular fibres. Their exact mode of termination has not been ascertained. Other fibres from the plexus terminate in a network on the anterior surface of the iris. The fibres derived from the motor root of the lenticular ganglion (oculomotor nerve) supply the circular fibres, while those derived from the sympathetic supply the radiating fibres.

Membrana Pupillaris.—In the foetus the pupil is closed by a delicate transparent vascular membrane, the membrana pupillaris, which divides the space into which the iris is suspended into two distinct chambers. This membrane contains numerous minute vessels, continued from the margin of the iris to those on the front part of the capsule of the lens. These vessels have a looped arrangement, and converge toward each other without anastomosing. Between the seventh and eighth months the membrane begins to disappear, by gradual absorption from the centre toward the circumference, and at birth only a few fragments remain. It is said sometimes to remain permanent and produce blindness.

III. The Tunica Interna or Retina (Figs. 736, 744, 746).

The retina is a delicate nerve membrane, in which the fibres of the optic nerve are spread out and upon the surface of which the images of external objects are received. Its outer surface is in contact with the choroid; its inner with the vitreous body. Behind, it is continuous with the optic nerve; it gradually diminishes in thickness from behind forward; and, in front, extends nearly as far as the ciliary body, where it appears to terminate in a jagged margin, the ora serrata (Figs. 736, 745, and 757). Here the nerve tissues of the retina end, but a thin prolongation of the membrane extends forward over the back of the ciliary processes and iris, forming the pars ciliaris retinae and pars iridica retinae, already referred to (Figs. 740 and 757). This forward prolongation consists of the pigmented layer of the retina, together with a stratum of columnar epithelium. The portion back of the ora serrata is called the physiological retina (pars optica retinae) (Fig. 757). The retina is soft, semitransparent, and of a purple tint in the fresh state, owing to the presence of a coloring-material named rhodopsin or visual purple; but it soon becomes clouded, opaque, and bleached when exposed to sunlight. Exactly in the centre of the front surface of the posterior part of the retina, corresponding to the visual axis, and at a point in which the sense of vision is most perfect, is an oval yellowish
THE TUNICA INTERNA OR RETINA

1131

spot, called, after its discoverer, the yellow spot of Sömmerring (macula lutea) (Figs. 727 and 746), having a central depression, the fovea centralis. The retina in the situation of the fovea centralis is exceedingly thin, and the dark color of the choroid is distinctly seen through it; so that it presents more the appearance of a foramen, and hence the name foramen of Sömmerring at first given to it. It exists only in man, the quadruped, and some saurian reptiles. About one-eighth of an inch (3 mm.) to the nasal side of the yellow spot and one-twenty-fourth of an inch below it, is the point of entrance of the optic nerve, the optic disk (porus opticus) (Figs. 744 and 746). The circumference of the optic disk is slightly raised so as to form an eminence, the optic papilla (colliculus nervi optici); the central portion is depressed and is called the optic cup (excavatio papillae nervi optici). The arteria centralis retinae pierces its centre. This is the only part of the surface of the retina from which the power of vision is absent, and is termed the blind spot.

![Diagram of the Retina](image)

**Fig. 744.—The terminal portion of the optic nerve and its entrance into the eyeball, in horizontal section. (Toldt.)**

**Structure.**—The optical portion of the retina is an exceedingly complex structure, and, when examined microscopically by means of sections made perpendicularly to its surface, is found to consist of many layers of nerve structure. These nerve structures are bound together and supported by the sustentacular fibres. There are three layers: a middle or neuro-epithelial layer, an inner layer, and an outer or pigmentary layer. The neuro-epithelial layer is subdivided into four, and the middle layer into six layers; hence the retina consists of eleven layers. The layers from within outward are as follows (Figs. 745, 747, 748, and 749):

1. Inner layer

   1. Membrana limitans interna.
   2. Layer of nerve-fibres (stratum opticum).
   3. Ganglionic layer, consisting of nerve-cells.
   4. Inner molecular, or plexiform, layer.
   5. Inner nuclear layer, or layer of inner granules.
   6. Outer molecular, or plexiform, layer.

2. Neuro-epithelial layer

   8. Outer nuclear layer, or layer of outer granules.
   10. Jacob's membrane (layer of rods and cones).

3. Outer layer

   11. Pigmentary layer (tapetum nigrum).
1. The **Membrana Limitans Interna** (Figs. 745, 747, and 748), is the most internal layer of the retina, and is in contact with the hyaloid membrane of the vitreous humor. It is derived from the supporting framework of the retina, with which tissue it will be described.

2. The **Layer of Nerve-fibres** (Figs. 745, 747, and 748) is formed by the expansion of the optic nerve. This nerve passes through all the other layers of the retina, except the membrana limitans interna, to reach its destination. As the nerve passes through the lamina cribrosa of the sclerotic coat, the fibres of which it is composed lose their myelin sheaths and are continued onward, through the choroid and retina, as simple axones. When these amylelinic axones reach the internal surface of the retina, they radiate from their point of entrance over the surface of the retina, become grouped in bundles, and in many places, according to Michel, arranged in plexuses. Most of the axones in this layer are **centripetal**, and are the direct continuations of the axones of the...
cells of the next layer. A few of the axones are centrifugal, which are axones of ganglion-cells within the brain. The centrifugal fibres in the layer of nerve-fibres pass through it and the next succeeding layer to ramify in the inner molecular and inner nuclear layers, where they terminate in enlarged extremities. The layer is thickest at the optic nerve entrance, and gradually diminishes in thickness toward the ora serrata.

3. The Ganglionic Layer or the Inner Ganglionic Layer (Figs. 745, 747, and 748) consists of a single layer of large ganglion-cells; except in the macula lutea, where there are several strata. The cells are somewhat flask-shaped, the rounded internal margin of each cell resting on the preceding layer and sending off an axone which is prolonged as a nerve-fibre into the fibrous layer. From the opposite extremity numerous thicker processes (dendrites) extend into the inner molecular layer, where they branch out into flattened arborizations at different levels. The ganglion-cells vary much in size, and the dendrites of the smaller ones, as a rule,

arborize in the inner molecular layer as soon as they enter it; while the processes of the larger cells ramify close to the inner nuclear layer.

4. The Inner Molecular, the Plexiform or the Inner Reticular Layer (Figs. 745, 747, and 748) is made up of a dense reticulum of minute fibris, formed by the interlacement of the dendrites of the ganglion-cells with those of the cells contained in the next layer, immediately to be described. Within the reticulum formed by these fibris a few branched spongioblasts are sometimes embedded.

5. The Inner Nuclear or Inner Granular Layer (Figs. 745, 747, and 748) is made up of a number of closely packed cells, of which there are three different kinds. (1) A large number of oval cells, which are commonly regarded as bipolar nerve-cells, and are much more numerous than either of the other kind. They each consist of a large oval body placed vertically to the surface, and containing a distinct nucleus. The protoplasm is prolonged into two processes; one of these passes inward into the inner molecular layer, is varicosc in appearance, and ends in a terminal ramification, which is often in close proximity to the ganglion-cells (Fig. 749, 1, c). The outer process passes outward into the outer molecular layer, and there breaks up into a
THE ORGANS OF SPECIAL SENSE

Fig. 725.—Elements of the retina of mammals, displayed by the chronaxie of silver method of Golgi. (Cajal.) (Copied from Quinac's Anatomy.)
number of branches. According to Cajal, there are two varieties of these bipolar cells: one in which the outer process arborizes around the knobbed ends of the rod-fibres, and the inner around the cells of the ganglionic layer; these he calls rod-bipolars (Fig. 749, i); the others are those in which the outer process breaks up in a horizontal ramification, in contact with the end of a cone-fibre; these are the cone-bipolars, and their inner process breaks up into its terminal ramifications in the inner molecular layer (Fig. 749, i). (2) At the innermost part of this inner nuclear layer is a stratum of cells, which are named amacrine cells of Cajal, from the fact that they have no axis-cylinder process, but they give a number of short protoplasmic processes which extend into the inner molecular layer and there ramify (Fig. 749, i). There are also at the outermost part of this layer some cells; the processes of which extend into and ramify in the outer molecular layer. These are the horizontal cells of Cajal. (3) Some few cells are also found in this layer, connected with the fibres of Müller, and will be described with those structures.

6. The Outer Molecular or Outer Reticular Layer or the Plexiform Layer (Figs. 745, 747, and 748) is much thinner than the inner molecular layer; but, like it, consists of a dense network of minute fibrils, derived from the processes of the horizontal cells of the preceding layer and the outer processes of the bipolar cells, which ramify in it, forming arborizations around the ends of the rod-fibres and with the branched foot-plates of the cone-fibres.

7. Henle's Fibre Layer is a non-granular layer in the neighborhood of the macula lutea, and is produced by elongations from the inner segments of rod-fibres and cone-fibres.

8. The Outer Nuclear or Outer Granular Layer (Figs. 745, 747, and 748), like the inner nuclear layer, contains several strata of clear oval nuclear bodies; they are of two kinds, and on account of their being respectively connected with the rods and cones of Jacob's membrane (rod-fibres and cone-fibres) are named rod-granules and cone-granules.

The rod-granules are much the more numerous, and are placed at different levels throughout the layer. Their nuclei present a peculiar cross-striped appearance, and prolonged from either extremity of the granule is a fine process; the outer process is continuous with a single rod of Jacob's membrane; the inner passes inward toward the outer molecular layer and terminates in an enlarged extremity.

DESCRIPTION OF FIG. 749.

I. Section of the dog's retina. a. Cone-fibre. b. Rod-fibre and nucleus. c, d. Bipolar cells (inner granules) with vertical ramification of outer processes destined to receive the enlarged ends of rod-fibres. e. Bipolar with flattened ramification for ends of cone-fibres. f. Giant bipolar with flattened ramifications. g. Cell sending a neurone or nerve-fibre process to the outer molecular layer. h. Amacrine cell with diffuse arborization in inner molecular layer. i. Nerve-fibres passing to outer molecular layer. j. Centrifugal fibres passing from nerve-fibre layer to inner molecular layer. k. Nerve-fibril passing into inner molecular layer. l. Ganglion-cells. m. Amacrine cells.

II. Horizontal or basal cells of the outer molecular layer of the dog's retina. a. Small cell with dense arborization. b. Large cell, lying in inner nuclear layer, but with its processes branching in the outer molecular. c. Its horizontal neurone. d. Medium-sized cell of the same character.

III. Cells from the retina of the ox. a. Rod-bipolars with vertical arborizations. b, c, d, e. Cone-bipolars with horizontal ramification of outer process. f. Cell lying on the outer surface of the outer molecular layer, and ramifying within it. i, j, m. Amacrine cells within the substance of the inner molecular layer.

IV. Neurones or axis-cylinder processes belonging to horizontal cells of the outer molecular layer, one of them, b, ending in a close ramification at a.

V. Nervous elements connected with the inner molecular layer of the ox's retina. a. Amacrine cell, with long processes ramifying in the outermost stratum. b. Large amacrine with thick processes ramifying in second stratum. c. Flattened amacrine with long and fine processes ramifying mainly in the first and fifth strata. d. Amacrine with radiating tuft of fibrils destined for third stratum. e. Large amacrine, with processes ramifying in fifth stratum. f. Small amacrine, branching into second stratum. g. h. Other amacrines destined for fourth stratum. i. Small ganglion-cell sending its processes to fourth stratum. k. A small ganglion-cell with ramifications in three strata. l. A small cell ramifying ultimately in first stratum. m. A medium-sized ganglion-cell ramifying in fourth stratum.

e. Giant-cell, branching in third stratum. f. A bistriated cell ramifying in second and fourth strata.

VI. Amacrines and ganglion-cells from the dog. a. Amacrine with radiating tuft. b. Large amacrine passing to third stratum. c and d. Small amacrines with radiations in second stratum. e. Small amacrine passing to third stratum. f. Amacrine with diffuse arborization. g. Amacrine belonging to fourth stratum. h. i. j. g. Small ganglion-cells ramifying in various strata. k, l, m. Large ganglion-cells showing two different characters of arborization. n. Bistriated cell.

VII. Amacrines from the dog. a. B. c. e. Small amacrines ramifying in middle of molecular layer. b, d, g, h, f. Small ganglion-cells showing various kinds of arborization. j. A larger cell, similar in character to g, but with longer branch. a, c, e. Giant-cells with thick branches ramifying in the first, second, and third layers. k, l. Ends of bipolaris branching over ganglion-cells.
and is embedded in the tuft into which the outer process of the rod-bipolars breaks up. In its course it presents numerous varicosities.

The cone-granules, fewer in number than the rod-granules, are placed close to the membrana limitans externa, through which they are continuous with the cones of Jacob's membrane. They do not present any cross-striping, but contain a pyri-form nucleus which almost completely fills the cell. From their inner extremity a thick process passes inward to the outer molecular layer, upon which it rests by a somewhat pyramidal enlargement, from which are given off numerous fine fibrils, which enter the outer molecular layer, where they come in contact with the outer processes of the cone-bipolars.

9. The Membrana Limitans Externa (Figs. 745, 747, and 748), like the membrana limitans interna, is derived from the fibres of Müller, with which structures it will be described.

10. Jacob's Membrane or the Layer of Rods and Cones (Figs. 745, 747, and 748) consists of visual cells, and the elements which compose it are of two kinds, rod-cells and cone-cells, the former being much more numerous than the latter.

The rod-cells (Fig. 750) are of nearly uniform size, and arranged perpendicularly to the surface. A rod-cell consists of a rod and a rod-fibre, and the fibre contains the nucleus. The rods are cylindrical and each consists of two portions, an outer segment and an inner segment, which are of about equal length. The segments differ from each other as regards refraction and in their behavior with coloring reagents, the inner portion becoming stained by carmine, iodine, etc., the outer portion remaining unstained with these reagents, but staining yellowish-brown with osmic acid. The outer portion of each rod is marked by transverse striae, and is made up of a number of thin disks superimposed on one another. It also

![Figure 750](image-url)
exhibits faint longitudinal markings. The inner portion of each rod, at its deeper part where it is joined to the outer process of the rod-granule, is indistinctly granular; its more superficial part presents a longitudinal striation, being composed of fine, bright, highly refracting fibres. In most vertebrates the outer portion of the inner segment contains a fibrous body, the ellipsoid of Krause. The visual purple, or rhodopsin, is found only in the outer segments of the rods. At its inner end each rod is prolonged into a very fine fibre, the rod-fibre, which contains a nucleus, and which terminates in the outer nuclear layer, being somewhat enlarged at its termination.

The cone-cells (Fig. 751) are conical or flask-shaped, their broad ends resting upon the membrana limitans externa, the narrow pointed extremity being turned to the choroid. Each cone-cell consists of two parts, the cone and the cone-fibre. The cones are shorter than the rods and exhibit an outer and an inner segment.

The outer segment is a short conical process, which, like the outer segment of a rod, presents transverse striae. The inner segment resembles the inner portion of the rods in structure, presenting a superficial striated and deeper granular part; but differs from it in size, being bulged out laterally and presenting a flask shape.

The inner segment of the cone, as does the rod, contains an ellipsoid of Krause. Each cone is prolonged into a cone-fibre, and at the junction of the cone with the fibre is the nucleus of the cone-cell. The cone-fibre passes to the outer nuclear layer, and terminates as an expansion from which very minute fibrils are given off. The chemical and optical characters of the rod-cells and cone-cells are identical.

11. The Pigmentary Layer or Tapetum Nigrum (Fig. 745).—The most external layer of the retina, formerly regarded as a part of the choroid, consists of a single layer of hexagonal epithelial cells, loaded with pigment-granules. Each cell contains a flattened nucleus in the outer portion of the cell which is free from pigment at this point. These cells are smooth externally, where they are in contact with the choroid, but internally they are prolonged into fine, straight processes, which extend between the rods, this being especially the case when the eye is exposed to light. The pigment changes its position under the influence of light, and is distributed through the entire cell. In the eyes of albinos, the cells of the pigmentary layer are present, but they contain no coloring-matter. In the eyes of many mammals also, as in the horse, and many of the carnivora, there is no pigment in the cells of this layer, and the choroid possesses a beautiful iridescent lustre, which is termed the tapetum lucidum.

Supporting Framework of the Retina.—Almost all these layers of the retina are connected together by a supporting framework, formed by the supporting cells or supporting fibres of Müller or radiating fibres, from which the membrana limitans interna et externa are derived. These fibres are found stretched between the two limiting layers (Fig. 745), "like columns between a floor and a roof," and they pass through all the nervous layers except Jacob's membrane. Each commences on the inner surface of the retina by a conical hollow base, which sometimes contains a spheroidal body which stains deeply with haematoxylin, the edges of the bases of adjoining fibres being united and thus forming a boundary line, which is the membrana limitans interna. As they pass through the nerve-fibre and ganglionic layers they give off few lateral branches; in the inner nuclear layer they give off numerous lateral processes for the support of the inner granules, while in the outer nuclear layer they form a network, the fibre-baskets, around the rod and cone-fibrils, and unite to form the external limiting membrane at the bases of the rods and cones. In the inner nuclear layer each fibre of Müller presents a clear oval nucleus, which is sometimes situated at the side of, sometimes altogether within, the fibre. The supporting framework of the retina contains neuroglia cells.

The Path of Light Stimuli.—The stimulus is first received by the rod and cone-cells (the visual cells), and is transmitted to the bipolar cells of the inner nuclear layer and then to the cells of the ganglionic layer, which send fibres by way of the optic nerve to the brain.
Macula Lutea and Fovea Centralis.—The structure of the retina at the yellow spot presents some modifications. In the macula lutea (1) the nerve-fibres are wanting as a continuous layer; (2) the ganglionic layer consists of several strata of cells, instead of a single layer; (3) in Jacob's membrane there are no rods, but only cones, and these are longer and narrower than in other parts; and (4) in the outer nuclear layer there are only cone-fibres, which are very long and arranged in curved lines. At the fovea centralis the only parts which exist are the cones of Jacob's membrane, the outer nuclear layer, the cone-fibres of which are almost horizontal in direction, and an exceedingly thin inner granular layer, the pigmentary layer, which is thicker and its pigment more pronounced than elsewhere. The color of the macula seems to imbue all the layers except Jacob's membrane; it is of a rich yellow, deepest toward the centre, and does not appear to consist of pigment-cells, but simply a staining of the constituent parts.

At the Ora Serrata (Fig. 736) the nerve layers of the retina terminate abruptly, and the retina is continued onward as a single layer of elongated columnar cells covered by the pigmented layer. This prolongation is known as the pars ciliaris retinae (Fig. 740), and can be traced forward from the ciliary processes on to the back of the iris, where it is termed the pars iridica retinae or uvea.

From the description given of the nerve elements of the retina it will be seen that there is no direct continuity between the structures which form its different layers except between the ganglionic and nerve-fibre layers, the majority of the nerve-fibres being formed of the axones of the ganglionic cells. In the inner molecular layer the dendrites of the ganglionic layer interlace with those of the cells of the inner nuclear layer, while in the outer molecular layer alike synapsis occurs between the processes of the inner granules and the rod and cone elements.

The Arteria Centralis Retinae (Figs. 736 and 744) and its accompanying vein, vena centralis retinae, pierce the optic nerve, and enter the globe of the eye through the porus opticus. It immediately bifurcates into an upper and a lower branch, and each of these again divides into an upper or nasal, and an outer or temporal, branch, which at first run between the hyaloid membrane and the nerve layer; but they soon enter the latter, and pass forward, dividing dichotomously. From these branches a minute capillary plexus is given off, which does not extend beyond the inner nuclear layer. The macula receives small twigs from the temporal branches and others directly from the central artery; these do not, however, reach as far as the fovea centralis, which has no blood-vessels. The branches of the arteria centralis retinae do not anastomose with each other—in other words, they are "terminal arteries." In the fœtus, a small vessel passes forward, through the hyaloid canal in the vitreous body, to the posterior surface of the capsule of the lens (Fig. 728).

THE REFRACTING MEDIA.

The Refracting media are three, viz.:

Aqueous humor. 
Vitreous body. 
Crystalline lens.

I. The Aqueous Humor (Humor Aqueus).

The aqueous humor completely fills the lympath space known as the aqueous chamber, the space which is bounded in front by the cornea and behind by the lens and its suspensory ligament and the ciliary body (Fig. 757). The aqueous chamber
THE VITREOUS BODY

is partly divided by the iris into two communicating parts, the anterior and posterior chambers (Figs. 727, 728, and 757). The posterior chamber (cumera oculi posterior) is only a narrow chink between the peripheral part of the iris, the suspensory ligament of the lens, and the ciliary processes. The anterior chamber (cumera oculi anterior) is bounded in front by the cornea and behind by the iris. The external angle of the anterior chamber is bounded by the periphery of the cornea and of the iris. It is called the angle or sinus of the anterior chamber or the filtration angle (angulus iridis). It is by way of the filtration angle that any excess of aqueous humor passes by way of the spaces of Fontana and the canal of Schlemm (Fig. 740) to the anterior ciliary veins and relieves tension. The aqueous humor is small in quantity (scarcely exceeding, according to Petit, four or five grains in weight), has an alkaline reaction, in composition is little more than water, less than one-fiftieth of its weight being solid matter, chiefly chloride of sodium.

In the adult, these two chambers communicate through the pupil; but in the fetus of the seventh month, when the pupil is closed by the membrana pupillaris, the two chambers are quite separate.

II. The Vitreous Body (Corpus Vitreum) (Figs. 725, 728, 752).

The vitreous body forms about four-fifths of the entire globe. It is composed of a jelly-like tissue containing 98 per cent. water, some salts, and a little albumin, and called the vitreous humor (humor vitreus), connective-tissue fibres, and connective-tissue cells. It fills the concavity of the retina, and is hollowed in front, forming a deep concavity, the fossa patellaris (fossa hyaloidea) (Fig. 752), for the reception of the lens. It is perfectly transparent, of the consistence of thin jelly, and is composed of an albuminous fluid enclosed in a delicate transparent membrane, the hyaloid membrane (membrana hyaloidea), the outside of which is in contact with the membrana limitans interna of the retina. It has been supposed by Hannover, that from its inner surface numerous thin lamellae (stroma vitreum) are prolonged inward in a radiating manner, forming spaces in which the fluid is contained. In the adult, these lamellae cannot be detected even after careful microscopic examination in the fresh state, but in preparations hardened in weak chromic acid it is possible to make out a distinct lamellation at the periphery of the body; and in the fetus a peculiar fibrous texture pervades the mass, the fibres joining at the numerous points, and presenting minute nuclear granules at their point of junction. In the centre of the vitreous humor, running from the entrance of the optic nerve to the posterior surface of the lens, is a canal, filled with fluid and lined by a prolongation of the hyaloid membrane. This is the canal of Stilling, the hyaloid canal, or the canal of Cloquet (canalis hyaloides) (Fig. 728), which in the embryonic vitreous humor conveyed the minute vessel from the central artery of the retina to the back of the lens.

The hyaloid membrane encloses the whole of the vitreous humor. In front of the ora serrata it is thickened by the accession of radial fibres and is termed the zonule of Zinn (zonula ciliaris) (Figs. 755 and 757). It presents a series of radially arranged furrows, in which the ciliary processes are accommodated and to which they are adherent, as evidenced by the fact that when removed some of their pigment remains attached to the zonule. The zonule of Zinn splits into two layers, one of which is thin and lines the fossa patellaris; the other is named the suspensory ligament of the lens; it is thicker, and passes over the ciliary body to be attached to the capsule of the lens a short distance in front of its equator. Scattered and delicate fibres are also attached to the region of the equator itself. This ligament retains the lens in position, and is relaxed by the contraction of the radial fibres of the Ciliary muscle, so that the lens is allowed to become more convex. Behind
the suspensory ligament there is a sacculated canal, the canal of Petit (*spatia zonularia*); which enircles the margin of the lens and which can be easily inflated through a fine blow-pipe inserted through the suspensory ligament. It is bounded in front by the anterior layer of the suspensory ligament of the lens, behind by the hyaloidea membrana, and internally by the capsule of the lens. The canal of Petit is a lymph-space. All the spaces of the canal of Petit communicate with the posterior chamber of the eye.

In the fetus, the centre of the vitreous humor presents the hyaloid canal or canal of Stilling, already referred to, which transmits a minute artery, the hyaloid artery, to the capsule of the lens. In the adult, no vessels penetrate its substance, although a lymph channel remains; so that its nutrition must be carried on by the vessels of the retina and ciliary processes, situated upon its exterior.

III. The Crystalline Lens (Lens Crystallina) (Figs. 729, 736, 753, 754, 755, 756, 757).

The crystalline lens, enclosed in its capsule, is situated immediately behind the pupil, in front of the vitreous body, and is encircled by the ciliary processes, which slightly overlap its margin.

The capsule of the lens (capsula lenti) (Fig. 757) is a transparent, highly elastic, and brittle membrane, which closely surrounds the lens, and is composed in part of cuticular and in part of connective tissue. It is not white fibrous tissue, and is not true elastic tissue (Szymonowicz). Its outer surface is composed of lamella and possesses transverse striations. It rests, behind, in the fossa patellaris in the fore-part of the vitreous body (Fig. 752); in front, it is in contact with the free border of the iris, this latter reeding from it at the circumference, thus forming the posterior chamber of the eye (Fig. 757); and it is retained in its position chiefly by the suspensory ligament of the lens, already described (Fig. 757). The capsule is much thicker in front than behind, and when ruptured the edges roll up with the outer surface innermost, like the elastic lamina of the cornea.

The substance of the lens (substantia lenti) is an epithelial structure and takes origin from the ectoderm. It consists early in development of transparent cylindrical cells, which at a later period become higher at the posterior surface of the lens. Eventually very long cells form; they are known as *lens-fibres* (fibrae lenti), and are joined by a cement substance. The adult lens consists of lens-fibres, the anterior surface being covered by one layer of cubical epithelial cells, known as *lens epithelium* (epithelium lenti). This layer extends to the margin of the lens, at which point the cells gain in height and form lens-fibres. The lens-fibres at the margin are nucleated, the others are not. The lens-fibres run as meridians from the anterior surface backward. There is no epithelium on the posterior surface.
In the foetus, a small branch from the arteria centralis retinae runs forward, as already mentioned, through the vitreous humor to the posterior part of the capsule of the lens, where its branches radiate and form a plexiform network, which covers its surface, and they are continuous around the margin of the capsule with the vessels of the pupillary membrane and with those of the iris. In the adult no vessels enter its substance.

Structure.—The lens is a transparent, biconvex body, the convexity being greater on the posterior than on the anterior surface (Fig. 754). The central points of its anterior and posterior surfaces are known as its anterior and posterior poles (polus anterior lentis et polus posterior lentis) (Fig. 754). It measures from 9 to 10 mm. in the transverse diameter, and about 4 mm. in the antero-posterior. It consists of concentric layers (Fig. 753), of which the external in the fresh state are soft and easily detached (substantia corticalis) (Fig. 757); those beneath are firmer, the central ones forming a hardened nucleus (nucleus lentis) (Fig. 753). These laminae are best demonstrated by boiling or immersion in alcohol, and consist of minute parallel fibres, which are hexagonal prisms, the edges being dentated, and the dentations fitting accurately into each other; their breadth is about $\frac{1}{5}$ of an inch. Faint lines radiate from the anterior and posterior poles to the circumference of the lens. In the adult there may be six or more of these, but in the foetus they are only three in number and diverge from each other at angles of $120^\circ$ (Fig. 756). On the anterior surface one line ascends vertically and the other two diverge downward and outward. On the posterior surface one ray descends vertically and the other two diverge upward. They correspond with the free edges of an equal number of septa in the lens, along which the ends of the lens-fibres come into

![Diagram](image-url)

**Fig. 755.**—The zonule of Zinn or the suspensory ligament of the lens viewed from behind in connection with the lens and the ciliary body. (Toldt.)

**Fig. 756.**—Diagram to show the direction and arrangement of the radiating lines on the front and back of the foetal lens. A, from the front; B, from the back.
apposition and are joined together by transparent amorphous substance. The fibres run in a curved manner from the septa on the anterior surface to those on the posterior surface. No fibres pass from pole to pole, but they are arranged in such a way that fibres which commence near the pole on one aspect of the lens terminate near the peripheral extremity of the plane on the other, and vice versa. Each fibre of the outer layers of the lens contains a nucleus, and these nuclei form a layer, the **nuclear layer** on the surface of the lens. The nuclear layer is most distinct toward the circumference of the lens.

---

The **changes produced in the lens by age** are the following:

In the **foetus** its form is nearly spherical, its color of a slightly reddish tint, it is not perfectly transparent, and is so soft as to break down readily on the slightest pressure.

In the **adult** the posterior surface is more convex than the anterior; it is colorless, transparent, and firm in texture.

In **old age** it becomes flattened on both surfaces, slightly opaque, of an amber tint, and increases in density.

**Arteries of the Globe of the Eye.**—The arteries of the globe of the eye are the short posterior ciliary, long posterior ciliary, and anterior ciliary arteries, and the **arteria centralis retinae**.
The short posterior ciliary arteries (aa. ciliares posteriores breves) (Figs. 734, 736, and 738) are from eight to sixteen in number. They arise from the ophthalmic branch of the internal carotid, pass through the sclerotic coat near the optic nerve, and are distributed to the choroid.

There are two long posterior ciliary arteries (aa. ciliares posteriores longae) (Figs. 734, 736, and 743), one on each side of the optic nerve. They are branches of the ophthalmic. They pass through the sclerotic external to the short ciliary arteries, and extend forward in the choroid. In the ciliary body they form an anastomosis with the anterior ciliary arteries. The anastomosis is known as the circulum iridis major (Figs. 736 and 757). Branches from this circle pass to the iris, and at the periphery of the sphincter of the iris form the circulum iridis minor. The muscular branches and the lachrymal branch of the ophthalmic give off the anterior ciliary arteries (aa. ciliares anteriores), six or eight in number. They pass along tendons of the muscles of the eyeball, reach the sclera, and pass upon the sclera to the corneal margin (Fig. 743). Branches are given off which pass backward to supply the anterior half of the sclera, and which are known as episcleral arteries (aa. episclerales) (Fig. 736). Two branches are given off which pass forward to the conjunctiva bulbi, which are known as the anterior conjunctival arteries (aa. conjunctivales anteriores), which anastomose with the posterior conjunctival branches from the palpebral arteries, and which give branches to the delicate vascular network of the corneal margin which is in the annulus conjunctivae (Spalteholz). Eight or even more branches form the anterior ciliary arteries. They pass through the sclerotic near the sclero-corneal junction, and participate in the formation of the circulum iridis major.

The Veins of the Globe of the Eye (Figs. 734, 735, and 736).—The veins are seen on the outer surface of the choroid. They have a whorl-like formation and empty into four or five large veins, the venae vorticosae. These four, five, or six equidistant venae vorticosae pierce the sclerotic midway between the margin of the cornea and the entrance of the optic nerve, and empty into the ophthalmic vein. Another set of veins accompany the anterior ciliary arteries, and are known as the anterior ciliary veins (vv. ciliares anteriores). They are derivatives of the venous sinus of the sclera in the canal of Schlemm. They form a circular plexus. They receive vessels, the ciliary muscle, and pass through the sclera close to the corneal margin. Posterior ciliary veins (vv. ciliares posteriores) receive vessels which gather venous blood from the outer surface of the sclera near the optic nerve. The posterior ciliary veins join anteriorly with the venae vorticosae. After emerging from the sclera they receive anterior conjunctival branches, and by means of episcleral veins communicate with the venae vorticosae.

The Lymphatic Passages of the Eyeball.—The conjunctiva contains lymph-vessels. The eyeball contains lymph-spaces, but no lymph-vessels.

There are two sets of lymph-spaces in the eyeball, the anterior and posterior. The anterior lymph-spaces are the spaces of the cornea, of the iris, of the anterior chamber, and of the posterior chamber. The lymph from the intralamellar lymph-spaces of the cornea enters the conjunctival lymphatics at the margin of the cornea.

The lymph-spaces of the iris open into the anterior chamber by the crypts of the iris and at the margin of the iris join the spaces of Fontana. The aqueous humor fills the anterior and posterior chambers, but is furnished by the vessels in the posterior chamber; in part by the vessels of the ciliary body, and in part by the vessels of the posterior surface of the iris. The lymph thus secreted passes by way of the pupil into the anterior chamber, and then is taken up by the spaces of Fontana, the canal of Schlemm, and the anterior ciliary veins.¹

¹ Deaver's Anatomy.
The posterior lymph-spaces are the hyaloid canal, the perichoroidal lymph-space, the space of Ténon, the intervaginal space of the optic nerve, and the supravaginal space (Deaver).

The hyaloid canal (Figs. 725 and 728) passes between the posterior surface of the lens and the optic disk. In the embryo the canal holds an artery; the hyaloid artery. During development the artery disappears, but a lymph channel remains. The hyaloid canal opens into the intervaginal space of the optic nerve. Between the sclerotic and the choroid is the perichoroidal lymph-space (Fig. 757). It is around the choroid vessels and the venae vorticosae, and empties into Ténon's space by means of openings through the sclera about the venae vorticosae.

Ténon's space (Figs. 725 and 726) is between the sclera and the capsule of Ténon. It receives lymph from the perichoroidal space, and empties into the supravaginal space.

The optic nerve (Fig. 744) has a sheath of dura and a sheath of pia, and between these sheaths is the intervaginal lymph-space. It is divided by a prolongation of the cerebral arachnoid into a subdural space and a subarachnoid space, which empty into the corresponding spaces of the membranes of the brain.

The supravaginal space is between the dural portion of the sheath of the optic nerve and a posterior prolongation of Ténon's capsule.1

The Nerves of the Globe of the Eye.—The long ciliary nerves (nn. ciliares longi), two in number, are derived from the nasal branch of the ophthalmic and the short ciliary nerves (nn. ciliares breves), twelve to fifteen in number, are derived from the ciliary or ophthalmic ganglion. Both the long and short ciliary nerves perforate the sclera in the neighborhood of the optic nerve (Fig. 734). They pass along the perichoroidal lymph-space, forming a plexus, and send filaments to the choroid vessels. In front of the Ciliary muscle they form a second plexus, and from it come branches which go to the Ciliary muscle and the muscular fibres and vessels of the iris, sclera, choroid, ciliary body, and iris (Fig. 742). The ciliary nerves supply the cornea. The circular fibers of the iris are innervated by the oculomotor nerve and the radiating fibres by the sympathetic.

Surgical Anatomy.—From a surgical point of view the cornea may be regarded as consisting of three layers: (1) of an external epithelial layer, developed from the epiblast, and continuous with the external epithelial covering of the rest of the body, and therefore in its lesions resembling those of the epidermis; (2) of the cornea proper, derived from the mesoblast, and associated in its diseases with the fibro-vascular structures of the body; and (3) the posterior elastic layer with its endothelium, also derived from the mesoblast and having the characters of a serous membrane, so that inflammation of it resembles inflammation of the other serous and synovial membranes of the body.

The cornea contains no blood-vessels, except at its periphery, where numerous delicate loops, derived from the anterior ciliary arteries, may be demonstrated on the anterior surface of the cornea. The rest of the cornea is nourished by lymph, which gains access to the proper substance of the cornea and the posterior layer through the spaces of Fontana. This lack of a direct blood-supply renders the cornea very apt to inflame in the cachectic and ill-nourished. In spite of the absence of blood-vessels, wounds of the cornea usually heal rapidly. A wound which penetrates the cornea opens the anterior chamber, and aqueous humor escapes. An ulcer may also open the anterior chamber. Through a wound or a perforated ulcer the pupillary margin of the iris may prolapse. A trivial injury of the cornea is repaired by transparent tissue. A severe injury is repaired by fibrous tissue, and opacity results. A slight opacity resembling a cloud of gray smoke is called nebula; a more marked white opacity is called leucoma.

In abscess of the cornea pus gravitates between the layers to the lower part of the cornea and the purulent collection assumes a crescentic shape (onix). The areus senilis, seen in the aged, is a condition of haziness or opacity at the corneal margin due to fatty degeneration of the tissue of the cornea. It signifies interference with the blood-supply, because of senile degeneration of adjacent vessels. In cases of granular lids there is a peculiar affection of the cornea, called pusius, in which the anterior layers of the cornea become vascularized, and a rich network of blood-vessels may be seen on the cornea: and in interstitial keratitis new vessels extend into the cornea, giving it a pinkish hue, to which the term salmon patch is applied. The cornea is richly supplied with nerves, derived from the ciliary nerves, which

1 For the lymphatic channels of the eyeball see Deaver's Surgical Anatomy, vol. ii. p. 392.
enter the cornea through the forepart of the sclerotic and form plexuses in the stroma, terminating between the epithelial cells by free ends or in corpusescles. In cases of glaucoma the ciliary nerves may be pressed upon as they course between the choroid and sclerotic (Fig. 732), and in consequence of the pressure upon them, the cornea, to which they are distributed, becomes anesthetic. When a scar forms on the cornea and the iris becomes adherent, the scar and the iris, and sometimes even the lens, may bulge forward from intraocular tension. This condition is *staphyloma of the cornea.* In conditions of impaired nutrition the cornea may be bulged forward by intraocular pressure. The line of least resistance is a little below the centre of the cornea, and it is bulged forward and strongly curved. This condition is known as *conical cornea.* The sclerotic has very few blood-vessels and nerves. The blood-vessels are derived from the anterior ciliary, and form an open plexus in its substance. As they approach the corneal margin this arrangement is peculiar. Some branches pass through the sclerotic to the ciliary body; others become superficial and lie in the episcleral tissue, and form arches, by anastomosing with each other, some little distance behind the corneal margin. From these arches numerous straight vessels are given off, which run forward to the cornea, forming its marginal plexus. In *inflammation of the sclerotic and episcleral tissue* these vessels become conspicuous, and form a pinkish zone of straight vessels radiating from the corneal margin, commonly known as the zone of ciliary injection. In *inflammation of the iris and ciliary body* this zone is present, since the sclerotic speedily becomes involved when these structures are inflamed. But in *inflammation of the cornea* the sclerotic is seldom much affected, though the cornea and sclerotic are structurally continuous. This would appear to be due to the fact that the nutrition of the cornea is derived from a different source from that of the sclerotic. The *sclerotic* may be ruptured subcutaneously without any laceration of the conjunctiva, and the rupture usually occurs near the corneal margin, where the tunic is thinnest. It may be complicated with lesions of adjacent parts—laceration of the choroid, retina, iris, or suspensory ligament of the lens—and is then often attended with hemorrhage into the anterior chamber, which masks the nature of the injury. In some cases the lens has escaped through the rent in the sclerotic, and has been found under the conjunctiva. *Wounds of the sclerotic,* if they do not perforate, usually heal readily. If they extend through the sclerotic they cause diminished tension, are always dangerous, and are often followed by inflammation, suppuration, and by sympathetic ophthalmia. The sclerotic may be weakened by injury, inflammation, etc., and the weakened portion may bulge from intraocular pressure, and even a healthy sclera may bulge from excessive intraocular pressure. According to its situation the lesion is known as *ciliary staphyloma, equatorial staphyloma,* or *posterior staphyloma.*

One of the functions of the choroid is to provide nutrition for the retina and to convey vessels and nerves to the ciliary body and iris. *Inflammation of the choroid* is therefore followed by grave disturbance in the nutrition of the retina, and is attended with early interference with vision. *Purulent choroiditis* is not confined to the choroid; the retina, the vitreous, and the entire uveal tract become involved, and even other structures may suffer. In its diseases it bears a considerable analogy to those which affect the skin, and, like it, is one of the places from which *melanotic sarcoma* may grow. These tumors contain a large amount of pigment in their cells, and grow only from those parts where pigment is naturally present. The choroid may be ruptured without injury to the other tunics, as well as participating in general injuries of the eyeball. In cases of uncomplicated rupture the injury is usually at its posterior part, and is the result of a blow on the front of the eye. It is attended by considerable hemorrhage, which for a time may obscure vision, but in most cases this is restored as soon as the blood is absorbed.

The *iris* is the seat of a malformation, termed *coborama,* which consists in a deficiency or cleft, which in a great number of cases is clearly due to an arrest in development. In these cases it is found at the lower aspect, extending directly downward from the pupil, and the gap frequently extends through the choroid to the entrance of the optic nerve. In some rarer cases the gap is found in other parts of the iris, and is then not associated with any deficiency of the choroid. The iris is abundantly supplied with blood-vessels and nerves, and is therefore very prone to become inflamed. And when inflamed, in consequence of the fact that the iris and ciliary body are continuous, and that their vessels communicate, *iritis* is usually associated with *cyclitis,* the disease being called *irido-cyclitis.* And, in addition, inflammation of adjacent structures, the cornea and sclerotic, is apt to spread into the iris. The iris is covered with endothelium, and partakes of the character of a serous membrane, and, like these structures, is liable to pour out a plastic exudation when inflamed, and contract adhesions, either to the cornea in front (synecchia anterior), or to the capsule of the lens behind (synecchia posterior). In iritis the lens may become involved, and the condition known as *secondary cataract* may be set up. *Tumors* occasionally commence in the iris; of these, *cysts,* which are usually congenital and *sarcomatous tumors,* are the most common and require removal. *Gummata* are not unfrequently found in this situation. In some forms of injury of the eyeball, as the impact of a spent shot, the rebound of a twig, or a blow with a whip, the iris may be detached from the Ciliary muscle, the amount of detachment varying from the slightest degree to the separation of the whole iris from its ciliary connection.

The *Argyll-Robertson pupil* shows no reaction to light, but retains reaction to accommodation and vision remains good.
The retina, with the exception of its pigment-layer and its vessels, is perfectly transparent, and is invisible when examined by the ophthalmoscope, so that its diseased conditions are recognized by its loss of transparency. In retinitis, for instance, there is more or less dense and extensive opacity of its structure, and not unfrequently extravasations of blood into its substance. Hemorrhages may also take place into the retina from rupture of a blood-vessel without inflammation.

In optic neuritis, papillitis, or choked disk, the ophthalmoscope shows increase in vascularity, and swelling and opacity of the nerve, which extend beyond the disk margins. Optic atrophy is apt to follow. (Fig. 758 shows a normal optic disk.)

The retina may become displaced from effusion of serum between it and the choroid or by blows on the eyeball, or may occur without apparent cause in progressive myopia, and in this case the ophthalmoscope shows an opaque, tremulous cloud. Glioma, a form of sarcoma, and essentially a disease of early life, is occasionally met with in connection with the retina.

The lens has no blood-vessels, nerves, or connective tissue in its structure, and therefore is not subject to those morbid changes to which tissues containing these structures are liable. It does, however, present certain morbid or abnormal conditions of various kinds. Thus, variations in shape, absence of the whole or a part of the lens, and displacements are amongst its congenital defects. Opacities may occur from injury, senile changes, malnutrition, or errors in growth or development. An opacity of the capsule, of the lens, or of both, is known as a cataract. Senile changes may take place in the lens, impairing its elasticity and rendering it harder than in youth, so that its curvature can only be altered to a limited extent by the Ciliary muscle. And, finally, the lens may be dislocated or displaced by blows upon the eyeball, and its relations to surrounding structures altered by adhesions or the pressure of new growths.

There are two particular regions of the eye which require special notice: one of these is known as the "filtration area," and the other as the "dangerous area." The filtration area is the circumcorneal zone immediately in front of the iris. Here are situated the cavernous spaces of Fontana, which communicate with the canal of Schlemm, through which the chief transudation of fluid from the eye is now believed to take place. The dangerous area of the eye is the region in the neighborhood of the ciliary body, and wounds or injuries in this situation are peculiarly dangerous; for inflammation of the ciliary body is liable to spread to many of the other structures of the eye, especially to the iris and choroid, which are intimately connected by nervous and vascular supplies. Moreover, wounds which involve the ciliary region are especially liable to be followed by sympathetic ophthalmia, in which destructive inflammation of one eye is excited by some irritation in the other.

Emmetropia is normal vision. In normal vision the practically parallel light rays from distant objects focus on the retina without effort; divergent rays from near objects are focused on the retina by an effort of accommodation.

Hyperopia or hypermetropia is far-sightedness. In this condition the retina is in front of the principal focus when the eye is at rest. The patient endeavors to correct the failure by constant and tiresome efforts at accommodation. The condition is usually due to inordinate shortness of the axis of the eye, but may be due to loss of the lens, decreased convexity of the refractive surfaces, or lessened refractive power in the refractive media of the eye. It is corrected by the use of convex glasses.
**Myopia** is near-sightedness. In this condition the rays of light come to a focus in front of the retina, and the patient is subjected to continued eye-strain. It is usually due to too great length of the axis of the eye, but may result from increase in refractive power of refractive media. It is corrected by concave glasses. Sometimes, as a person with hyperopia begins to age, an increased refractive power of the lens causes myopia. The occurrence of myopia in a hyperopic eye is called *second sight*, and it enables the individual to cease wearing convex glasses.

Exenteration of the contents of the orbit means removal of all the contents except those at the orbital apex. Even the periosteum is taken away. It is performed for malignant disease.

Excision of the eyeball is performed by making a circular incision at the corneal margin and removing the internal and middle coats and the contents of the globe. The sclera is not removed. A glass ball is inserted into the scleral sheath, and the sclera is closed over the ball by vertical stitches, and the conjunctiva is closed over it by transverse stitches. The operation is performed for leucoma or staphyloma of the cornea. An artificial eye (a shell) is placed over the stump when healing is complete.

Excision, or excision of the eyeball, differs from exenteration of the orbital contents in the fact that only the eyeball is removed. A circular incision through the ocular conjunctiva is carried around and near to the corneal margin. The conjunctiva and capsule of Ténon are pushed back and the Rectus muscles are clamped and divided back of the clamp. Traction is made upon the globe in a forward and inward direction, and the optic nerve and adjacent structures are cut with scissors from the outer aspect of the globe. The eye is then pulled out of the orbit, and all structures which tend to retain it are divided. The stumps of the Recti muscles are sewed together.

**THE APPENDAGES OF THE EYE (TUTAMINA OCULI).**

The appendages of the eye include the *eyebrows*, the *eyelids*, the *conjunctiva*, and the *lachrymal apparatus*—viz., the *lachrymal gland*, the *lachrymal sac*, and the *nasal duct*.

**The Eyebrow (Supercilium).**

The eyebrows are two arched eminences of integument which surmount the upper circumference of the orbit on each side, and support numerous short, thick hairs, directed obliquely on the surface. The hairs may entangle foreign bodies and lessen somewhat the force of blows. In structure the eyebrows consist of thickened integument, connected beneath with the Orbicularis palpebrarum, Corrugator supercilli, and Occipito-frontalis muscles. These muscles serve, by their action on this part, to control to a certain extent the amount of light admitted into the eye.

**The Eyelid (Palpebra) (Figs. 760, 761).**

The eyelids are two thin, movable folds placed in front of the eye, and by closure protecting the eye from injury. The eyelids are composed of skin, superficial fascia, and areolar tissue, fibres of the Orbicularis palpebrarum muscle, palpebral and orbito-tarsal ligaments, tarsal cartilages, and conjunctiva. The upper lid also contains the Levator palpebrae superioris muscle. In the lids are blood-vessels, lymph-vessels, nerves, and Meibomian glands. There are two lids, the *upper* (*palpebra superior*) and the *lower* (*palpebra inferior*). The upper lid is the larger and the more movable of the two, and is furnished with a separate elevator muscle, the *Levator palpebrae superioris*. Each lid consists of two portions. The part near the orbital margin, "whose groundwork is formed merely by the *thin palpebral fascia (septum orbitale)"", is called the *orbital portion* (*pars orbitalis*). The part in which the tarsus lies is called the *tarsal portion* (*pars tarsalis*). Between the two portions in each lid is a sulcus, called, in the upper lid, the *superior orbito-palpebral sulcus* (*sulcus orbitopalpebralis superior*), and, in the lower lid, the *inferior orbito-palpebral sulcus* (*sulcus orbitopalpebralis inferior*). When the eyelids are

---

open an elliptical space, the **interpalpebral slit** (*fissura palpebrarum*), is left between their margins, the angles of which correspond to the junction of the upper and lower lids, and are called **canthi**.

**The Canthi.**—The *outer canthus* (*angulus oculi lateralis*) is more acute than the inner, and the lids here lie in close contact with the globe; but the *inner canthus* (*angulus oculi medialis*) is prolonged for a short distance inward toward the nose. The two lids are separated at the inner canthus by a triangular space, the **lacus lacrimalis**. At the commencement of the lacus lacrimalis, on the margin of each eyelid, is a small conical elevation, the **lachrymal papilla**, the apex of which is pierced by a small orifice, the **punctum lacrimale** (Fig. 764), the commencement of the lachrymal canal (Fig. 763). When the lids are closed a space remains between them and the globe to permit of the flow of tears inward (*rivus lacrimalis*).

**The Eyelashes** (*cilia*) (Fig. 761).—The eyelashes are attached to the free edges of the eyelids; they are short, thick, curved hairs, arranged in a double or triple row at the margin of the lids; those of the upper lid, more numerous and longer than the lower, curve upward; those of the lower lid curve downward. Because of this arrangement the two sets do not interlace in closing the lids. Near the attachment of the eyelashes are the openings of **sebaceous glands** (*glandulae sebaceae*) (Fig. 761) and of a number of glands, **glands of Moll** (*glandulae ciliares [Moll]*) (Fig. 761), arranged in several rows close to the free margin of the lid. They are regarded as enlarged and modified sweat-glands. On the inner surface are the **Meibomian glands** (Fig. 763). Internal to the openings of the lachrymal canaliculi there are neither lashes nor Meibomian glands.

---

**Structure of the Eyelids** (Fig. 761).—The eyelids are composed of the following structures, taken in their order from without inward:

Integument, areolar tissue, fibres of the Orbicularis muscle, tarsal plate, and its ligament, Meibomian glands, and conjunctiva. The upper lid has, in addition, the aponeurosis of the Levator palpebrae.

The **integument** is extremely thin, and continuous at the margin of the lids with the conjunctiva.

The **subcutaneous areolar tissue** is very lax and delicate, seldom contains any fat, and is extremely liable to serous infiltration.

The **fibres of the Orbicularis muscle**, where they cover the palpebrae (*m. ciliaris [Rioland]*) , are thin, pale in color, and possess an involuntary action.
The tarsal plates are two thin elongated plates of dense connective tissue about an inch in length. They are placed one in each lid, contributing to their form and support.

The superior tarsal plate, superior tarsus or superior tarsal body (tarsus superior) (Fig. 760), the larger, is of a semilunar form, about one-third of an inch in breadth at the centre, and becoming gradually narrowed at each extremity. To the anterior surface of this plate the aponeurosis of the Levator palpebrae is attached.

The inferior tarsal plate, inferior tarsus or inferior tarsal body (tarsus inferior) (Fig. 760), the smaller of the two, is thinner and of an elliptical form.

The free or ciliary margin of these plates is thick, and presents a perfectly straight edge. The attached or orbital margin is connected to the circumference of the orbit by the fibrous membrane of the lids, with which it is continuous. The outer angle of each plate is attached to the malar bone by the external tarsal or external lateral ligament, or the external palpebral ligament or raphé (ligamentum palpebrale lateralis) (Fig. 760). The inner angles of the two plates terminate at the commencement of the lacus lacrimalis; they are attached to the nasal process of the superior maxilla by the internal tarsal or internal lateral or internal palpebral ligament or the tendo oculi (ligamentum palpebrale mediale) (Fig. 760).

The fibrous membrane of the lids constitutes the orbito-tarsal ligaments or the palpebral fasciae. In reality these so-called ligaments are fascial expansions situated one in each lid, and are attached marginally to the edge of the orbit, where they are continuous with the periosteum. The superior ligament blends with the tendon of the Levator palpebrae, the inferior with the inferior tarsal plate. Externally the superior and inferior ligaments fuse to form the external tarsal ligament or raphé just referred to; internally they are much thinner, and, becoming separated from the internal tarsal ligament, are fixed to the lachrymal bone immediately behind the lachrymal sac. Together the ligaments form an incomplete septum, the orbital septum (septum orbitale), which is perforated by the vessels and nerves which pass from the orbital cavity to the face and scalp.

The Meibomian or Tarsal Glands (glandulae tarsales [Meibomi]) (Figs. 761 and 763) — The Meibomian or tarsal glands are situated upon the inner surface of the eyelids between the tarsal plates and conjunctiva, and may be distinctly seen through the mucous membrane on evertting the eyelids, presenting the appearance of parallel strings of pearls. They are about thirty in number in the upper eyelid, and somewhat fewer in the lower. They are embedded in grooves in the inner
surface of the tarsal plates, and correspond in length with the breadth of each plate; they are, consequently, longer in the upper than in the lower eyelid. Their ducts open on the free margin of the lids by minute foramina, which correspond in number to the follicles. The use of their secretion is to prevent adhesions of the lids.

Structure of the Meibomian Glands.—These glands are a variety of the cutaneous sebaceous glands, each consisting of a single straight tube or follicle, having a caecal termination, and with numerous small secondary follicles opening into it. The tubes consist of basement-membrane, lined at the mouths of the tubes by stratified epithelium; the deeper parts of the tubes and the secondary follicles are lined by a layer of polyhedral cells. They are thus identical in structure with the sebaceous glands.

The Conjunctiva (Figs. 727, 728, 740, 762).

The conjunctiva is the mucous membrane of the eye. It lines the inner surface of the eyelids, is reflected over the forepart of the sclerotic and cornea, and joins the lids to the eyeball. In each of these situations its structure presents some peculiarities.

The Palpebral Portion (tunica conjunctiva palpebrarum) (Fig. 763).—The palpebral portion of the conjunctiva lines the posterior surface of the lids. It is thick, opaque, highly vascular, and covered with numerous papillae, its deeper parts presenting a considerable amount of lymphoid tissue. At the margin of the lids it becomes continuous with the lining membrane of the ducts of the Meibomian glands, and, through the lachrymal canals, with the lining membrane of the lachrymal sac and nasal duct. At the outer angle of the upper lid the lachrymal ducts open on its free surface; and at the inner angle of the eye it forms a semi-lunar fold, the plica semilunaris (plica semilunaris conjunctiva) (Fig. 764). The folds formed by the reflection of the conjunctiva from the lids on to the eye are called the superior and inferior palpebral folds, the former being the deeper of the two. These folds form the superior and inferior conjunctival fornix (Fig. 762).

The Bulbar Portion (tunica conjunctiva bulbi).—Upon the sclerotic the conjunctiva is loosely connected to the globe; it becomes thinner, loses its papillary structure, is transparent, and only slightly vascular in health. Upon the cornea the conjunctiva consists only of epithelium, constituting the anterior layer of the cornea (conjunctival epithelium) already described (p. 1119). Lymphatics arise in the conjunctiva in a delicate zone around the cornea, from which the vessels run to the ocular conjunctiva.

Fornix of Conjunctiva. — At the point of reflection of each fold of the conjunctiva from the lid on to the globe of the eye a pocket or arch is formed. These arches are termed the fornix conjunctivae (Fig. 762).

Glands of Conjunctiva.—In the conjunctiva there are a number of mucous glands which are much convoluted. They are chiefly found in the upper lid. Other glands, analogous to lymphoid follicles, and called by Henle *trachoma glands*, are found in the conjunctiva, and, according to Stromeeyer, are chiefly situated near the inner canthus of the eye. They were first described by Brush, in his description of Peyer's patches of the small intestines, as "identical structures existing in the under eyelid of the ox."

The Nerves of the Conjunctiva. — The nerves in the conjunctiva are numerous and form rich plexuses. According to Krause, they terminate in a peculiar form of tactile corpuscle, which he terms the *terminal bulb*.

The Caruncula Lacrimalis.—The caruncula lacrimalis is a small, reddish, conical-shaped body, situated at the inner canthus of the eye, and filling up the small
triangular space in this situation, the lacus lacrimalis. It consists of an island of skin containing sebaceous and sweat-glands, and is the source of the whitish secretion which constantly collects at the inner angle of the eye. A few slender hairs are attached to its surface. On the outer side of the caruncula is a slight semilunar fold of conjunctiva, the concavity of which is directed toward the cornea; it is called the plica semilunaris (Fig. 764). Müller found smooth muscular fibres in this fold, and in some of the domesticated animals a thin plate of cartilage has been discovered. This structure is considered to be the rudiment of the third eyelid in birds, the membrana nictitans.

**The Lachrymal Apparatus (Apparatus Lacrimaïis)** (Figs. 763, 764).

The lachrymal apparatus consists of the lachrymal gland, which secretes the tears, and its excretory ducts, which convey the fluid to the surface of the eye. This fluid is carried away by the lachrymal canals into the lachrymal sac, and along the nasal duct into the cavity of the nose.

**The Lachrymal Glands** (glandula lacrimalis).—The lachrymal gland is lodged in a depression at the outer angle of the orbit, on the inner side of the external angular process of the frontal bone. It is of an oval form, about the size and shape of an almond. Its upper convex surface is in contact with the periosteum of the orbit, to which it is connected by a few fibrous bands. Its under concave surface rests upon the convexity of the eyeball and upon the Superior and External recti muscles. Its vessels and nerves enter its posterior border, whilst its anterior margin is closely adherent to the back part of the upper eyelid, where it is covered to a slight extent by the reflection of the conjunctiva. The forepart of the gland is separated from the rest by a fibrous septum; hence it is sometimes described as a separate lobe, called the inferior lachrymal gland, palpebral portion of the gland, or the accessory gland of Rosenmuller (glandula lacrimalis inferior), the back part of the gland then being called the superior lachrymal gland (glandula lacrimalis superior). The ducts of the lachrymal gland, from six to twelve in number, run obliquely beneath the mucous membrane for a short distance, and, separating from each other, open by a series of minute orifices on the upper and outer half of the conjunctiva near its reflection on to the globe. These orifices are arranged in a row, so as to disperse the secretion over the surface of the membrane.

**Structure of the Lachrymal Gland.**—In structure and general appearance the lachrymal resembles the serous salivary glands. In the recent state the cells are so
crowded with granules that their limits can hardly be defined. Each cell contains an oval nucleus, and the cell-protoplasm is finely fibrillated.

The Lachrymal Canaliculi or Canals (Fig. 764) commence at the minute orifices, puncta lacrimalia, on the summit of a small conical elevation, the lachrymal papilla or caruncle (carunculus lacrimalis), seen on the margin of the lids at the outer extremity of the lacus lacrimalis. The superior canal (ductus lacrimalis superior), the smaller and shorter of the two, at first ascends, and then bends at an acute angle, and passes inward and downward to the ampulla. The inferior canal (ductus lacrimalis inferior) at first descends, and then, abruptly changing its course, passes almost horizontally inward to the ampulla. These canals are dense and elastic in structure and somewhat dilated at their angle. The mucous membrane is covered with scaly epithelium. The two canals join in a dilatation, the ampulla (ampulla ductus lacrimalis), which empties into the lachrymal sac.

The Lachrymal Sac (saccus lacrimalis) (Fig. 764).—The lachrymal sac is the upper dilated extremity of the nasal duct, and is lodged in a deep groove formed by the lachrymal bone and the nasal process of the superior maxillary bone. It is oval in form, its upper extremity being closed in and rounded, whilst below it is continued into the nasal duct. It is covered by a fibrous expansion derived from the tendo oculi, and on its deep surface it is crossed by the Tensor tarsi muscle (Horner’s muscle, p. 373), which is attached to the ridge on the lachrymal bone.

Structure.—It consists of a fibrous elastic coat, lined internally by mucous membrane, the latter being continuous, through the ampulla and lachrymal canals, with the mucous lining of the conjunctiva, and, through the nasal duct, with the pituitary membrane of the nose.

The Nasal Duct (ductus nasolacrimalis) (Fig. 764).—The nasal duct is a membranous canal, about three-quarters of an inch in length, which extends from the lower part of the lachrymal sac to the inferior meatus of the nose, where it terminates by a somewhat expanded orifice, provided with an imperfect valve, the valve of Hasner (plica lacrimalis [Hasneri]), formed by the mucous membrane. It is contained in an osseous canal formed by the superior maxillary, the lachrymal, and the inferior turbinated bones, is narrower in the middle than at each extremity, and takes a direction downward, backward, and a little outward. It is lined by mucous membrane, which is continuous below with the pituitary lining of the nose. The membrane in the lachrymal sac and nasal duct is covered with columnar epithelium, as in the nose. This epithelium is in places ciliated.

Surface Form.—The palpebral fissure, or opening between the eyelids, is elliptical in shape, and differs in size in different individuals and in different races of mankind. In the Mongolian races, for instance, the opening is very small, merely a narrow fissure, and this makes the eyeball appear small in these races, whereas the size of the eye is relatively very constant. The normal direction of the fissure is slightly oblique, in a direction upward and outward, so that the outer angle is on a slightly higher level than the inner. This is especially noticeable in the Mongolian races, in whom, owing to the upward projection of the malar bone and the shortness of the external angular process of the frontal bone, the tarsal plate of the upper lid is raised at its outer part and gives an oblique direction to the palpebral fissure.
When the eyes are directed forward, as in ordinary vision, the upper part of the cornea is covered by the upper lid, and the lower margin of the cornea corresponds to the level of the lower lid, so that about the lower three-fourths of the cornea is exposed under ordinary circumstances. On the margins of the lids, about a quarter of an inch from the inner canthus, are two small openings, the puncta lachrymalis, the commencement of the lachrymal canals. They are best seen by exerting the eyelids. In the natural condition they are in contact with the conjunctiva of the eyeball, and are maintained in this position by the Tensor tarsi muscle, so that the tears running over the surface of the globe easily find their way into the lachrymal canals. The position of the lachrymal sac into which the canals open is indicated by a little tubercle, which is plainly to be felt on the lower margin of the orbit. The lachrymal sac lies immediately above and to the inner side of this tubercle, and a knife passed through the skin in this situation would open the cavity. The position of the lachrymal sac may also be indicated by the tendo oculi or internal tarsal ligament. If both lids be drawn outward, so as to tense the skin at the inner angle, a prominent cord will be seen beneath the thickened skin. This is the tendo oculi, which lies immediately over the lachrymal sac, bisecting it, and thus forming a useful guide to its situation. A knife entered immediately beneath the tense cord would open the lower part of the sac. A probe introduced through this opening can be readily passed downward through the duct into the inferior meatus of the nose. The direction of the duct is downward, outward, and backward, and this course should be borne in mind in passing the probe, otherwise the point may be driven through the thin bony walls of the canal. A convenient plan is to direct the probe in such a manner that if it were pushed onward it would strike the first molar tooth of the lower jaw on the same side of the body. In other words, the surgeon standing in front of his patient should carry in his mind the position of the first molar tooth, and should push his probe onward in such a way as if he desired to reach this structure.

Beneath the internal angular process of the frontal bone the pulley of the Superior oblique muscle of the eye can be plainly felt by pushing the finger backward between the upper and inner angle of the eye and the roof of the orbit; passing backward and outward from this pulley, the tendon can be felt for a short distance.

Surgical Anatomy.—The eyelids are composed of various tissues, and consequently are liable to a variety of diseases. The skin which covers them is exceedingly thin and delicate, and is supported on a quantity of loose and lax subeutaneous tissue which contains no fat. In consequence of this it is very freely movable, and is liable to be drawn down by the contraction of neighboring cicatrices. Such contractions may produce an elision of the lid known as ectropion. Inversion of the lids (entropion) from spasm of the Orbicularis palpbralorum or from chronic inflammation of the palpebral conjunctiva may also occur. In some individuals there is an extra row of eyelashes on the inner margin of the lid, directed toward the cornea (distichiasis). Trichiasis is a condition in which the lashes are directed toward the eye, but there is not inversion of the lid. The eyelids are richly supplied with blood, and are often the seat of vascular growths, such as navi. Rodent ulcer also frequently commences in this situation. The loose cellular tissue beneath the skin is liable to become extensively infiltrated either with blood or inflammatory products, producing very great swelling. Even from very slight injuries to this tissue the extravasation of blood may be so great as to produce considerable swelling of the lids and complete closure of the eye, and the same is the case when inflammatory products are poured out. The follicles are liable to become inflamed, constituting the disease known as marginal blepharitis, blepharitis ciliaris, or "blear-eye." Irregular or disorderly growth of the eyelashes not frequently occurs, some of them being turned toward the eyeball and producing inflammation and follicles of the eyelashes or the sebaceous glands associated with these follicles may be the seat of inflammation, constituting the ordinary hordeolum or "sty." The Meibomian glands are affected in the so-called "tarsal tumors," the tumor, according to some, being caused by the retained secretion of these glands; by others it is believed to be a neoplasm connected with the gland. The Orbicularis palpbralorum may be the seat of spasm (blepharospasm), either in the form of slight quivering of the lids or repeated twitchings, most commonly due to errors of refraction in children, or more continuous spasm, due to some irritation of the fifth or seventh cranial nerves. The Orbicularis may be paralyzed, generally associated with paralysis of the other facial muscles. Under these circumstances the patient is unable to close the lids, and if he attempts to do so, rolls the eyeball upward under the upper lid. The tears overflow from displacement of the lower lid, and the conjunctiva and cornea, being constantly exposed and the patient being unable to wink, become irritated from dust and foreign bodies. As a result there may be ulceration of the cornea, and possibly eventually complete destruction of the eye. In paralysis of the Levator palpbrae superioris there is drooping of the upper eyelid (ptosis) and other symptoms of implication of the third nerve. The eyelids may be the seat of bruises, wounds, or burns. After wounds or burns adhesions of the margins of the lids to each other or adhesion of the lids to the globe may take place. The eyelids are sometimes the seat of emphysema after fracture of some of the thin bones forming the inner wall of the orbit. If shortly after such an injury the patient blows his nose, air is forced from the nostrils through the lacerated structure into the
connective tissue of the eyelids, which suddenly swell up and present the peculiar crackling on pressure which is characteristic of this affection.

Foreign bodies frequently get into the conjunctival sac and cause great pain, especially if they come in contact with the corneal surface, during the movements of the lid and the eye on each other. The conjunctiva is frequently involved in severe injuries of the eyeball, but is seldom ruptured alone; the most common form of injury to the conjunctiva alone is from a burn, either from fire, strong acids, or lime. In these cases union is liable to take place between the eyelid and the eyeball. The conjunctiva is often the seat of inflammation arising from many different causes, and the arrangement of the conjunctival vessels should be remembered as affording a means of diagnosis between this condition and injection of the sclerotic, which is present in inflammation of the deeper structures of the globe. The inflamed conjunctiva is bright red; the vessels are large and tortuous, and greatest at the circumference, shading off toward the corneal margin; they anastomose freely and form a dense network, and they can be emptied by gentle pressure.

The lacrimal gland is occasionally, though rarely, the seat of inflammation (dacyroadenitis), either acute or chronic; it is also sometimes the seat of tumors, benign or malignant, and for these may require removal. This may be done by an incision through the skin just below the eyebrow; and the gland, being invested with a special capsule of its own, may be isolated and removed without opening the general cavity of the orbit. The canaliculi may be obstructed, either as a congenital defect or by some foreign body, as an eyelash or a dacryolith, causing the tears to run over the cheek. The canaliculi may also become occluded as the result of burns or injury; overflow of tears may in addition result from deviation of the puncta or from chronic inflammation of the lacrimal sac. When there is failure of the lacrimal tubes to drain off the tears and the fluid gathers beneath and flows over the lids, the condition is known as epiphora or stilićidium. This latter condition is set up by some obstruction to the nasal duct frequently occurring in tuberculous subjects. In consequence of this the tears and mucus accumulate in the lacrimal sac, distending it. Suppuration in the lacrimal sac (dacyrocytitis) is sometimes met with; this may be the sequel of a chronic inflammation; or may occur after some of the eruptive fevers in cases where the lacrimal passages were previously quite healthy. It may lead to lacrimal fistula.

THE EAR (ORGANON AUDITUS).

The organ of hearing is divisible into three parts—the external ear, the middle ear or tympanum, and the internal ear or labyrinth.

THE EXTERNAL EAR (AURIS EXTERNA).

The external ear consists of an expanded portion named pinna or auricle, and the auditory canal or meatus. The former serves to collect the vibrations of the air by which sound is produced; the latter conducts those vibrations to the tympanum.

The Pinna or Auricle (Auricula) (Fig. 765).

The pinna or auricle is attached to the side of the head midway between the forehead and occiput. "Its level is indicated by horizontal lines extending backward from the eyebrows above and from the tip of the nose below." (Hensman.) It is of an ovoid form, with its larger end directed upward. Its outer surface is irregularly concave, directed slightly forward. The angle which it bears to the head is called the cephalo-auricular angle. In some cases this angle is almost absent. In others it is nearly a right angle. The pinna of one side may vary in size, shape, and angle from the pinna of the other side. The pinna of a woman is apt to be smaller than that of a man, and is less often deformed. The outer surface of the pinna presents numerous eminences and depressions which result from the foldings of its fibro-cartilaginous element. To each of these, names have been assigned. Thus the external prominent rim of the auricle is called the helix. Another curved prominence, parallel with and in front of the helix, is called the antihelix; this bifurcates above and forms the crus (crura antihelicis), which encloses a triangular depression, the fossa of the antihelix (fossa triangularis [auriculae]). The narrow curved depression between the helix and antihelix is called the fossa of the helix or the scaphoid
fossa (scapha); the antihelix describes a curve around a deep, capacious cavity, the concha auriculae, which is partially divided into two parts by the crus of the helix (crus helicis), or the commencement of the helix; the upper part is termed the cymba-

conchae, the lower part the cavum conchae. In front of the concha, and projecting backward over the meatus, is a small pointed eminence, the tragus, so called from its being generally covered on its under surface with a tuft of hair resembling a goat's beard. Opposite the tragus, and separated from it by a deep notch (incisura intertragica), is a small tubercle, the antitragus. Below this is the lobule (lobulus auriculae), composed of tough areolar and adipose tissue, wanting the firmness and elasticity of the rest of the pinna. Sometimes the lobule does not hang freely, but is adherent. Where the helix turns downward a small tubercle, tubercle of Darwin (tuberculum auriculae [Darwini]), is frequently seen. This tubercle is very evident about the sixth month of foetal life; at this stage the human pinna has a close resemblance to that of some of the adult monkeys.
The cranial surface of the pinna presents elevations which correspond to the depressions on its outer surface and after which they are named, e.g., eminentia conchae, eminentia fossae triangularis, etc.

The eminentia conchae and the fossae triangularis are separated by a furrow (sulcus antihelicis transversus), which corresponds to the inferior crus of the antihelix, or groove (sulcus cruris helicis), and upon the eminence there is a vertical ridge, the ponticus, which indicates the point of insertion of the Retrahens auriculam muscle.

**Structure of the Pinna.**—The pinna is composed of a thin plate of yellow fibro-cartilage, covered with integument, and connected to the surrounding parts by the extrinsic ligaments and muscles, and to the commencement of the external auditory canal by fibrous tissue.

**The Integument.**—The integument is thin, closely adherent to the cartilage, and covered with hairs furnished with sebaceous glands, which are most numerous in the concha and scaphoid fossa. The hairs are most numerous and largest on the tragus and antitragus.

**The Cartilage of the Pinna** (cartilago auriculare) (Fig. 767).—The cartilage of the pinna consists of one single piece; it gives form to this part of the ear, and upon its surface are found all the eminences and depressions above described. It does not enter into the construction of all parts of the auricle; thus it does not form a constituent part of the lobule; it is deficient also between the lamina of the tragus and beginning of the crus helix, the notch between (incisura terminalis auris) them being filled up by dense fibrous tissue. At the front part of the pinna, where the helix bends upward, is a small projection of cartilage, called the spine of the helix (spina helicis), while the lower part of the helix is prolonged downward as a tail-like process, the cauda helicis; this is separated from the antihelix by a fissure, the fissura antitragohelicina. The fissures of Santorini are usually two in number: one in the substance of the tragus, which partially separates the different parts, and one in the cartilage of the meatus. The fissure of the helix is a short vertical slit, situated at the forepart of the pinna. Another fissure, the fissure of the tragus, is seen upon the anterior surface of the tragus. Anteriorly and inferiorly the cartilage of the pinna is continuous with the cartilage of the external auditory meatus by a cartilaginous isthmus (isthmus cartilaginis auris). Some authors regard the tragus as part of the cartilage of the meatus. The cartilage of the pinna is very pliable, elastic, of a yellowish color and belongs to that form of cartilage which is known under the name of yellow fibro-cartilage.

**The Ligaments of the Pinna** (ligamenti auriculare [Valsalvæ]).—The ligaments of the pinna consist of two sets: 1. The extrinsic set, or those connecting it to the side of the head. 2. The intrinsic set, or those connecting the various parts of its cartilage together.

The Extrinsic Ligaments, the most important, are three in number: superior, anterior, and posterior. The superior ligament (ligamentum auriculare superioris) extends from the suprameatal spine to the spine of the helix. The anterior ligament (ligamentum auriculare anterius) extends from the spina helicis and tragus to the
root of the zygoma. The posterior ligament (ligamentum auriculare posterius) passes from the posterior surface of the concha to the outer surface of the mastoid process of the temporal bone.

The chief Intrinsic Ligaments are: (1) a strong fibrous band, stretching across from the tragus to the commencement of the helix, completing the meatus in front, and partly encircling the boundary of the concha; and (2) a band which extends between the antihelix and the cauda helicis. Other less important bands are found on the cranial surface of the pinna.

The Muscles of the Pinna (Figs. 766 and 768).—The muscles of the pinna consist of two sets: 1. The extrinsic, which connect it with the side of the head, moving the pinna as a whole—viz., the Attollens, Attrahens, and Retrahens auriculam (p. 372). 2. The intrinsic, which extend from one part of the auricle to another, viz.:

- Helicis major
- Helicis minor
- Tragicus
- Antitragicus
- Transversus auriculae
- Obliquus auriculae

The Helicis Major (m. helicis major) is a narrow vertical band of muscular fibres, situated upon the anterior margin of the helix. It arises, below, from the spina helicis, and is inserted into the anterior border of the helix, just where it is about to curve backward. It is pretty constant in its existence.

The Helicis Minor (m. helicis minor) is an oblique fasciculur which covers the crus helicis.

The Tragicus (m. tragicus) is a short, flattened band of muscular fibres situated upon the outer surface of the tragus, the direction of its fibres being vertical.

The Antitragicus (m. antitragicus) arises from the outer part of the antitragus; its fibres are inserted into the cauda helicis and antihelix. This muscle is usually very distinct.

The Transversus Auriculæ (m. transversus auriculæ) is placed on the cranial surface of the pinna. It consists of scattered fibres, partly tendinous and partly muscular, extending from the convexity of the concha to the prominence corresponding with the groove of the helix.

The Obliquus Auriculæ (Tod) (m. obliquus auriculæ) consists of a few fibres extending from the upper and back part of the concha to the convexity immediately above it.

The Arteries of the Pinna.—The arteries of the pinna are the posterior auricular from the external carotid, the anterior auricular from the temporal and an auricular branch from the occipital artery.

The Veins of the Pinna.—The veins of the pinna accompany the corresponding arteries.

The Lymphatics of the Pinna.—The lymphatics enter into the pre-auricular glands and the glands upon the Sterno-mastoid muscle at its insertion.
The Nerves of the Pinna.—The nerves of the pinna are: the great auricular, from the cervical plexus; the auricular branch of the vagus; the auriculo-temporal branch of the inferior maxillary nerve; the small occipital from the cervical plexus, and the great occipital or internal branch of the dorsal division of the second cervical nerve. The muscles of the pinna are supplied by the facial nerve.

The External Auditory or External Acoustic Canal or External Auditory Meatus (Meatus Acusticus Externus or Meatus Auditorius Externus).

The external auditory or acoustic canal or meatus extends from the bottom of the concha to the membrana tympani (Figs. 765, 769, and 770). It is about an inch and a half in length if measured from the tragus; from the bottom of the concha its length is about an inch. It forms a sort of S-shaped curve, and is directed at first inward, forward, and slightly upward (pars externa); it then passes inward and backward (pars media), and lastly is carried inward, forward, and slightly downward (pars interna). It forms an oval cylindrical canal, the greatest diameter being in the vertical direction at the external orifice, but in the transverse direction at the tympanic end. It presents two constrictions, one near the inner end of the cartilaginous portion, and another, the isthmus, in the osseous portion, about three-quarters of an inch from the bottom of the concha. The membrana tympani (Figs. 769 and 770), which occupies the termination of the meatus, is directed obliquely, in consequence of which the floor of the canal is longer than the roof, and the anterior wall longer than the posterior. The auditory canal is formed partly by cartilage and membrane, partly by bone, and is lined by perichondrium and periosteum, which is covered with skin.

The Cartilaginous Portion (meatus acusticus externus cartilagineus).—The cartilaginous portion is about one-third of an inch (8 mm.) in length; it is formed by the cartilage of the pinna, prolonged inward, and firmly attached to a greater portion of the circumference of the auditory process of the temporal bone. The cartilage is deficient at its upper and back part, its place being supplied by fibrous membrane. This part of the canal is rendered extremely movable by two or three deep fissures, the fissures of Santorini (incisurae cartilaginis meatus acustici externi [Santorini]), which extend through the cartilage in a vertical direction. It is firmly attached at its lower and front part to the middle root of the zygoma and to the lateral edge of the tympanic portion of the temporal bone.
The Osseous Portion (meatus acusticus externus osseus).—The osseous portion is about two-thirds of an inch (16 mm.) in length, and narrower than the cartilaginous portion. It is directed inward and a little forward, forming a slight curve in its course, the convexity of which is upward and backward. Its inner end, which communicates, in the dry bone, with the cavity of the tympanum, is smaller than the outer and sloped, the anterior wall projecting beyond the posterior about two lines; it is marked, except at its upper part, by a narrow groove, the tympanic sulcus (sulcus tympanicus), for the insertion of the membrana tympani. Its outer edge is dilated and rough in the greater part of its circumference, for the attachment of the cartilage of the pinna. Its vertical transverse section is oval, the greatest diameter being from above downward. The front and lower parts of this canal are formed by a curved plate of bone, which, in the foetus, exists as a separate ring (annulus tympanicus), incomplete at its upper part. (See Section on Osteology.)

The Skin of the Meatus.—The skin lining the meatus is a prolongation of the external skin; it is thin, adheres closely to the cartilaginous and osseous portions of the tube, and covers the surface of the membrana tympani, forming a very thin outer layer. After maceration the thin pouch of epidermis, when withdrawn, preserves the form of the meatus. In the thick subcutaneous tissue of the cartilaginous part of the meatus are numerous ceruminous glands (glandulae ceruminosae) which secrete the ear-wax. They resemble in structure sweat-glands, and their ducts open on the surface of the skin.

Relations of the Meatus.—In front of the osseous part is the glenoid fossa, which receives the condyle of the mandible (Fig. 762), which, however, is separated from the cartilaginous part by the retromandibular part of the parotid gland. The movements of the jaw influence to some extent the lumen of the cartilaginous portion. Behind the osseous part are the mastoid air-cells (cellulae mastoideae), separated from it by a thin layer of bone (Fig. 46).

The Arteries of the External Meatus.—The arteries supplying the external meatus are branches from the posterior auricular, internal maxillary, and superficial temporal.
The Veins of the External Meatus.—Veins accompany the corresponding arteries and pass to the internal maxillary, temporal, and posterior auricular veins.

The Lymphatics of the External Meatus.—The lymphatics accompany the veins and enter the parotid and posterior auricular lymph-glands.

The Nerves of the External Meatus.—The nerves are derived from the auriculotemporal branch of the inferior maxillary nerve, the auriculotemporalis magnus, and the auricular branch of the vagus.

Surface Form.—The point of junction of the osseous and cartilaginous portions of the tube is an obtuse angle, which projects into the canal at its antero-inferior wall. This produces a sort of constriction in this situation, and renders it the narrowest portion of the canal—an important point to be borne in mind in connection with the presence of foreign bodies in the ear. The cartilaginous is connected to the bony part by fibrous tissue, which renders the outer part of the tube very movable, and therefore by drawing the pinna upward and backward the canal is rendered almost straight. At the external orifice are a few short, crisp hairs which serve to prevent the entrance of small particles of dust, flies or other insects. In the external auditory meatus the secretion of the ceruminous glands serves to catch any small particles which may find their way into the canal, and prevent their reaching the membrana tympani, where their presence might excite irritation. In young children the meatus is short, the osseous part being very deficient, and consisting merely of a bony ring (annulus tympanicus), which supports the membrana tympani. In the fetus the osseous part is entirely absent. The shortness of the canal in children should be borne in mind in introducing the aural speculum, so that it shall not be pushed in too far, at the risk of injuring the membrana tympani; indeed, even in the adult the speculum should never be introduced beyond the constriction which marks the junction of the osseous and cartilaginous portions. In using this instrument it is advisable that the pinna should be drawn upward, backward, and a little outward, so as to render the canal as straight as possible, and thus assist the operator in obtaining, by the aid of reflected light, a good view of the membrana tympani. Just in front of the membrane is a well-marked depression, situated on the floor of the canal and bounded by a somewhat prominent ridge; in this foreign bodies may become lodged. By aid of the speculum, combined with traction of the auricle upward and backward, the whole of the membrana tympani is rendered visible. It is a pearly-gray membrane, slightly glistening in the adult, placed obliquely, so as to form with the floor of the meatus a very acute angle (about 55 degrees), while with the roof it forms an obtuse angle. At birth it is more horizontal—being situated in almost the same plane as the base of the skull. About midway between the anterior and posterior margins of the membrane, and extending from the centre obliquely upward, is a reddish-yellow streak; this is the handle of the malleus, which is inserted into the membrane (Fig. 773). At the upper part of this streak, close to the roof of the meatus, a little white rounded prominence is plainly to be seen; this is the processus brevis of the malleus, projecting against the membrane. The membrana tympani does not present a plane surface; on the contrary, its centre is drawn inward, on account of its connection with the handle of the malleus, and thus the external surface is rendered concave.

**THE MIDDLE EAR, DRUM OR TYMPANUM (AURIS MEDIA)**

(Figs. 769, 770, 771, 775).

The middle ear or tympanum is an irregular cavity, compressed from without inward, and is situated within the petrous portion of the temporal bone. It is placed above the jugular fossa; the carotid canal lying in front, the mastoid cells behind, the external auditory meatus externally, and the labyrinth internally. It is lined with mucous membrane, is filled with air, and communicates with the mastoid cells, and with the naso-pharynx by the Eustachian tube. The tympanum is traversed by a chain of movable bones, which connect the membrana tympani with the labyrinth, and serve to convey the vibrations communicated to the membrana tympani across the cavity of the tympanum to the internal ear. In shape it is roughly biconcave, the concave surfaces being placed vertically and forming the external and internal walls. The cavity forms an angle of 45 degrees with the median plane (Spalteholz).

The Tympanic Cavity (cavum tympani) (Figs. 775 and 776).—The tympanic cavity consists of two parts: the atrium or tympanic cavity proper (Fig. 776), opposite the tympanic membrane, and the attic or epitympanic recess or aditus ad antrum (recessus epitympanicus) (Figs. 774 and 775), above the level of the
upper part of the membrane; the latter contains the upper half of the malleus and the greater part of the incus. The diameter of the tympanic cavity, including the attic, measures about \( \frac{3}{8} \) inch (15 mm.) vertically and transversely. From without inward it measures about \( \frac{1}{4} \) inch (6 mm.) above and \( \frac{1}{4} \) inch (4 mm.) below; opposite the centre of the tympanic membrane it is only about \( \frac{1}{10} \) inch (2 mm.). It is bounded externally by the membrana tympani and neatus; internally, by the outer surface of the internal ear; and communicates behind with the mastoid antrum and through it with the mastoid cells; and in front with the Eustachian tube and canal for the Tensor tympani. Its roof and floor are formed by thin osseous laminae, the one forming the roof being a thin plate situated on the anterior surface of the petrous portion of the temporal bone, close to its angle of junction with the squamous portion of the same bone.

The Roof of the Tympanum (paries tegmental).—The roof of the tympanum is broad, flattened, and formed of a thin plate of bone (tegmen tympani) (Fig. 775), which separates the cranial and tympanic cavities. It is prolonged backward so as to roof in the mastoid antrum; it is also carried forward to cover in the canal for the Tensor tympani muscle.

The Floor (paries jugularis) (Fig. 775).—The floor is narrow, and is separated by a thin plate of bone (fondus tympani) from the jugular fossa. It frequently presents numerous small notches in the bone (cellulae tympanicae). There is one small aperture in the floor. It is near the inner wall and is the opening of the canaliculus tympanicus, for the transmission of Jacobson’s nerve (n. tympanicus). On the floor near the posterior wall there is often to be found a slight bony projection (prominentia styloidea).

The Outer Wall (Fig. 770).—The outer wall is formed mainly by the membrana tympani, partly by the ring of bone into which this membrane is inserted. This part formed by the membrana tympanum is called the paries membranaceus. This ring of bone is incomplete at its upper part, forming a notch, the notch of Rivinus (incisura tympanica [Rivini]) (Fig. 773). The anterior edge of the notch is known as the spina tympanica major, the posterior edge as the spina tympanica minor. The groove for the reception of the membrana tympani is the sulcus tympanicus. Close to the notch are three small apertures: the iter chordae posterior, the Glaserian fissure, and the iter chordae anterius.

The iter chordae posterior or the tympanic aperture (canaliculus chordae tympani) (Fig. 774) is in the angle of junction between the posterior and external walls of the tympanum, immediately behind the membrana tympani and on a level with the upper end of the handle of the malleus; it leads into a minute canal, which descends
in front of the aquaeductus Fallopii, and terminates in the aqueduct near the stylomastoid foramen. Through it the chorda tympani nerve enters the tympanum.

The Glaserian or petro-tympanic fissure (fissura petrotympanica [Glaseri]) (Fig. 774) opens just above and in front of the ring of bone into which the membrana tympani is inserted; in this situation it is a mere slit about a line in length. It lodges the long process and anterior ligament of the malleus, and gives passage to the tympanic branch of the internal maxillary artery.

The iter chordae anterius (Fig. 774) is seen at the inner end of the preceding fissure; it leads into a canal, the canal of Huguer, which runs parallel with the Glaserian fissure. Through it the chorda tympani nerve leaves the tympanum.

The outer wall bounds the epitympanic recess externally.

The Internal Wall of the Tympanum (paries labyrinthica) (Figs. 771 and 775).—The internal wall of the tympanum is adjacent to the labyrinth, is vertical in direction, and looks directly outward. It presents for examination the following parts:

Fenestra ovalis. Promontory.
Fenestra rotunda. Ridge of the aquaeductus Fallopii.
Prominence of the external semicircular canal.

The Fenestra Ovalis, the Oval or the Vestibular Window (fenestra vestibuli) (Fig. 771) is a reniform opening leading from the tympanum into the vestibule. It is situated in the depths of a fossa (fossula fenestrae vestibuli). Its long diameter is directed horizontally, and its convex border is upward. The opening in the recent state is occupied by the base of the stapes (Figs. 770 and 776), which is connected to the margin of the foramen by an annular ligament.

The Fenestra Rotunda, the Round or Cochlear Window (fenestra cochleae) (Fig. 771), is an aperture placed at the bottom of a funnel-shaped depression (fossula fenestrae cochleae) leading into the cochlea. It is situated below and rather behind the fenestra ovalis, from which it is separated by a rounded elevation, the promontory; at its border is a narrow ridge of bone (crista fenestrae cochleae), which is closed in the recent state by a membrane, the membrane of Scarpa or the secondary ear-drum membrane (membrana tympani secundaria). This membrane is concave toward the tympanum, convex toward the cochlea. It consists of three layers: the external or mucous, derived from the mucous lining of the tympanum; the internal, from the lining membrane of the cochlea; and an intermediate or fibrous layer.

The Promontory (promontorium) (Fig. 775) is a rounded hollow prominence, formed by the projection outward of the first turn of the cochlea; it is placed between the fenestrae, and is furrowed on its surface (sulcus promontorii) for the lodgement of the tympanic plexus. A minute spicule of bone frequently connects the promontory to the pyramid.

The Rounded Eminence of the Aquaeductus Fallopii (prominentia canalis facialis) (Fig. 775), the prominence of the bony canal in which the facial nerve is contained, traverses the inner wall of the tympanum above the fenestra ovalis, and behind that opening curves nearly vertically downward along the posterior wall.

Just above the eminence of the aquaeductus Fallopii the wall is bulged by the external semicircular canal (prominentia canalis semicircularis lateralis).

The Posterior Wall of the Tympanum (paries mastoidea) (Fig. 775).—The posterior wall of the tympanum is wider above than below, and the lower portion of the posterior wall contains many tympanic cells. The posterior wall presents for examination the—

Opening of the antrum. Prominentia styloideae.
Fossa incudis. Pyramid.
Apertura tympanica canaliculi chordae.
The Opening of the Antrum is a large irregular aperture, which extends backward from the epitympanic recess and leads into a considerable air space, the mastoid antrum (antrum tympanicum), which is the entrance to the mastoid cells (p. 87). The antrum communicates with large irregular cavities contained in the interior of the mastoid process, the mastoid air-cells. These cavities vary considerably in number, size, and form; they are lined by mucous membrane continuous with that lining the cavity of the tympanum.

The Fossa Incudis (Fig 775) is placed in the posterior and inferior part of the epitympanic recess. It lodges the short process of the incus.

The Prominentia Styloideae is sometimes seen below the aperture tympanica canaliculi chordae. It is a prominence produced by a prolongation of the styloid process.

The Pyramid (eminentia pyramidalis) (Fig. 771) is a conical eminence situated immediately behind the fenestra ovalis, and in front of the vertical portion of the eminence above described; it is hollow in the interior, and contains the Stapedius muscle; its summit projects forward toward the fenestra ovalis, and presents a small aperture which transmits the tendon of the muscle. The cavity in the pyramid is prolonged into a minute canal, which communicates with the aquaeductus Fallopii and transmits the nerve which supplies the Stapedius.

The Apertura Tympanica Canaliculi Chordae is just back of the posterior edge of the tympanic membrane, nearly level with the superior end of the manubrium mallei.

The Anterior Wall of the Tympanum (partes carotica).—The anterior wall of the tympanum is bony on its lower portion. Its upper part is the tympanic opening of the Eustachian tube. The long anterior wall contains tympanic cells. The anterior wall is wider above than below; it corresponds with the carotid canal, from which it is separated by a thin plate of bone (Fig. 775), perforated by the canaliculi caroticotympanici, which transmit the tympanic branch of the internal carotid artery and the carotico-tympanic nerves. It presents for examination the—

Canal for the Tensor tympani. Orifice of the Eustachian tube.

The processus cochleariformis.

The orifice of the canal for the Tensor tympani and the orifice of the Eustachian tube are situated at the upper part of the anterior wall, being incompletely separated from each other by a thin, delicate, horizontal plate of bone, the processus cochleariformis (septum canalis musculotubarius) (Figs. 49 and 771). The canalis musculotubarius is divided by this long process into the canal for the Tensor tympani and the canal for the Eustachian tube. These canals run from the tympanum forward, inward, and a little downward, to the retiring angle between the squamous and petrous portions of the temporal bone.

The Canal for the Tensor Tympani (semicanalis m. tensoris tympani) (Figs. 49, 771, and 775) is the superior and the smaller of the two; it is rounded and lies beneath the forward prolongation of the tegmen tympani. It extends on to the inner wall of the tympanum and ends immediately above the fenestra ovalis. The processus cochleariformis passes backward below this part of the canal, forming its outer wall and floor; it expands above the anterior extremity of the fenestra ovalis and terminates by curving outward so as to form a pulley over which the tendon passes. The bony wall of this canal is incomplete, and the osseous vacancy is filled by tough connective tissue.

The Eustachian Tube or Ear Trumpet (tuba auditiva [Eustachii]) (Figs. 49, 771, and 772) is the channel through which the tympanum communicates with the pharynx. Its length is an inch and a half (36 mm.), and its direction downward, inward, and forward, forming an angle of about 45 degrees with the sagittal plane and one of from 30 to 40 degrees with the horizontal plane.
The canal for the Eustachian tube (semicanalis tubae auditivae) (Fig. 772) is formed partly of bone, partly of cartilage and fibrous tissue.

The Osseous Portion (pars ossea tubae auditivae or semicanalis tubae auditivae) is about half an inch in length. It is the outer portion of the tube. It commences in the anterior wall of the tympanum, below the processus cochleariformis (ostium tympanicum tubae auditivae), and, gradually narrowing, terminates at the angle of junction of the petrous and squamous portions of the temporal bone, its extremity presenting a jagged margin which serves for the attachment of the cartilaginous portion. The roof of the osseous portion is the tegmen tympani. The inner wall is formed in part by the inner wall of the tympanum and in part by the canal for the Tensor tympani muscle. The outer wall is the tympanic portion of the temporal bone. The floor is a groove which near the tympanum contains the openings of air-cells (cellulae pneumatici tubarii).

The Cartilaginous Portion (pars cartilaginea tubae auditivae), about an inch in length, is formed of a triangular plate of elastic fibro-cartilage (cartilago tubae auditivae), the apex of which is attached to the margin of the inner extremity of the osseous canal, while its base lies directly under the mucous membrane of the naso-pharynx, where it forms an elevation or cushion above and behind the pharyngeal orifice of the tube. The upper edge of the cartilage is curled upon itself, being bent outward so as to present on transverse section the appearance of a hook (lamina lateralis); a groove or furrow is thus produced, which opens below and externally, and this part of the canal is completed by fibrous membrane. On transverse section the cartilage exhibits the laminae which above are continuous with each other: the hard, thick lamina medialis and the thin and hooked lamina lateralis. The cartilage of the Eustachian tube, with a hood plate of cartilage, forms the posterior portion of the inner wall (the lamina medialis). The cartilage is fixed to the base of the skull, and lies in a groove (sulcus tubae auditivae) between the petrous-temporal and the greater wing of the sphenoid; this groove ends opposite the middle of the internal pterygoid plate, in a projection, the
processus tubarius. At the pharyngeal orifice the entire wall of the tube is cartilaginous, but the breadth of the cartilage progressively lessens as the isthmus is approached. Here and there the cartilage is deficient or pieces lie separate from the rest, the spaces between the islands being occupied by fibrous tissue. The Tensor palati muscle is placed to the outer side of the tube. The fibres of the muscle which take origin from the lamina lateralis are known as the dilator tubae muscle of Rudinger. The Tensor palati muscle and the mucous membrane of the pharynx lie to the inner side of the tube. The under and outer portion of the canal is completed by the membranous part (lamina membranacea), which is a strong fibrous membrane, passing between the two margins of the cartilage. It is thin above, but thick below, and the thick portion is called the fascia salpingopharyngea of Tröltzsch, and from it arise some fibres of the Tensor palati (m. salpingopharyngeus). The cartilaginous and bony portions of the tube are not in the same plane, the former inclining downward a little more than the latter. They join each other at a large obtuse angle, open below. The diameter of the canal is not uniform throughout, being greatest at the pharyngeal orifice and least at the junction of the bony and cartilaginous portions, where it is named the isthmus (isthmus tubae auditivae); it again expands somewhat as it approaches the tympanic cavity. The position and relations of the pharyngeal orifice (ostium pharyngeum tubae auditivae) are described with the anatomy of the naso-pharynx. Through this canal the mucous membrane of the pharynx is continuous with that which lines the tympanum. The mucous membrane is covered with ciliated epithelium and is thin in the osseous portion, while in the cartilaginous portion it contains many mucous glands and near the pharyngeal orifice a considerable amount of adenoid tissue, which has been named by Gerlach the tube-tonsil. The tube is opened during deglutition by the Salpingo-pharyngeus and Dilator tubae muscles.

The Drumhead or Membrana Tympani (Figs. 770, 772, 773, and 774).—The membrana tympani or drumhead separates the cavity of the tympanum from

![Diagram](image-url)
the bottom of the external meatus. It is a thin, semi-transparent membrane, nearly oval in form, somewhat broader above than below, and directed very obliquely downward and inward, so as to form an angle of about 55 degrees with the floor of the meatus (Fig. 770). The antero-inferior portion is, therefore, placed at the greatest distance from the external orifice of the meatus. It is asserted that in musicians the membrana tympani is placed more nearly perpendicular, and that in deaf-mutes and cretins it is placed more obliquely than the usual 55 degrees. In a newborn child the membrana tympani is almost horizontal. The greatest diameter of the membrana tympani is from 9 to 10 mm.;

its least diameter is from 8 to 9 mm. (Cunningham). The greater part of its circumference (limbus membranae tympanae) is thickened to form an annular ring (annulus fibrocartilagineus), which is fixed in a groove, the sulcus tympanicus, at the inner extremity of the external meatus. This sulcus is deficient superiorly at the incisure or notch of Rivinus (incisura tympanica [Rivini]) (Fig. 773). From the extremities of the notch (spinae tympanicae) two folds pass and converge to the short process of the malleus (Fig. 773). One is known as the anterior tympano-malleolar fold or ligament (plica membranae tympani anterior). The other is known as the posterior tympano-malleolar fold or ligament (plica membranae tympani posterior). These are not to be confused with the anterior and posterior malleolar folds (p. 1172). The small, somewhat triangular part of the membrane situated above these folds is lax and thin, and is named the flaccid portion or the membrana flaccida of Shrapnell (Figs. 773 and 774). In it a small orifice is sometimes seen, which is of artificial and pathological formation. The larger lower portion of the drum membrane is stretched tightly, and is called the tense portion or pars tensa (Figs. 773 and 774).
The handle of the malleus is firmly attached to the inner aspect of the membrane tympani as far as its centre (Fig. 774). It draws the central part of the membrane inward and makes its outer aspect concave. The most depressed part of the concavity is called the umbo or navel (umbo membranae tympanae) (Fig. 773). The walls of the umbo are concave outward.

On the outer surface of the drum membrane a light stripe (stria malleolaris) is seen. It runs from in front and above downward and backward, and is produced by the handle of the malleus, showing through the membrane (Fig. 773).

Structure.—This membrane is composed of three layers: an external (cuticular), a middle (fibrous), and an internal (mucous). The cuticular lining (stratum cutaneum) is derived from the integument lining the meatus. The fibrous or middle layer (membrana propria) consists of two strata: an external, of radiating fibres (stratum radiatum), which diverge from the handle of the malleus, and an internal, of circular fibres (stratum circulare), which are plentiful around the circumference, but sparse and scattered near the centre of the membrane. Branched or dendritic fibres, as pointed out by Grüber, are also present, especially in the posterior half of the membrane. Both muscular layers are connected to the annulus fibrocartilagineus, and both are absent in the pars flaccida. The inner or epithelial layer is mucous membrane (stratum mucosum), which is a portion of the mucous membrane of the drum cavity.

The Arteries are derived from the deep auricular branch of the internal maxillary, which ramifies beneath the cuticular layer and from the stylo-mastoid branch of the posterior auricular and tympanic branch of the internal maxillary, which are distributed on the mucous surface. The arteries of the cutaneous set anastomose with the arteries of the mucous set by minute branches which penetrate the drum membrane near its margin. The superficial veins open into the external jugular; those on the mucous surface drain themselves partly into the lateral sinus and veins of the dura and partly into a plexus on the Eustachian tube.
The outer surface of the drum membrane receives its nerve supply from the auriculo-temporal branch of the inferior maxillary and the auricular branch of the vagus. The inner surface is supplied by the tympanic branch of the glosso-pharyngeal.

There are two sets of lymphatics, the cutaneous and mucous, which freely communicate. The spaces between the dendritic fibres of Grüber are lymph-spaces (Kessel).

The Ossicles of the Tympanum (Ossicula Auditus) (Fig. 776).

The tympanum contains in its upper part a chain of movable bones, three in number, the malleus, incus, and stapes. The first is attached to the membrana tympani, the last to the fenestra ovalis. The incus is placed between the two, and is connected to both by delicate articulations.

The Malleus or Hammer (Fig. 777).—The malleus or hammer, so named from its fancied resemblance to a hammer, is placed farthest in front and outward. It consists of a head, neck, and three processes—the handle or manubrium, the processus gracilis, and the processus brevis.

The Head (capitulum mallei).—The head is the large upper extremity of the bone, and is situated in the epitympanic recess (Fig. 774). It is oval in shape, and articulates posteriorly with the incus, being free in the rest of its extent. The facet for articulation with the incus is covered with cartilage, is constricted near the middle, and is divided by a ridge into an upper, larger, and a lower, lesser part, which form nearly a right angle with each other. Opposite the constriction the lower margin of the facet projects in the form of a process, the cog-tooth or spur of the malleus. On the back of the head below the spur is a crest (crista mallei), to which the posterior ligament of the malleus is attached.

The Neck (collum mallei).—The neck is the narrow contracted part just beneath the head; and below this is a prominence, to which the various processes are attached. The outer surface of the neck faces the membrana flaccida. The chorda tympani nerve crosses the inner surface (Fig. 774).

The Handle or Manubrium (manubrium mallei).—The manubrium is a vertical process of bone, which is connected by its outer margin with the fibrous layer of the membrana tympani, its entire length being fastened to the fibrous layer of the drum membrane by its own periosteum and by a layer of cartilage (Grüber) (Figs. 774 and 776). It is directed downward, inward, and backward; it decreases in size toward its extremity, where it is curved slightly forward, and is flattened from within outward. The handle forms a variable angle with the head of the hammer. It averages about 130 degrees, but is always greater in the right ear than in the left. It forms an angle with the horizontal, averaging on the right side 50 degrees and on the left side 45 degrees (Spalteholz). Internally the handle is covered by the mucous membrane of the tympanum. On the inner side, near its upper end, is a slight projection, into which the tendon of the Tensor tympani is inserted (Fig. 774).

The Processus Gracilis or Long Process (processus anterior [Folii]).—The processus gracilis is a long and very delicate process, which passes from the front of
THE OSSICLES OF THE TYMPANUM

the neck forward and outward to the Glaserian fissure, to which it is connected by ligamentous fibres, constituting the broad ligament of Meckel. In the foetus this is the longest process of the malleus, and is in direct continuity with the cartilage of Meckel.

The Processus Brevis (processus lateralis).—The processus brevis is a slight conical projection, which springs from the root of the manubrium; it is directed outward, and is attached to the upper part of the tympanic membrane by cartilage and to the margins of the notch of Rivinus by the two malleolar folds.

The Incus or Anvil (Fig. 778).—The incus or anvil has received its name from its supposed resemblance to an anvil, but it is more like a bicuspid tooth with two roots, which differ in length, and are widely separated from each other. It consists of a body and two processes. The body and the short process are placed in the epitympanic recess (Fig. 776).

The Body (corpus incudis).—The body is somewhat quadrilateral, but compressed laterally. On its anterior surface is a deeply concavo-convex facet, which articulates with the head of the malleus, and the lower part is hollowed for the spur of the malleus. In the fresh state the articular surface is covered with cartilage and the joint is lined with synovial membrane.

Processes.—The two processes diverge from one another at an angle of from 90 to 100 degrees.

The Short Process (crus breve), somewhat conical in shape, projects nearly horizontally backward, and articulates with a depression, the incus fossa (fossa incudis), in the lower and back part of the epitympanic recess.

The Long Process (crus longum), longer and more slender than the preceding, descends nearly vertically behind and parallel to the handle of the malleus, and,
bending inward, terminates in a rounded globular projection, the os orbiculare or lenticular process (processus lenticularis), which is tipped with cartilage, and articulates with the head of the stapes. In the fetus the os orbiculare exists as a separate bone.

The Stapes or Stirrup (Fig. 779).—The stapes or stirrup, so called from its close resemblance to a stirrup, consists of a head, neck, two crura, and a base.

The Head (capitulum stapedis).—The head presents a depression, tipped with cartilage, which articulates with the os orbiculare.

The Neck.—The neck, the constricted part of the bone succeeding the head, receives the insertion of the Stapedius muscle.

The Crura.—The two crura (crus anterius and crus posterius) diverge from the neck and are connected at their extremities by a flattened, oval-shaped plate, the foot-plate or base (basis stapedis), which forms the foot-plate of the stirrup and is fixed to the margin of the fenestra ovalis by ligamentous fibres. The foot-plate almost fills the oval window (Fig. 770). Of the two crura, the anterior is shorter and less curved than the posterior. In a recent specimen a membrane will be observed filling the space between the crura and the foot-plate. This membrane is connective tissue and is called the membrana obturatoria stapedis. The stirrup lies practically horizontal.

Articulations of the Ossicles of the Tympanum (articulationes ossiculorum auditus) (Fig. 776).—These small bones are connected with each other and with the walls of the tympanum by ligaments, and are moved by small muscles. There is an articulation between the head of the hammer and the body of the anvil; one between the os orbiculare of the anvil and the head of the stirrup; and there is a syndesmosis between the margins of the oval window and the base of the stirrup. The bones are fastened in the tympanum, the handle of the hammer being fastened in the drum membrane and the base of the stirrup to the oval window. The articular surfaces of the malleus and incus and the orbicular process of the incus and head of the stapes are covered with cartilage, connected together by delicate capsular ligaments and lined by synovial membrane.

Ligaments Connecting the Ossicula with the Walls of the Tympanum (ligamenta ossiculorum auditus).—The malleus is fastened to the wall of the tympanum by three ligaments: the anterior, superior, and external ligaments.

The Anterior Ligament of the Malleus (ligamentum mallei anterius) consists of two parts, the band of Meckel and the anterior ligament of Helmholtz.

The band of Meckel is attached to the base of the processus gracilis and passes through the Glaserian fissure to reach the spine of the sphenoid. It was formerly described by Sömmering as a muscle, and it was called the laxator tympani muscle. It is now, however, believed by most observers to consist of ligamentous fibres only.

The anterior ligament of Helmholtz extends from the anterior margin of the notch of Rivinus to the anterior portion of the malleus, just above the processus gracilis.

The Superior Ligament of the Malleus (ligamentum mallei superius) is a delicate round bundle of fibres which descends perpendicularly from the root of the epi-tympanic recess to the head of the malleus. It is sometimes called the suspensory ligament.

The External Ligament of the Malleus (ligamentum mallei laterale) is a triangular plane of fibres passing from the posterior part of the notch in the tympanic ring...
to the crest of the malleus. The posterior portion of the external ligament is sometimes called the posterior ligament of Helmholtz (ligamentum mallei posterius [Helmholtzi]). The malleus rotates around an axis composed of the external and anterior ligaments, hence these two ligaments constitute what Helmholtz called the axis ligament of the malleus.

The incus is fastened to the wall of the tympanum by two ligaments, the posterior and the superior.

The Posterior Ligament of the Incus (ligamentum incudis posterius) is a short, thick, ligamentous band which connects the extremity of the short process of the incus to the posterior and lower part of the epitympanic recess, near the margin of the opening of the mastoid cells.

A Superior Ligament of the Incus (ligamentum incudis superius) has been described by Arnold, but it is little more than a fold of mucous membrane.

The inner surface and the circumference of the base of the stapes are covered with hyaline cartilage, and the annular ligament of the stapes (ligamentum annulare baseos stapedis) connects the circumference of the base to the margin of the fenestra ovalis.

The Muscles of the Tympanum (m. ossiculorum auditus).—The muscles of the tympanum are two:

Tensor tympani. Stapedius.

The Tensor Tympani (m. tensor tympani) (Fig. 775), the larger, is contained in the bony canal above the osseous portion of the Eustachian tube, from which it is separated by the processus cochleariformis. It arises from the under surface of the petrous bone, from the cartilaginous portion of the Eustachian tube, and from the osseous canal in which it is contained. Passing backward through the canal, it terminates in a slender tendon which enters the tympanum and makes a sharp bend outward around the extremity of the processus cochleariformis, and is inserted into the handle of the malleus near its root. Its nerve-supply is from the motor root of the trigeminal nerve by way of the otic ganglion.

The Stapedius (m. stapedius) (Fig. 775) arises from the side of a conical cavity hollowed out of the interior of the pyramid; its tendon emerges from the orifice at the apex of the pyramid, and, passing forward, is inserted into the neck of the stapes. Its surface is aponeurotic, its interior fleshy, and its tendon occasionally contains a slender bony spine, which is constant in some mammalia. It is supplied by the tympanic branch of the facial nerve.

Actions.—The Tensor tympani draws the handle of the malleus inward and thus heightens the tension of the drum membrane. It also causes slight rotation of the bone around its long axis. When the Stapedius contracts it draws the head of the stirrup backward, and in consequence the anterior end of the footplate passes outward toward the tympanum, and the posterior end inward toward the vestibule, and the annular ligament is made tense.

Movements of the Ossicles of the Tympanum.—The chain of bones is a lever-like arrangement, by means of which the vibrations of the membrana tympani are transferred to the membrane covering the oval window, and from this to the perilymph in the labyrinth. When the drum membrane moves inward, the handle of the malleus moves with it. The movement of the malleus moves the incus, and the movement of the incus drives the foot of the stapes toward the labyrinth. When the handle of the malleus moves inward, the spur on the head becomes locked with the body of the incus. During outward movement it is unlocked. The ordinary outward movement of the drum membrane causes the above-described movements to be reversed. When there is overforcible outward movement the incus does not go outward quite as far as the malleus, but slides at the joint between the malleus and incus. This reluctance of the incus saves the foot of the stapes from being pulled away from the oval window.
The Mucous Membrane of the Tympanum (tunica mucosa tympanica).—The mucous membrane of the tympanum is continuous with the mucous membrane of the naso-pharynx through the Eustachian tube, and is firmly united to the periosteum. It invests the ossicula, and the muscles and nerves contained in the tympanic cavity; forms the internal layer of the membrana tympani, and the outer layer of the membrana tympani secundaria, and is reflected into the mastoid antrum and air-cells, which it lines throughout. It forms several vascular folds (plicae), which extend from the walls of the tympanum to the ossicles. In these folds the ossicles are enveloped.

The anterior malleolar fold (plica malleolaris anterior) comes off from the membrane tympani between the anterior edge of the notch of Rivinus and the handle of the malleus, envelops the processus gracilis of the malleus, the anterior ligament of the malleus, and the anterior portion of the chorda tympani nerve, and terminates in a free concave edge (Spalteholz). The posterior malleolar fold (plica malleolaris posterior) is the larger of the two. It comes off from the margin of the notch of Rivinis, envelops the external ligament of the malleus, the posterior part of the chorda tympani nerve, is attached to the handle of the malleus, and ends in a free concave margin (Spalteholz). The fold of the incus (plica incudis) takes origin from the roof of the epitympanic recess and passes to the body and short process of the incus; and a similar fold passes from the head of the malleus to the anterior wall of the epitympanic recess. The entire stapes, with its obturator membrane, is enwrapped by the fold of the stapes (plica stapidis). This fold also ensheaths the tendon of the stapedius muscle and often reaches to the posterior wall of the cavity of the tympanum. The mucous membrane over the round window forms the membrana tympani secundaria. These folds separate off pouch-like cavities, and give the interior of the tympanum a somewhat honey-comb appearance. One of these pouches is well marked—viz., the pouch of Prussak, which lies between the neck of the malleus and the membrana flaccida.

The inferior external pouch of the tympanum or the pouch of Prussak (recessus membranae tympani superior) is between the flaccid portion of the membrana tympani, the external ligament of the malleus, and the neck of the malleus. The anterior and posterior malleolar folds with the tympanic membrane form two pouches. These are the anterior and posterior pouches or recesses of Tröltsch (recessus membranae tympani, anterior and posterior). The anterior pouch is blind above and has a slit-like opening below. The posterior pouch is continued into the blind superior pouch of the drum membrane. In the tympanum this membrane is pale, thin, slightly vascular, and covered for the most part with columnar ciliated epithelium, but that covering the pyramid, ossicula, and membrana tympani possesses a flattened, non-ciliated epithelium. In the antrum and mastoid cells its epithelium is also non-ciliated. In the osseous portion of the Eustachian tube the membrane is thin; but in the cartilaginous portion it is very thick, highly vascular, covered with ciliated epithelium, and provided with numerous mucous glands.

The Arteries of the Tympanum.—The arteries supplying the tympanum are six in number. Two of them are larger than the rest—viz., the tympanic branch of the internal maxillary, which enters by way of the Glaserian fissure and supplies the membrana tympani; and the stylo-mastoid branch of the posterior auricular, which passes through the stylo-mastoid foramen and the aqueduct of Fallopian, and supplies the inner wall and floor of the tympanum, the mastoid cells, and antrum and the Stapedius muscle. This vessel anastomoses around the drum membrane with the tympanic. The medidural sends a small branch to the Tensor tympani muscle near its origin. The petrosal branch of the medidural enters the tympanum by way of the hiatus Fallopii. Minute branches from the posterior branch of the medidural pass through the petro-squamous fissure and are dis-
tributed to the antrum and epitympanic recess (Cunningham). Two tympanic branches come off from the internal carotid artery in its course through the carotid canal. A branch from the ascending pharyngeal and another from the Vidian accompany the Eustachian tube. The two tympanic branches from the internal carotid are given off in the carotid canal and perforate the thin anterior wall of the tympanum.

The Veins of the Tympanum.—The veins of the tympanum terminate in the pterygoid plexus, the medidural vein, and the superpetrosal sinus.

The Nerves of the Tympanum.—The nerves of the tympanum constitute the tympanic plexus (plexus tympanicus [Jacobsoni]), which ramifies upon the surface of the promontory (Fig. 775). The plexus is formed by (1) the tympanic branch of the glosso-pharyngeal; (2) the small deep petrosal nerve; (3) the small superficial petrosal nerve; and (4) a branch which joins the great superficial petrosal.

The Tympanic Branch of the Glosso-pharyngeal or Jacobson's Nerve (n. tympanicus) enters the tympanum by an aperture in its floor close to the inner wall and divides into branches, which ramify on the promontory and enter into the formation of the plexus. The small deep petrosal nerve (n. petrosus profundus), from the carotid plexus of the sympathetic, passes through the wall of the carotid canal, and joins the branches of Jacobson's nerve. The branch to the great superficial petrosal passes through an opening on the inner wall of the tympanum in front of the fenestra ovalis. The small superficial petrosal nerve (n. petrosus superficialis minor), derived from the otic ganglion, passes through a foramen in the middle fossa of the base of the skull (sometimes through the foramen ovale), passes backward and enters the petrous bone through a small aperture, situated external to the hiatus Fallopii on the anterior surface of this bone; it then courses downward through the bone, and, passing by the gangliform enlargement of the facial nerve, receives a connecting filament from it (Fig. 779) and enters the tympanic cavity, where it communicates with Jacobson's nerve, and assists in forming the tympanic plexus.

The branches of distribution of the tympanic plexus are distributed to the mucous membrane of the tympanum; one special branch passing to the fenestra ovalis, another to the fenestra rotunda, and a third to the Eustachian tube. The small superficial petrosal may be looked upon as a branch from the plexus to the otic ganglion.

In addition to the tympanic plexus there are the nerves supplying the muscles. The Tensor tympani is supplied by a branch from the third division of the trigeminal through the otic ganglion, and the Stapedius by the tympanic branch of the facial.

The chorda tympani (Figs. 771 and 774) crosses the tympanic cavity. It is given off from the facial as it passes vertically downward at the back of the tympanum, about a quarter of an inch before its exit from the stylo-mastoid foramen. It passes from below upward and forward in a distinct canal, and enters the cavity of the tympanum through an aperture, iter chordae posterius, already described (p. 1161), and becomes invested with mucous membrane. It passes forward, through the cavity of the tympanum, crossing internal to the membrana tympani and over the handle of the malleus to the anterior inferior angle of the tympanum, and emerges from that cavity through the iter chordae anterius or canal of Huguier (p. 1162). It is invested by the fold of mucous membrane already mentioned, and therefore lies between the mucous and fibrous layers of the membrana tympani.

THE INTERNAL EAR OR LABYRINTH (AURIS INTERNA).

The internal ear is the essential part of the organ of hearing, receiving the ultimate distribution of the auditory nerve. It is called the labyrinth, from the
complexity of its shape, and consists of two parts: the **osseous labyrinth**, a series of cavities channelled out of the substance of the petrous bone, and the **membranous labyrinth**, the latter being contained within the former.

**The Osseous Labyrinth (Labyrinthus Osseus)** (Fig. 780).

The osseous labyrinth consists of three parts: the **vestibule**, **semicircular canals**, and **cochlea**. These are cavities hollowed out of the substance of the bone, and lined by periosteum. A clear fluid is contained in the space between the osseous labyrinth and the membranous labyrinth. The space is called the **perilymph space**, and the fluid is called **perilymph** or **liquor Cotunnii**.

**The Vestibule** (**vestibulum**) (Figs. 776 and 780).—The vestibule is the common central cavity of communication between the parts of the internal ear. It is situated on the inner side of the tympanum, behind the cochlea, and in front of the semicircular canals. It is somewhat ovoidal in shape from before backward, flattened from within outward, and measures about one-fifth of an inch from before back-

![Diagram of the internal ear](https://via.placeholder.com/150)

**Fig. 780.**—The osseous labyrinth laid open (enlarged).

ward, as well as from above downward, and about one-eighth of an inch from without inward. On its **outer** or tympanic wall is the **fenestra ovalis** (**fenestra vestibuli**), closed, in the recent state, by the base of the stapes, and its annular ligament. On its **inner wall**, at the forepart, is a small circular depression, **fovea hemisphaerica** or **spherical recess** (**recessus sphaericus**), in which the saccule is placed. This recess is perforated, at its anterior and inferior part, by about a dozen minute holes (**macula cribrosa media**), for the passage of filaments of the auditory nerve to the saccule. Above and behind this depression is an oblique ridge, the **crista vestibuli**. The anterior extremity of the crista vestibuli is the shape of a triangle, and is called the **pyramid** (**pyramis vestibuli**). This ridge bifurcates posteriorly to enclose a small depression, the **recessus cochlearis of Reichert**, which is perforated by eight small holes for the passage of filaments of the auditory nerve which supply the posterior end of the ductus cochlearis. An oval depression is placed in the roof and inner wall of the vestibule above and behind the crista vestibuli. It is called the **fovea hemielliptica**, **elliptical recess** or **spherical recess** (**recessus ellipticus**), and receives the utricle. The pyramid and the adjacent elliptical recess are perforated by numerous minute foramina (**macula cribrosa superior**),
The openings in the pyramid transmit filaments from the vestibular nerve to the utricle; the openings in the elliptical recess transmit filaments from the vestibular nerve to the ampullae of the superior and external semicircular canals. Below and behind the elliptical recess is a groove which deepens into a canal and is called the *aquaeductus vestibuli*. This canal passes to the posterior surface of the petrous portion of the temporal bone and opens as a mere crack between the internal auditory meatus and the groove for the lateral sinus. It transmits a small vein, and contains a tubular prolongation of the lining membrane of the vestibule, the *ductus endolymphaticus*, which ends in a cul-de-sac between the layers of the dura within the cranial cavity. *Behind*, the semicircular canals open into the vestibule by five orifices. *In front* is an elliptical opening, which communicates with the scala vestibuli of the cochlea by an orifice, *apertura scalae vestibuli cochleae*. This opening is bounded below by a thin plate of bone (*lamina spiralis ossea*), which takes origin from the vestibular floor external to the spherical recess and in the cochlea forms the bony portion of the partition between the scala tympani and the scala vestibuli. In the anterior portion of the vestibular floor is a fissure (*fissura vestibuli*), which passes into the bony part of the canal of the cochlea. The external boundary of this fissure is a small, thin plate of bone (*lamina spiralis secundaria*).

**The Semicircular Canals** (*canales semicirculares ossei*) (Fig. 780).—The semicircular canals are three bony canals situated above and behind the vestibule. They are of unequal length, compressed from side to side, and each describes the greater part of a circle. They measure about one-twentieth of an inch in diameter, and each presents a dilatation at one end, called the *ampulla ossea*, which measures more than twice the diameter of the tube. These canals open into the vestibule by five orifices, one of the apertures being common to two of the canals.

**The Superior Semicircular Canal** (*canalis semicircularis superior*).—The superior semicircular canal is vertical in direction, and is placed transversely to the long axis of the petrous portion of the temporal bone, on the anterior surface of which its arch forms a round projection. It describes about two-thirds of a circle. Its outer extremity, which is ampullated, communicates by a distinct orifice with the upper part of the vestibule; the opposite end of the canal, which is not dilated, joins with the corresponding part of the posterior canal to form the *crus commune*, which opens into the upper and inner part of the vestibule.

**The Posterior Semicircular Canal** (*canalis semicircularis posterior*).—The posterior semicircular canal, also vertical in direction, is directed backward, nearly parallel to the posterior surface of the petrous bone; it is the longest of the three; its ampullated end commences at the lower and back part of the vestibule, its opposite end joining to form the common canal already mentioned. In the wall of the ampulla of the posterior canal are a number of small openings (*macula cribrosa inferior*) for the entrance of nerves to the ampulla.

**The External or Horizontal Canal** (*canalis semicircularis lateralis*).—The external or horizontal canal is the shortest of the three, its arch being directed outward and backward; thus each semicircular canal stands at right angles to the other two. Its ampullated end corresponds to the upper and outer angle of the vestibule, just above the fenestra ovalis, where it opens close to the ampullary end of the superior canal; its opposite end opens by a distinct orifice at the upper and back part of the vestibule.

**The Cochlea** (Figs. 780, 781, 782, and 783).—The cochlea bears some resemblance to a common snail-shell; it forms the anterior part of the labyrinth, is conical in form, and placed almost horizontally in front of the vestibule; its apex is directed forward and outward, with a slight inclination downward, toward the upper and front part of the inner wall of the tympanum; its base corresponds with the anterior depression at the bottom of the internal auditory meatus, and is perforated by numerous
apertures for the passage of the cochlear divisions of the auditory nerve. It measures nearly a quarter of an inch (5 mm.) from base to apex, and its breadth across

the base is somewhat greater (about 9 mm.). It consists of a conical-shaped central axis, the modiolus or columnella; of a canal, the bony canal of the cochlea, the inner wall of which is formed by the central axis, wound spirally around it for two

turns and three-quarters, from the base to the apex, and of a delicate lamina, the lamina spiralis ossea, which projects from the modiolus, and, following the windings
of the canal, partially subdivides it into two. In the recent state certain membranous layers are attached to the free border of this lamina, which project into the canal and completely separate it into two passages, which, however, communicate with each other at the apex of the modiolus by a small opening, named the helicotrema.

The Modiolus (Figs. 782 and 783).—The modiolus or columella is the central axis or pillar of the cochlea. It is conical in form, and extends from the base to the apex of the cochlea. Its base (basis modioli) is broad, and appears at the bottom of the internal auditory meatus, where it corresponds with the area cochleae. It is perforated by numerous orifices, which transmit filaments of the cochlear division of the auditory nerve, the nerves for the first turn and a half being transmitted through the foramina of the tractus spiralis foraminosus; the fibres for the apical turn passing up through the foramen centrale. The foramina of the tractus spiralis foraminosus pass up through the modiolus and successively bend outward to reach the attached margin of the lamina spiralis ossea. Here they become enlarged, and by their apposition form a spiral canal (canalis spiralis modioli), which follows the course of the attached margin of the lamina spiralis ossea and lodges the ganglion of Corti (ganglion spirale cochleae). The foramen centrale is continued as a canal up the middle of the modiolus to its apex, and from this canal numerous minute foramina pass outward to the unattached edge of the lamina spiralis. In the foramina are vessels and nerves. The axis diminishes rapidly in size in the second and succeeding coil.

![Image](783.-The cochlea laid open (enlarged).

The Bony Canal or the Spiral Canal of the Cochlea (canalis spiralis cochleae) (Fig. 783).—The bony canal of the cochlea takes two turns and three-quarters round the modiolus. The first turn of the canal is called the basal coil, the second is called the central coil, the third turn is called the apical coil. The promontory on the inner wall of the tympanic cavity is caused by the basal coil. The bony canal of the cochlea is a little over an inch in length (about 30 mm.), and diminishes gradually in size from the base to the summit, where it terminates in a cul-de-sac, the cupula (cupula), which forms the apex of the cochlea. The commencement of this canal is about the tenth of an inch in diameter; it diverges from the modiolus toward the tympanum and vestibule, and presents three openings. One, the fenestra rotunda, communicates with the tympanum; in the recent state this aperture is closed by a membrane, the membrana tympani secundaria. Another aperture, of an elliptical form, enters the vestibule. The third is the aperture of the aquaeductus cochleae, leading to a minute funnel-shaped canal, which opens on the basilar surface of the petrous bone internal to the jugular fossa, and transmits a small vein, and also forms a communication between the subarachnoidian space of the skull and the perilymph contained in the scala tympani.

The Lamina Spiralis Ossea.—The lamina spiralis ossea is a bony shelf or ledge which projects outward from the modiolus into the interior of the spiral canal,
and, like the canal, takes two and three-quarter turns around the modiolus. It reaches about half-way toward the outer wall of the spiral tube, and partially divides its cavity into two passages or scalae, of which the upper is named the scala vestibuli, while the lower is termed the scala tympani. Near the summit of the cochlea the lamina terminates in a hook-shaped process, the hamulus (hamulus laminae spiralis), which assists in forming the boundary of a small opening, the helicotrema, by which the two scalae communicate with each other. From the canalis spiralis modioli numerous foramina pass outward through the osseous spiral lamina as far as its outer or free edge. In the lower part of the first turn a second bony lamina (lamina spiralis secundaria) projects inward from the outer wall of the bony tube; it does not, however, reach the primary osseous spiral lamina, so that if viewed from the vestibule a narrow fissure, the fissura vestibuli, is seen between them.

The membrana basilaris (Fig. 781) is stretched from the unattached edge of the lamina spiralis ossea to the outer wall of the cochlea. The lamina spiralis makes an incomplete septum between the scala tympani and scala vestibuli; the membrana basilaris completes the septum. Even with the perfected septum the two scalae communicate at the apex of the cochlea by means of the helicotrema.

The Fundus of the Internal Auditory Meatus (fundus meatus acustici interni).—This structure is the inner wall of the vestibule and the base of the modiolus. A transverse ridge (cista transversa) maps it off into two parts, the fossula superior and the fossula inferior. The facial area (area n. facialis) is in the anterior portion of the fossula superior. The opening seen here is the beginning of the aqueduct of Fallopius (canalis facialis) for the transmission of the facial nerve. The superior area of the vestibule (area vestibularis superior) is the posterior portion of the fossula superior. Here the nerves perforate which supply the utricle and the ampullae of the superior and external semicircular canals (Cunningham). The area cochleae is the anterior portion of the fossula inferior. In it is the canalis centralis for the nerve-fibres to the apical turn of the cochlea; and the tractus spiralis foraminosa for the transmission of nerves to the first turn and a half of the cochlea. The

![Diagram of the inner ear](image_url)
in inferior area of the vestibule (area vestibularis inferior) is back of the area cochleae and a ridge separates the two. It transmits nerves to the saccule. At the posterior part of the fossula inferior is a solitary foramen, the foramen singulare, which transmits nerves to the ampulla of the posterior semicircular canal.

The Membranous Labyrinth (Labyrinthus Membranaceus) (Figs. 784, 785).

The membranous labyrinth is contained within the bony cavities just described, having the same general form as the cavities in which it is contained, though considerably smaller, being separated from the bony walls by a quantity of fluid, the perilymph or liquor Cotunnii (perilymph). It does not, however, float loosely in this fluid, but in places is fixed to the walls of the cavity. The membranous sac contains fluid, the endolymph (endolympha), and on the sac the ramifications of the auditory nerve are distributed.

Within the osseous vestibule the membranous labyrinth does not quite preserve the form of the bony cavity, but presents two membranous sacs, the utricle and the saccule.

The Utricle (utriculus).—The utricle is the larger of the two, of an oblong form, compressed laterally, and occupies the upper and back part of the vestibule, lying in contact with the fovea semi-elliptica and the part below it. The highest portion of the utricle is called the recess (recessus utriculi); it is placed in the elliptical recess, and opening into it are the ampulla of the superior and external semicircular canals. The central portion of the recess of the utricle receives upon the side the external semicircular canal. This opening has not an ampulla. The superior sinus is a prolongation upward and backward from the central portion of the utricle and in the superior sinus the crus commune and the superior and posterior semicircular canals open. The lower and inner portion of the utricle is the inferior sinus, and into it the ampulla of the posterior semicircular canal opens. The floor and anterior wall of the recess of the utricle are much thicker than elsewhere, and form the macula acustica utriculi, which receives the utricular filaments of the auditory nerve and has attached to its internal surface a layer of calcareous particles which are called otothls. The cavity of the utricle communicates behind with the membranous semicircular canals by five orifices. From its anterior wall is given off a small canal (ductus utriculosaccularis), which joins with a canal from the saccule, the ducus endolymphaticus. The utricle is joined to the bony wall by numerous fibrous bands.

![Diagram of the memranous labyrinth](image)
The Saccule (sacculus).—The saccule is the smaller of the two vesicular sacs; it is globular in form, lies in the elliptical recess near the opening of the scala vestibuli of the cochlea. Its anterior part exhibits an oval thickening, the macula acustica sacculi, to which are distributed the saccular filaments of the auditory nerve. Its cavity does not directly communicate with that of the utricle. From the posterior wall is given off a canal, the ductus endolymphaticus. This duct passes along the aquaeductus vestibuli and ends in a blind pouch on the posterior surface of the petrous portion of the temporal bone, where it is in contact with the dura. The upper extremity of the saccule looks upward and backward and forms the sinus utricularis sacculi. This lies in contact with but is not a part of the wall of the utricle. The vestibule contains the closed end of the ductus cochlearis. This is known as the caecum vestibulare. The ductus cochlearis lies below the saccule in what Reichert described as the recessus cochlearis, and it enters the spiral canal. From the lower part of the saccule a short tube, the canalis reunies of Hensen (ductus reunies [Hensen]), passes downward and outward to open into the ductus cochlearis. The saccule is held in position by numerous fibrous bands which pass between the saccule and the bony wall.

The Membranous Semicircular Canals (ductus semicirculares).—The membranous semicircular canals are about one-third the diameter of the osseous canals, but in number, shape, and general form they are precisely similar, and present at one end within the osseous ampulla a membranous ampulla. These ampullae are called ampullae membranaceae. The canals open by five orifices into the utricle, one opening being common to two canals. In the ampullae the wall is thickened, and projects into the cavity as a fiddle-shaped, transversely placed elevation, the septum transversum, in which the nerves end.

The membranous canals are attached here and there to the bone by numerous fibrous bands, the so-called ligaments (ligamenta labyrinthi canaliculorum).

Structure.—The walls of the utricle, saccule, and membranous semicircular canals consist of three layers. The outer layer is a loose and flocculent structure, apparently composed of ordinary fibrous tissue, containing blood-vessels and pigment-cells analogous to those in the pigment coat of the retina. The middle layer, thicker and more transparent, bears some resemblance to the hyaloid membrane, but it presents on its internal surface, especially in the semicircular canals, numerous papilliform projections, and, on the addition of acetic acid, presents an appearance of longitudinal fibrillation and elongated nuclei. The inner layer is formed of polygonal nucleated epithelial cells. The raphé of each semicircular canal is a line upon the concave side of the canal. Along the raphé the height of the epithelial cells is distinctly increased. In the ampullae adjacent to the crista acusticae the cells are cylindrical and constitute the plana semilunata. In the maculae of the utricle and saccule, and in the transverse septa of the ampullae of the canals, the middle coat is thickened and the epithelium is columnar, is increased in height, and passes into the neuro-epithelium. The neuro-epithelium consists of supporting cells and hair-cells.

1. The supporting cells are long, wider at the ends than in the centre, contain an oval nucleus, and the lower end of the cell is fissured.

2. The hair-cells are columnar, with bulged lower ends and free upper ends. The bulged lower ends, each of which contains a spherical nucleus, do not reach higher than the middle of the epithelial layer. Each free upper end is surmounted by a long, tapering filament. These filaments constitute auditory hair, and they project into the cavity. The filaments of the auditory nerve enter these parts, and, having pierced the outer and thickened middle layer, they lose their medullary sheath, and their axis-cylinders divide into three or four branches at the larger and deeper ends of the hair-cells. These branches form a horizontal plexus
"These surround the hair-cells like the calyx of a flower, and give off ascending branches, which, however, do not reach the surface. In this way one branch usually comes in contact with many hair-cells."

Numerous small prismatic bodies termed **statoliths**, **otokonien crystals** or **otoliths**, and consisting of a mass of minute crystalline grains of carbonate of lime, held together in a mesh of delicate fibrous tissue, are contained in the walls of the utricle and saccule opposite the distribution of the nerves. The membrane is

Histology and Microscopic Anatomy. By Dr. Ladislaus Szymonowicz. Translated and edited by John Bruce MacCallum, M.D.
called the otolith membrane. A calcareous material is also, according to Bowman, sparingly scattered in the cells lining the ampullae of the semicircular canals. The conical thickening in the ampulla corresponds to the otolith membrane and is called the cupola.

The Membranous Cochlea, Ductus Cochlearis or Scala Media consists of a spirally arranged tube enclosed in the bony canal of the cochlea and lying along its outer wall. It begins as a blind end in the recessus cochlearis of the vestibule. This beginning is the caecum vestibulare. It ascends inside the bony cochlea and terminates at the apex of the cochlea by a blind end, the lagenæ (caecum cupulare). The manner in which it is formed will now be described.

The osseous spiral lamina, as above stated, extends only part of the distance between the modiolus and the outer bony wall of the cochlea. A membrane, the basilar membrane (membrana basilaris) (Fig. 786), stretches from its free edge to the outer wall of the cochlea, and completes the roof of the scala tympani. A second and more delicate membrane, the membrane of Reissner (membrana vestibularis [Reissneri]) (Fig. 786), extends from the thickened periosteum covering the lamina spiralis ossea to the outer wall of the cochlea, to which it is attached at some little distance above the membrana basilaris. A canal is thus shut off between the scala tympani below and the scala vestibuli above; this is the membranous canal of the cochlea (ductus cochlearis or scala media) (Fig. 787). It is triangular on transverse section, its roof being formed by the membrane of Reissner, its outer wall by the periosteum which lines the bony canal, and its floor by the membrana basilaris, and the outer part of the lamina spiralis ossea, on the former of which is placed the organ of Corti. Reissner's membrane is thin and homogeneous, and is covered on its upper and under surfaces by a layer of epithelium. The periosteum, which forms the outer wall of the ductus cochlearis, is greatly thickened and altered in character, forming what is called the spiral ligament of the cochlea (ligamentum spirale cochleae) (Fig. 786). It projects inward below as a triangular prominence, the crista basilaris, which gives attachment to the outer edge of the membrana basilaris, and immediately above which is a concavity, the sulcus spiralis externus (Fig. 786). The upper portion of the ligamentum spirale contains numerous capillary loops and small blood-vessels, and forms what is termed the stria vascularis. The stria is limited below by a prominence (prominencia spiralis), in which a blood-vessel (vas prominens) is distinctly visible.

The lamina spiralis ossea (Fig. 787) consists of two plates of bone extending outward; between these are the canals for the transmission of the filaments of the auditory nerve. On the upper plate of that part of the osseous spiral lamina which is outside Reissner's membrane the periosteum is thickened to form the limbus laminae spiralis, and this terminates externally in a concavity, the sulcus spiralis internus, which presents, on section, the form of the letter C; the upper part of the letter, formed by the overhanging extremity of the limbus, is named the labium vestibulare; the lower part, prolonged and tapering, is called the labium tympanicum, and is perforated by 4000 foramina (foramina nervosa) for the passage of the cochlear nerves. Externally, the labium tympanicum is continuous with the membrana basilaris. The upper surface of the labium vestibulare is intersected at right angles by a number of furrows, between which are numerous elevations; these present the appearance of teeth along the free margin of the

![Fig. 788.—Part of the cochlear nerve, highly magnified. (Hindle.)](image)
labium, and have been named by Huschke the auditory teeth. There are 7000 auditory teeth. The basilar membrane may be divided into two areas, inner and outer. The inner is thin, and is named the zona arcuata or zona tecta (Fig. 786); it supports the organ of Corti. The outer is thicker and striated, and is termed the zona pectinata. The under surface of the membrane is covered by a layer of vascular connective tissue. One of these vessels is somewhat larger than the rest, and is named the vas spirale (Fig. 789); it lies below Corti's tunnel.

Organ of Corti\(^1\) (organon spirale [Cortii]) (Figs. 786, 787, 789, and 790).—The inner part of the membrana basilaris—that is, the part directed toward the canal of the ductus cochlearis—is covered with epithelium, which is largely neuro-epithe-

---

\(^1\) Corti's original paper is in the Zeitschrift f. Wissen. Zool., iii., 109.
pianoforte. The organ of Corti consists of an inner part and an outer part. Each part contains auditory cells and supporting cells. Of these cells, the two central ones are rod-like bodies and are called the inner and outer rods of Corti. They are placed on the basilar membrane, at some little distance from each other, but are inclined toward each other, so as to meet at their opposite extremities, and form a series of arches roofing over a minute tunnel, the canal or tunnel of Corti, between them and the basilar membrane, which ascends spirally through the whole length of the cochlea.

The inner rods (Fig. 789), some 6000 in number, are more numerous than the outer ones, and rest on the basilar membrane, close to the labium tympanicum; they project obliquely upward and outward, and terminate above in expanded extremities which resemble in shape the upper end of the ulna, with its sigmoid cavity, coronoid and olecranon processes. On the outer side of the rod, in the angle formed between it and the basilar membrane, is a nucleated mass of protoplasm; while on the inner side is a row of epithelial cells, inner hair-cells (Fig. 789), surmounted by a brush of fine, stiff, hair-like processes. On the inner side of these cells are two or three rows of columnar supporting cells, which are continuous with the cubical cells lining the sulcus spiralis internus.

The outer rods (Fig. 789), numbering about 4000, also rest by a broad foot on the basilar membrane; they incline upward and inward, and their upper extremity resembles the head and bill of a swan; the back of the head fitting into the concavity—the analogue of the sigmoid cavity—of one or more of the internal rods, and the bill projecting outward as a phalangeal process of the membrana reticularis, presently to be described.

In the head of these outer rods is an oval portion, where the fibres of which the rod appears to be composed are deficient, and which stains more deeply with carmine than the rest of the rod. At the base of the rod, on its internal side—that is to say, in the angle formed by the rod with the basilar membrane—is a similar protoplasmic mass to that found on the outer side of the base of the inner rod; these masses of protoplasm are probably the undifferentiated portions of the cells from which the rods are developed. External to the outer rod are three or four successive rows of epithelial cells, more elongated than those found on the
internal side of the inner rod, but, like them, furnished with minute hairs or cilia. These are termed the outer hair-cells, in contradistinction to the inner hair-cells above referred to. There are about 12,000 outer hair-cells, and about 3500 inner hair-cells.

The hair-cells are somewhat oval in shape; their free extremities are on a level with the heads of Corti’s rods, and from each some twenty fine hairlets project and are arranged in the form of a crescent, the concavity of which opens inward. The deep ends of the cells are rounded and contain large nuclei; they reach only as far as the middle of Corti’s rods, and are in contact with the ramifications of the nervous filaments. Between the rows of the outer hair-cells are rows of supporting cells, called the cells of Deiters; their expanded bases are planted on the basilar membrane, while their opposite ends present a clubbed extremity or phalangeal process. Immediately to the outer side of Deiters’ cells are some five or six rows of columnar cells, the supporting cells of Hensen. Their bases are narrow, while their upper parts are expanded and form a rounded elevation on the floor of the ductus cochlearis. The columnar cells lying outside Hensen’s cells are termed the cells of Claudius. A space is seen between the outer rows of Corti and the adjacent hair-cells; this is called the space of Nuel.

The lamina reticularis or membrane of Kölliker is a delicate framework perforated by rounded holes. It extends from the inner rods of Corti to the external row of the outer hair-cells, and is formed by several rows of “minute fiddle-shaped cuticular structures” called phalanges, between which are circular apertures containing the free ends of the hair-cells. The innermost row of phalanges consists of the phalangeal processes of the outer rods of Corti; the outer rows are formed by the modified free ends of Deiters’ cells.

Covering over these structures, but not touching them, is the membrana tectoria or membrane of Corti (Figs. 786 and 789), which is attached to the vestibular surface of the lamina spiralis close to the attachment of the membrane of Reissner. It is thin near its inner margin, and overlies the auditory teeth of Huschke. Its outer half is thick, and along its lower edge, opposite the inner hair-cells, is a clear band, named Hensen’s stripe. Externally, the membrane becomes much thinner, and is attached to the outer row of Deiters’ cells (Retzius).

The fibres from the cochlear nerve enter the organ of Corti as axis-cylinders, which pass directly to the deepest portions of the inner and outer hair-cells by way of the canal of Corti or by the space of Nuel. The terminations arborize about the lower portions of the hair-cells and end on the surfaces of the hair-cells.

The inner surface of the osseous labyrinth is lined by an exceedingly thin fibroserous membrane, analogous to a periosteum, from its close adhesion to the inner surfaces of these cavities, and performing the office of a serous membrane by its free surface. It lines the vestibule, and from this cavity is continued into the semicircular canals and the scala vestibuli of the cochlea, and through the helicotrema into the scala tympani. A delicate tubular process is prolonged along the aqueduct of the vestibule to the inner surface of the dura. This membrane is continued across the fenestra ovalis and fenestra rotunda, and consequently has no communication with the lining membrane of the tympanum. Its attached surface is rough and fibrous, and closely adherent to the bone; its free surface is smooth and pale, covered with a layer of epithelium, and secretes a thin, limpid fluid, the aqua labyrinthi, liquor Cistumii or perilymph (Blainville).

The scala media is closed above and below. The upper blind extremity is termed the lagena, and is attached to the cupula at the upper part of the helicotrema; the lower end is lodged in the recessus cochlearis of the vestibule. Near this blind extremity, the scala media receives the canalis reuniens of Hensen (Fig. 785), a very delicate canal, by which the ductus cochlearis is brought into continuity with the saccule.
The Arteries of the Labyrinth.—The arteries of the labyrinth are the internal auditory, from the basilar, and the stylo-mastoid, from the posterior auricular. The internal auditory divides at the bottom of the internal auditory meatus into two branches, cochlear and vestibular.

The cochlear artery divides into numerous minute branches, which enter foramina in the tractus spiralis foraminosa and course in the lamina spiralis ossea to reach the membranous structures. The largest of the cochlear branches is in the canalis centralis.

The vestibular branches accompany the nerves, and supply the membranous structures in the vestibule and semicircular canals. Two arteries go to each canal. The two vessels enter opposite extremities of the canal, and anastomose at the summit of the canal. The vestibular vessels form a minute capillary network in the substance of each membranous labyrinth.

The Veins of the Labyrinth.—The veins of the vestibule and semicircular canals, the auditory veins, accompany the arteries, and receive those of the cochlea at the base of the modiolus, to form the internal auditory vein (vv. auditivae internae), which opens into the posterior part of the inferior petrosal sinus or into the lateral sinus.

The Nerves of the Labyrinth.—The auditory nerve (n. acusticus), the special nerve of the sense of hearing, divides, at the bottom of the internal auditory meatus, into two branches, the cochlear and vestibular.

The Vestibular Nerve (n. vestibularis), the posterior of the two, presents, as it lies in the internal auditory meatus, a ganglion, the vestibular ganglion or the ganglion of Scarpa (ganglion vestibulare); the nerve divides into three branches which pass through minute openings at the upper and back part of the bottom of the meatus (area vestibularis posterior), and, entering the vestibule, are distributed to the utricle and to the ampulla of the external and superior semicircular canals.

The nerve filaments enter the ampullary enlargements opposite the septum transversum, and arborize around the hair-cells. In the utricle and saccule the nerve-fibres pierce the membrana propria of the maculae, and end in arborizations around the hair-cells.

The Cochlear Nerve (n. cochlearis) gives off the branch to the saccule, the filaments of which are transmitted from the internal auditory meatus through the foramina of the area vestibularis inferior, which lies at the lower and back part of the floor of the meatus. It also gives off the branch for the ampulla of the posterior semicircular canal, which leaves the meatus through the foramen singulare.

The rest of the cochlear nerve divides into numerous filaments at the base of the modiolus; those for the basal and middle coils pass through the foramina in the tractus foraminosus, those for the apical coil through the canalis centralis, and the nerves bend outward to pass between the lamellae of the osseous spiral lamina. Occupying the spiral canal of the modiolus is the spiral ganglion or ganglion of Corti (ganglion spirale), consisting of bipolar nerve-cells, which really constitute the true cells of origin of this nerve, one pole being prolonged centripetally to the brain and the other peripherally to the hair-cells of Corti's organ. Reaching the outer edge of the osseous spiral lamina, the nerve fibres pass through the foramina in the labium tympanicum, where they lose their axis-cylinders. They enter the organ of Corti and pass directly to the deep portions of the inner and outer hair-cells by way of the canal of Corti and the space of Nuel. The terminations arborize about the lower portions of the hair-cells and end in the surfaces of the cells.

Surgical Anatomy.—Malformations, such as imperfect development of the external parts, absence of the meatus, or supernumerary auricles, are occasionally met with. Or the pinna may present a congenital fistula, which is due to defective closure of the first visceral cleft, or rather of that portion of it which is not concerned in the formation of the Eustachian tube, tympanum, and meatus. In some cases the cephalo-auricular angle is almost absent; in others it is nearly
THE MEMBRANOUS LABYRINTH

a right angle. Projecting ears and long ears are said by some observers to be more common among degenerates, criminals, and the insane than among the normal, the non-criminal, and the same. The skin of the auricle is thin and richly supplied with blood, but in spite of this it is frequently the seat of frost-bite, due to the fact that it is much exposed to cold, and lacks the usual underlying subcutaneous fat found in most other parts of the body. A collection of blood is sometimes found between the cartilage and perichondrium (haematoma auris), usually the result of traumaism, but not necessarily due to this cause. It is said to occur most frequently in the ears of the insane. Keloid sometimes grows in the auricle around the puncture made for ear-rings, and epithelioma occasionally affects this part. Deposits of urate of soda are often met with in the pinna in gouty subjects.

The external auditory meatus can be most satisfactorily examined by light reflected down a funnel-shaped speculum; by gently moving the latter in different directions the whole of the canal and membrana tympani can be brought into view. The points to be noted are: the presence of wax or foreign bodies, the size of the canal, and the condition of the membrana tympani. The accumulation of wax is often the cause of deafness, and may give rise to very serious consequences, causing ulceration of the membrane and even absorption of the bony wall of the canal. Foreign bodies are not infrequently introduced into the ear by children, and, when situated in the first portion of the canal, may be removed with tolerable facility by means of a minute hook or loop of fine wire, the parts being illuminated with reflected light; but when they have slipped beyond the narrow middle part of the meatus, their removal is in nowise easy, and attempts to effect it, in inexperienced hands, may be followed by destruction of the membrana tympani and possibly injury of the contents of the tympanum. The calibre of the external auditory canal may be narrowed by inflammation of its lining membrane, running on to suppuration; by periostitis; by polyypi, sebaceous tumors, and exostoses. The membrana tympani, when seen in a healthy ear, “reflects light strongly, and, owing to its peculiar curvature, presents a bright spot of triangular shape at its lower and anterior portion.”

From the apex of this, proceeding upward and slightly forward, is a white streak formed by the handle of the malleus, while near the upper part of the membrane may be seen a slight projection, caused by the short process of the malleus. In disease alterations in color, lustre, curvature or inclination, and perforation must be noted. Such perforations may be caused by a blow, a loud report, a wound, or as the result of suppuration in the middle ear.

The upper wall of the meatus is separated from the cranial cavity by a thin plate of bone; the anterior wall is separated from the temporo-mandibular joint and parotid gland by the bone forming the genoid fossa; and the posterior wall is in relation with the mastoid cells; hence inflammation of the external auditory meatus may readily extend to the membranes of the brain, to the temporo-mandibular joint, or to the mastoid cells; and, in addition to this, blows on the chin may cause fracture of the wall of the meatus.

The nerves supplying the meatus are the auricular branch of the vagus, the auriculo-temporal, and the auricularis magnus. The connections of these nerves explain the fact of the occurrence, in cases of any irritation of the meatus, of constant coughing and sneezing from implication of the vagus, or of yawning from implication of the auriculo-temporal. No doubt also the association of carache with toothache in cancer of the tongue is due to implication of the same nerve, a branch of the trigeminal, which supplies also the teeth and the tongue. The vessels of the meatus and membrana tympani are derived from the posterior auricular, temporal, and internal maxillary arteries. The upper half of the membrana tympani is much more richly supplied with blood than the lower half. For this reason, and also to avoid the chorda tympani nerve and ossicles, incisions through the membrane should be made at the lower and posterior part.

The principal point in connection with the surgical anatomy of the tympanum is its relations to other parts. Its roof is formed by a thin plate of bone, which, with the dura, is all that separates it from the temporal lobe of the brain. Its floor is immediately above the jugular fossa and the carotid canal, the fossa being behind and the canal in front. Its posterior wall presents the openings of the mastoid cells. On its anterior wall is the opening of the Eustachian tube. Thus it follows that in disease of the middle ear we may get subdural abscess, septic meningitis, or abscess of the cerebrum or cerebellum from extension of the inflammation through the bony roof; thrombosis of the lateral sinus, with or without pyemia, by extension through the floor; or mastoid abscess by extension backward. In addition to this, we may get fatal hemorrhage from the internal carotid in destructive changes of the middle ear; and in throat disease we may get the inflammation extending up the Eustachian tube to the middle ear. The Eustachian tube is accessible from the nose. If the nose and mouth be closed and an attempt made to expire air, a sense of pressure with dulness of hearing is produced in both ears, from the air finding its way up the Eustachian tube and bulging out the membrana tympani. During the act of swallowing, the pharyngeal orifice of the tube, which is normally closed, is opened, probably by the action of the Dilator tubea muscle. This fact was employed by Politzer in devising an easy method of inflating the tube. The nozzle of an india-rubber syringe is inserted into the nostril; the patient takes a mouthful of water and holds it in his mouth, both nostrils are closed with the finger and thumb to prevent the escape of air, and the patient is then requested to swallow; as he does so the
surgeon squeezes the bulb and the air is forced out of the syringe into his nose, and is driven into the Eustachian tube, which is now open. The impact of the air against the membrana tympani can be heard by the surgeon, if the membrane is intact, sound being conveyed by means of a piece of india-rubber tubing, one end of which is inserted into the meatus of the patient’s ear, the other into that of the surgeon. The direct examination of the Eustachian tube is made by the Eustachian catheter. This is passed along the floor of the nostril, close to the septum, with the point touching the floor, to the posterior wall of the pharynx. When this is felt, the catheter is to be withdrawn about half an inch, and the point rotated outward through a quarter of a circle, and pushed again slightly backward, when it will enter the orifice of the tube, and will be found to be caught, and air forced into the catheter will be heard impinging on the tympanic membrane if the ears of the patient and surgeon are connected by an india-rubber tube.

THE SKIN (INTEGUMENTUM COMMUNE).

The skin covers the body surface and is continuous with the mucous membrane at the origin and termination of the alimentary canal and at the openings of other canals. The skin is a protective coat, a regulator of body-temperature, contains multitudes of the terminations of sensor nerves, and is the seat of the organ of touch (organon tactus). These nerve-terminations are connected with nerve-fibres of temperature, pressure, and pain. Connected with the skin are sweat-glands which have important excretory functions and sebaceous glands. From its superficial part come appendages, the hairs, and nails. The skin is elastic and varies in thickness from 0.5 mm. to 4 mm. It is thinnest in the eyelids and prepuce, and thickest over the back of the neck, back of the shoulders, palms of the hands, and soles of the feet. Its color depends in part on the blood within it, and in part upon pigment. The deepest hue is about the anus, in the genital region, in the axillae, over the mammary glands, and in the parts exposed to air, light, and varied temperatures. The color varies with age, being pinkish in extreme youth and becoming yellow in old age. It varies with exposure and with climate, being deepest in those who brave all weathers and temperatures and in those who dwell beneath a tropical sun. It also varies with race, and this is so well recognized that races are classified by the color of the skin into the Black, White, Yellow, and Brown races. The color of the skin is also affected in certain diseases; being extremely pale in anaemia, brown in Addison’s disease, yellow in jaundice, etc.

In most situations the skin is movable, but in some it is attached closely to underlying structures, and is consequently immovable on the scalp, the palms of the hands, the soles of the feet, and the outer portion of the pinna of the ear. The skin is fairly smooth, but close examination discloses multitudes of openings, creases, furrows, depressions, folds, and hairs. Hair-follicles open upon the surface, and the ducts of sebaceous glands and of sweat-glands perforate the skin.

About the joints are folds of skin (retinacula cutis), and temporary folds or wrinkles are created by the contraction of superficial muscles. The facial wrinkles of advancing years are due to habitual expression and loss of skin elasticity. A dimple is a permanent pit or depression due to adhesion of the surface to parts beneath. The ridges and furrows on the palms, soles, and flexor aspects of the
digits are permanent, and over the palmar surface of the digits they are arranged in definite forms which endure through life and are so distinctive that they have been utilized by police officials in determining the identity of individuals. These folds are due to the papillae of the skin being arranged in rows; some of the papillae proliferate, and linear depressions occur in the horny layer (Philipppson).

**Fig. 793.**—Anterior surface.
The general course of the connective-tissue bundles of the corium, determined by the direction assumed by the linear clefts made in the skin when it is punctured by a round awl. (Langer.)

**Fig. 794.**—Posterior surface.

Fig. 792 shows skin ridges (*cristae cutis*), skin furrows (*sulci cutis*), furrows opposite joints due to acts of flexion, and called flexure furrows, and longitudinal furrows.

When the skin is punctured by a round awl it tends to split in a definite direction, which direction varies with the region stabbed. These clefts are known
as the lines of cleavage of Langer (Figs. 793 and 794), and depend upon the arrangement of the connective-tissue bundles of the corium. These connective-tissue bundles certainly influence the formation of folds and furrows. In many portions of the body the cutaneous surface is divided by linear furrows into irregularly shaped areas (Fig. 795). The skin consists of two layers: a superficial layer, the epidermis, and a deep layer, the corium or dermis.

The Corium, Cutis Vera, Dermis or True Skin (Figs. 796, 797, and 799) is a connective-tissue structure which arises from the mesoderm. It consists especially of connective tissue and elastic fibres; it contributes elasticity to the skin, and is the seat of the sensitive layer. The corium is composed of two layers, the reticular and the papillary.

The Deep or Reticular Layer or Tunica Propria (stratum reticulare) rests upon the subcutaneous tissue. It passes superficially into the papillary layer, and at most places into the subcutaneous tissue without a sharp line of differentiation. At some places, for instance in the nipple, the deep layer of the corium rests upon a layer of muscular fibre. In the face this muscle-fibre is striated and sends prolongations to the papillary layer; in the nipple and scrotum it is non-striated. The reticular layer is composed of bundles of white fibrous tissue, arranged in a network. In the meshes of the network are fat, blood-vessels, lymphatics, sebaceous glands, sweat-glands, and hair-follicles.

The Subcutaneous Areolar Tissue or Tela Subcutanea (panniculus adiposus) connects, the skin to the parts beneath; it is composed of bundles of connective tissue

---

**Fig. 796.**—Vertical section through the skin of the finger-tip. The layers of the epidermis and of the corium. The subcutaneous areolar tissue. The sudoriferous or sweat-gland. (Toldt.)

**Fig. 795.**—The furrows of the skin and the areas which these furrows delimit, reproduced from an impression of the dorsal surface of the wrist. (Toldt.)
which cross repeatedly and form spaces. In almost all regions the spaces contain fat, but in the scrotum and external ear they do not contain fat. When the connective tissue fibres of the panniculus adiposus are long and nearly parallel to the skin surface the skin becomes wrinkled; when they are short and nearly at right angles to the surface, the skin cannot wrinkle.

The Superficial or Papillary Layer or Corpus Papillare of the Corium (stratum papillare) lies just beneath the epidermis, contains the papillae, and is composed of a network of fine bundles of fibrous tissue. The papillae are composed of fine strands of connective tissue and elastic tissue. They project from the corium beneath the epidermis and enter into depressions of the epidermis. They vary greatly in size, averaging \( \frac{1}{20} \) of an inch in height and \( \frac{1}{50} \) of an inch in width at the base. In the face, especially in the eyelids, they are insignificant. On the glans penis, the palms of the hands, and the soles of the feet, and in the nipples, they are large. In the palmar surfaces of the hands and fingers and the plantar surfaces of the feet and toes they produce permanent ridges (Fig. 798). A ridge is composed of two or more rows of papillae, and the ducts of sweat-glands emerge between rows of papillae, and open on the curved surface ridges (Fig. 798). Most of the papillae contain loops of capillaries, and are called vascular papillae. Some contain nerve-terminations and are called nervous papillae. Between the papillary layer of the corium and the epidermis is a very thin and structureless membrane called the basal membrane.

![Diagram of the skin layers](image)

**The Cuticle, Scarf Skin or Epidermis** (Figs. 796, 797, 799, and 800).—The cuticle, scarf skin or epidermis is composed of layers of epithelium and is derived from the ectoderm. The epithelium is stratified, and there are no blood-vessels. Two layers can be readily made out, the superficial or horny layer and the deeper or Malpighian layer.

**The Horny Layer** (stratum corneum).—The horny layer is formed by several layers of non-nucleated scaly cells. The cells consist of keratin. The surface cells of the horny layers are being constantly rubbed off, and are being replaced by cells from the Malpighian layer, which are converted into keratin as they near the surface.
The Malpighian Layer.—The Malpighian layer of the epidermis is divided into four layers, named, from without inward, the stratum lucidum, the stratum granulosum, the stratum mucosum, and the stratum germinativum.

The Stratum Lucidum is not classified by all writers as part of the Malpighian layer. Some anatomists classify it as a separate layer. It is here regarded as the most superficial part of the Malpighian layer. It consists of several layers of flat cells, the nuclei of which are beginning to disappear. The cells contain eleidin granules. In regions where the epidermis is thin the stratum lucidum is absent.

The Stratum Granulosum consists of several layers of nucleated flat cells, containing keratohyaline granules. These granules are probably formed from the disintegrating nucleus, and in the stratum lucidum are converted into eleidin.

The Mucous Layer, the Stratum Spinosum or the Stratum Mucosum consists of numerous layers of nucleated, polygonal, spine-shaped cells known as prickle cells or finger cells. Between the cells of the stratum mucosum are spaces containing pigment granules and leukocytes. Processes from the prickle-cells join adjacent cells. This layer contains numerous connective-tissue fibres arranged in a network, and known as epidermic fibrils.

The Stratum Cylindricum or Stratum Germinativum is composed of cylindrical or prickle-cells, the points of which are directed downward. Fine fibrils pass up from the corium between the cells, and there is cement-substance as well between them.

Pigmentation of the Skin.—As previously stated, in certain regions the skin of the white race is brown because of pigmentation (areolae, nipples, around the anus, axillae, scrotum, labia majora). This is due to pigment within the epithelial and
connective-tissue cells of the papillary layer of the corium, and in the basal cells of the epidermis. There are few or none of these pigmented cells in the stratum corneum of one of the Caucasian race.

In negroes and other colored races the deep pigmentation is due to a similar distribution of the pigment granules in the entire epidermis; but even here the pigmentation decreases toward the surface, although the uppermost cells of the stratum corneum always contain some pigment. The nuclei of the cells are always free from coloring matter. The question as to the origin of the pigment is as yet unsolved."

The Arteries and Veins of the Skin (Fig. 802).—The arteries supplying the skin vary in number, and vary much in size, being largest in regions exposed to pressure, as the skin of the palms, soles, and buttocks. The arteries enter the skin from a network in the subcutaneous tissue, and by an anastomosis in the deepest part of the corium form a network (rete arteriosum cutaneum). The vessels send branches to the fat and to the sweat-glands. Branches from the network just described ascend and form a second network in the corium beneath the papillae. This is called the subpapillary network (rete arteriosum subpapillare). From this network fine capillary vessels pass into the papillae, forming, in the smaller papillae, a single capillary loop, but in the larger a more or less convoluted vessel. From this network branches go to the hair-follicles and sebaceous glands. The blood from the papillae passes into a plexus (rete venosum) beneath the papillae. This communicates with another plexus in the skin of the sole of the foot. (Spalteholz.)

In some regions one or more retia are interposed between these two. The veins from the sweat-glands, sebaceous glands, superficial fat, and hair-follicles are received by the retia venosa. From the deepest rete veins pass to the subcutaneous tissue, and these veins enter the large subcutaneous veins.

The Lymphatics of the Skin.—There are numerous lymphatics supplied to the skin which form two networks, superficial and deep, communicating with each other and with the lymphatics of the subcutaneous tissue by oblique branches. They originate in the cell-spaces of the tissue.

The Nerves of the Skin.—The nerves of the skin terminate partly in the epidermis (Figs. 796 and 800) and partly in the cutis vera (Fig. 796). The former are prolonged into the epidermis from a dense plexus in the superficial layer of the corium and terminate between the cells in bulbous extremities; or, according to some observers, in the deep epithelial cells themselves. The latter terminate in end-bulbs, touch-corpuscles, or Pacinian bodies (Figs. 524 and 796), in the manner already described; and, in addition to these, a considerable number of fibrils are distributed to the hair-follicles, which are said to entwine about the follicle in a circular
manner. Other nerve-fibres are supplied to the plain muscular fibres of the hair-follicles (arrectores pili) and to the muscular coat of the blood-vessels. These are probably amyelinic fibres.

The Appendages of the Skin.

The appendages of the skin are the nails, the hairs, the sudoriferous and sebaceous glands, and their ducts.

The nails and hairs are peculiar modifications of the epidermis, consisting essentially of the same cellular structure as that tissue.

The Nails (ungues) (Figs. 803, 804, 805, 806, 807, and 808).—The nails are flattened, elastic structures of a horny texture, placed upon the dorsal surface of the terminal phalanges of the fingers and toes. Each nail is convex on its outer surface, concave within. Its chief mass, called the body (corpus unguis), lies upon the nail-bed. The free edge is called the margo liber. Each lateral margin (margo lateralis), like the proximal short edge of the nail (margo occultus), lies in a groove of the cutis, the ungual fold (sulcus matrixis unguis). The ungual wall (vallum unguis) overlies the lateral and posterior edges. The nail is implanted by means of a portion, called the root (radix unguis), into a groove in the skin. The root is beneath the ungual wall and is composed of cells which have not yet become horny. It is white in color. The nail has a very firm adhesion to the cutis vera, being accurately moulded upon the surface of the true skin, as the epidermis is in other parts. The part of the cutis beneath the body and root of the nail is called the matrix (matrix unguis), because it is the part from which the nail is produced. Corresponding to the body of the nail, the matrix is thick, and raised into a series of longitudinal ridges (cristae matrixis unguis), which are very vascular, and the color is seen through the transparent tissue. Behind this, near the root of the nail, the papillae are small, less vascular, and have no regular arrangement, and here the tissue of the nail is somewhat more opaque; hence this portion is of a whiter color, and is called the lunula on account of its crescentic shape.
The cuticle, as it passes forward on the dorsal surface of the finger or toe, is attached to the surface of the nail, a little in advance of the nail root; at the extremity of the finger it is connected with the under surface of the nail a little behind its free edge. The cuticle and the horny substance of the nail (both epidermic structures) are thus directly continuous with each other. The nails consist of a greatly thickened stratum lucidum, the stratum corneum forming merely the thin cuticular fold (eponychium) which overlaps the lunula. The cells have a laminated arrangement, and are essentially similar to those composing the epidermis. The deepest layer of cells, which lie in contact with the papillae of the matrix, are columnar in form and arranged perpendicularly to the surface; those which succeed them are of a rounded or polygonal form, the more superficial ones becoming broad, thin, and flattened, and so closely compacted as to make the limits of each cell very indistinct. It is by the successive growth of new cells at the root and under surface of the body of the nail that it advances forward and maintains a due thickness, while, at the same time, the growth of the nail in the proper direction is secured. As these cells in their turn become displaced by the growth of new ones, they assume a flattened form, and finally become closely compacted together into a firm, dense, horny texture. In chemical composition the
The Hairs (pili) (Figs. 797, 799, 801, 809, 810, and 811).—The hairs are peculiar modifications of the epidermis, and consist essentially of the same structure as that membrane. They are found on nearly every part of the surface of the body, excepting the palms of the hands, soles of the feet, the vermillion borders of the lips, the dorsal surfaces of the phalanges, the nipples, the inner surface of the prepuce, and the glans penis. Hairs include hairs of the head (capilla); of the eyebrows (supercilia); of the beard (barba); of the ears (tragi); of the nostrils (vibrisseae); the eyelashes (cilia); hairs of the axilla (hirci); pubes (pubes); and the small hairs of the skin or woolly hairs (lanugo). They vary much in length, thickness, and color in different parts of the body and in different races of mankind. In some parts, as in the skin of the eyelids, they are so short as not to project beyond the follicles containing them; in others, as upon the scalp, they are of considerable length; again, in other parts, as the eyelashes, the hairs of the pubic region, and the whiskers and beard, they are remarkable for their thickness. Straight hairs are stronger than curly hairs, and present on transverse section a cylindrical or oval outline; curly hairs, on the other hand, are flattened. The hairs are usually oblique to the surface from which they arise (Fig. 797). Their direction depends upon the region from which they spring, being fairly regular in certain regions. Thus are formed hair-streams (flu-mina pilorum) and hair-whirlpools (vortices pilorum).

A hair consists of the root, the part implanted in the skin; the shaft or stem, the portion projecting from its surface; and the point.

The Root of the Hair (radix pili) presents at its extremity a bulbous enlargement, the hair-bulb (bulbus pili) (Figs. 799 and 809), which is whiter in color and softer in texture than the shaft, and is lodged in a follicular involution of the epidermis called the hair-follicle (folliculus pili) (Figs. 797 and 801). When the hair is of considerable length the follicle extends into the subcutaneous cellular tissue (Fig. 799). The hair-follicle commences on the surface of the skin with a funnel-shaped opening, and passes inward in an oblique or curved direction—the latter in curly hair—to become dilated at its deep extremity or fundus (fundus folliculi pili), where it corresponds with the bulbous condition of the hair which it contains. It has opening into it, near its free extremity, the orifices of the ducts of one or more sebaceous glands (Figs. 799, 801, 809, and 810). At the bottom of each hair-follicle is a small conical, vascular eminence or papilla, the hair-papilla (papilla pili) (Figs. 809 and 810),

nails resemble the upper layers of the epidermis, containing, however, a somewhat larger proportion of carbon and sulphur (Mulder).
similar in every respect to the papillae found upon the surface of the skin; it is continuous with the dermic layer of the follicle, is highly vascular, and is probably supplied with nerve fibrils. In structure the hair-follicle consists of two coats—an outer or dermic, and an inner or epidermic (Figs. 809 and 811).

The Outer or Dermic Coat is formed mainly of fibrous tissue; it is continuous with the corium, is highly vascular, and is supplied by numerous minute nerve filaments. It consists of three layers. The most internal, the cuticular lining of the follicle, consists of a hyaline basement-membrane, the hyaline layer, having a glassy, transparent appearance, which is well marked in the larger hair-follicles, but is not very distinct in the follicles of minute hairs. It is continuous with the basement-membrane of the surface of the corium. External to this is the inner fibrous layer, a compact layer of fibres and spindle-shaped cells arranged circularly around the follicle. This layer extends from the bottom of the follicle as high as the entrance of the ducts of the sebaceous glands. Externally is the outer fibrous layer, a thick layer of connective tissue, arranged in longitudinal bundles, forming a more open texture and corresponding to the reticular part of the corium. In this are contained the blood-vessels and nerves.

Fig. 810.—Vertical section through the skin of the head. The hairs of the head in longitudinal section. (Toldt.)

The Inner or Epidermic Layer is closely adherent to the root of the hair, so that when the hair is plucked from its follicle this layer most commonly adheres to it and forms what is called the root-sheath. It consists of two strata, named respectively the outer and inner root-sheaths; the former of these corresponds with the Malpighian layer of the epidermis, and resembles it in the rounded form and soft character of its cells; at the bottom of the hair-follicle these cells become continuous with those of the root of the hair. The inner root-sheath consists of a delicate cuticle next the hair, composed of a thin layer of imbricated scales having a downward direction, so that they fit accurately over the upwardly directed imbricated scales of the hair itself; then of one or two layers of horny, flattened nucleated cells, known as Huxley’s layer; and finally of a single layer of horny oblong cells without visible nuclei, called Henle’s layer.

The hair-follicle contains the root of the hair, which terminates in a bulbous extremity, and is excavated so as to exactly fit the papilla from which it grows. The bulb is composed of polyhedral epithelial cells, which as they pass upward into the root of the hair become elongated and spindle-shaped, except some in the centre which remain polyhedral. Some of these latter cells contain pigment-
granes, which give rise to the color of the hair. It occasionally happens that these pigment-granules completely fill the cells of the medullary substance in the centre of the bulb, which gives rise to the dark tract of pigment often found, of greater or less length, in the axis of the hair.

The Stem or Shaft of the Hair (scapus pili) (Fig. 809), consists of a central pith or medulla, the fibrous part of the hair, and the true cuticle externally. The medulla (substantia medullaris pili) occupies the centre of the shaft and ceases toward the point of the hair. It is usually wanting in the fine hairs covering the surface of the body, and commonly in those of the head. It is found in the shafts of all thick hairs and in the deeper parts of the root of most hairs. It is more opaque and deeper colored when viewed by transmitted light than the fibrous part; but when viewed by reflected light it is white. It is composed of rows of polyhedral cells, which contain granules of eleidin and frequently air-bubbles. The fibrous portion or cortical substance of the hair (substantia corticalis pili) constitutes the chief part of the shaft; its cells are elongated and unite to form flattened fusiform fibres. Between the fibres are found minute spaces which contain either pigment-granules in dark hair or minute air-bubbles in white hair. In addition to this there is also a

diffused pigment contained in the fibres. The cells which form the outer hair membrane or true cuticle (cuticula pili) consist of a single layer which surrounds those of the fibrous part; they are converted into thin, flat scales, having an imbricated arrangement.

Connected with the hair-follicles are minute bundles of involuntary muscular fibres, termed arrectores pili (mm. arrectores pilorum) (Figs. 797 and 809). They arise from the superficial layer of the corium, and are inserted into the outer surface of the hair-follicle, below the entrance of the duct of the sebaceous gland. They are placed on the side toward which the hair slopes, and by their action elevate the hair. When the hair is elevated a depression forms over the seat of origin of the muscle, and the parts about the hair are elevated. This condition is known as goose-skin. It is probable that the contraction of these muscles aids in emptying sebaceous glands.

Blood-vessels and Nerves (Fig. 799).—A hair-follicle possesses a rich network of capillaries about the hyaline membrane, and capillary loops pass to the papilla.

---

1 Arthur Thomson suggests that the contraction of these muscles on follicles which contain weak, flat hairs will tend to produce a permanent curve in the follicle, and this curve will be impressed on the hair which is moulded within it, so that the hair, on emerging through the skin, will be curled. Curved hair-follicles are characteristic of the scalp of the Bushman.—Ed. of 15th English edition.
We have little knowledge as to nerve-terminations of the human hair. "In other mammals the nerves end below the sebaceous glands. Myelinic fibres lose their medullary sheaths, divide, and penetrate to the hyaline membrane. Here some of the branches encircle the hair, while others end freely on the hyaline membrane as naked axis-cylinders. These branch regularly and run parallel to the long axis of the hair."

The Sudoriferous or Sweat-glands (glandulae sudoriferae) (Figs. 796, 797, 799, 801, and 810).—The sudoriferous or sweat-glands are the organs by which a large portion of the aqueous and gaseous substances is excreted by the skin. They are found in almost every part of this structure, being absent on the red border of the lips, the glans penis, and inner surface of the prepuce. On the eyelids they are somewhat modified, and are called ciliary glands (glandulae ciliares [Molli]); about the anus they are extremely large, and are called circumanal glands (glandulae circumanales). The sweat-glands are situated in small pits below the under surface of the corium, or, more frequently, in the subcutaneous areolar tissue, surrounded by a quantity of adipose tissue. They are small, lobular, reddish bodies, consisting of a single convoluted tube, from which the efferent duct (ductus sudoriferus) proceeds upward through the corium and cuticle. The duct in the corium has true walls; in the epidermis it has not individual walls, but is simply an epidermic tube. It becomes somewhat dilated at its extremity, and opens on the surface of the cuticle by an oblique valve-like aperture (porus sudoriferus). The duct, as it passes through the epidermis, presents a spiral arrangement, being twisted like a corkscrew, in those parts where the epidermis is thick; where, however, the epidermis is thin, the spiral arrangement does not exist. In the superficial layers of the corium the duct is straight, but in the deeper layers it is convoluted or even twisted. The spiral course of these ducts is especially distinct in the thick cuticle of the palm of the hand and sole of the foot. The size of the glands varies. They are especially large in those regions where the flow of perspiration is copious, as in the axillae, where they form a thin, mamillated layer of a reddish color, which corresponds exactly to the situation of the hair in this region; they are large also in the groin. Their number varies. They are most numerous on the palm of the hand, presenting, according to Krause, 2800 orifices on a square inch of the integument, and are rather less numerous on the sole of the foot. In both of these situations the orifices of the ducts are exceedingly regular, and open on the curved surface ridges. In other situations they are more irregularly scattered, but the number in a given extent of surface presents a fairly uniform average. In the neck and back they are least numerous, their number amounting to 417 on the square inch (Krause). Their total number is estimated by the same writer at 2,381,248, and, supposing the aperture of each gland to represent a surface of \( \frac{1}{37} \) of a line in diameter, he calculates that the whole of these glands would present an evaporating surface of about eight square inches. Each gland consists of a single tube intricately convoluted, terminating at one end by a blind extremity, and opening at the other end upon the surface of the skin.

The wall of the tubercle of the secreting coil is lined with cubical epithelial cells, external to these is a layer of smooth muscle-cells, and more externally a layer of connective tissue, the membrana propria. The duct in the corium, in contrast to the secreting coil, has no layer of muscle-cells, but instead a second layer of epithelial cells covered by connective tissue. As previously stated, the duct becomes spiral in the epidermis, its own wall disappears, and the channel is bounded by epidermic cells.

Blood-vessels and Nerves.—The blood-vessels are branches from the subcutaneous vessels and the arterial plexus of the deep part of the corium. Numerous

1 Histology and Microscopic Anatomy. By Dr. Ladislaus Szymonowicz. Translated and edited by John Bruce MacCallum, M.D.
anyeline nerve-fibres lie upon the membrana propria of a sweat-gland. From them fibrils pass inward and terminate by end-bulbs upon the cells of the gland.

The Sebaceous Glands (glandulae sebaceae).—The sebaceous glands are small, sacculated, glandular organs, lodged in the substance of the corium. They are found in most parts of the skin, and are usually connected with hair-follicles. This connection is so common that they are sometimes called hair-follicle glands. They are found in some regions which are devoid of hairs—the vermillion borders of the lips, the labia minora, the glans penis, and prepuce. These glands are especially abundant in the scalp and face; they are also very numerous around the apertures of the anus, nose, mouth, and external ear; but are wanting in the palms of the hands and soles of the feet. Each gland consists of a single duct, more or less capacious, which terminates in a cluster of small secreting pouches or saccules. The sacculi connected with each duct vary, in number, as a rule, from two to five, but in some instances may be as many as twenty. They are composed of a transparent, colorless membrane, enclosing a number of epithelial cells. Those of the outer or marginal layer are small and polyhedral, and are continuous with the lining cells of the duct. The remainder of the sac is filled with larger cells, containing fat, except in the centre, where the cells have become broken up, leaving a cavity containing their debris and a mass of fatty matter, which constitutes the sebaceous secretion. The orifices of the ducts open most frequently into the hair-follicles, but occasionally upon the general surface, as in the labia minora and the free margins of the lips. On the nose and face the glands are of large size, distinctly lobulated, and often become much enlarged from the accumulation of pent-up secretion. The largest sebaceous glands are those found in the eyelids—the Meibomian glands.
THE ORGANS OF DIGESTION.

THE Apparatus for the Digestion of the Food (apparatus digestorius) consists of the alimentary canal and of certain accessory organs.

THE ALIMENTARY CANAL.

The alimentary canal is a musculo-membranous tube, about thirty feet in length, extending from the mouth to the anus, and lined throughout its entire extent by mucous membrane. It has received different names in the various parts of its course; at its commencement, the mouth, we find provision made for the mechanical division of the food (mastication), and for its admixture with a fluid secreted by the salivary glands (insalivation); beyond this are the pharynx and the oesophagus, the organs which convey the food (deglutition) into that part of the alimentary canal, the stomach, in which the principal chemical changes occur, and in which the reduction and solution of the food take place; in the small intestines the nutritive principles of the food, the chyle, are separated, by its admixture with the bile, pancreatic and intestinal fluids, from that portion which passes into the large intestine, most of which is expelled from the system.

THE MOUTH, ORAL OR BUCCAL CAVITY (CAVUM ORIS).

The mouth is placed at the commencement of the alimentary canal; it is a nearly oval-shaped cavity, in which the mastication and insalivation of the food take place (Figs. 812, 831, and 837).

The aperture of the mouth (rima oris) is bounded by the lips. The angle of the mouth (angulus oris) is formed on each side by the meeting of the upper and lower lips (commissura labiorum). When at rest with the lips in contact, the rima is a slightly curved line. Every movement which the lips make alters the shape of the rima. When the mouth is closed the floor and roof are usually in contact and its sides are approximated to the dental arches. The mouth consists of two
parts: an outer, smaller portion, the vestibule, and an inner, larger part, the cavity proper of the mouth.

The Vestibule (vestibulum oris).—The vestibule is a slit-like space, bounded in front and laterally by the lips and cheeks; behind and internally by the gums and teeth. Above and below it is limited by the reflection of the mucous membrane from the lips and cheeks to the gum covering the upper and lower alveolar arch respectively. It receives the secretion from the parotid glands, and communicates, when the jaws are closed, with the cavum oris by an aperture on each side behind the wisdom teeth.

The Cavity of the Mouth Proper (cavum oris proprium).—The cavity of the mouth proper is bounded laterally and in front by the alveolar arches with their contained teeth; behind it communicates with the pharynx by a constricted aperture termed the isthmus faucium. It is roofed in by the hard and soft palate. The greater part of the floor is formed by the tongue, the remainder being completed by the reflection of the mucous membrane from the sides and under surface of the tongue to the gum lining the inner aspect of the mandible. It receives the secretion from the submaxillary and sublingual glands.

The Mucous Membrane.—The mucous membrane lining the mouth is continuous with the integument at the free margin of the lips and with the mucous lining of the pharynx behind; it is of a rose-pink tinge during life, and very thick where it covers the hard parts bounding the cavity. It is covered by stratified epithelium.

The Lips (Labia Oris).

The lips are two fleshy folds which surround the orifice of the mouth, formed externally by integument and internally by mucous membrane, between which are found the Orbicularis oris muscle (Fig. 263), the coronary vessels (Fig. 397), some nerves (Fig. 397), areolar tissue, and fat, and numerous small labial glands. The upper lip is called the labium superius; the lower lip is called the labium inferius. The inner surface of each lip is connected in the middle line to the gum of the corresponding jaw by a fold of mucous membrane, the frenulum (frenulum labii superius and frenulum labii inferioris). The frenulum labii superioris is the larger of the two. On each side, external to the angle of the mouth, the lips become continuous.

The Labial Glands (glandulae labiales) (Fig. 397):—The labial glands are situated between the mucous membrane and the Orbicularis oris muscle around the orifice of the mouth. They are rounded in form, about the size of small peas, and their ducts open by minute orifices upon the mucous membrane. In structure they resemble the salivary glands.
The Cheeks (Buccae).

The cheeks form the sides of the face and are continuous in front with the lips. They are composed externally of integument, internally of mucous membrane, and between the two of a muscular stratum, besides a large quantity of fat, areolar tissue, vessels, nerves, and buccal glands.

The Mucous Membrane.—The mucous membrane lining the cheek is reflected above and below upon the gums, where its color becomes lighter; it is continuous behind with the lining membrane of the soft palate. Opposite the second molar tooth of the upper jaw is a papilla, the summit of which presents the aperture of the duct of the parotid gland (ductus parotideus [Stenonis]) (Fig. 837). The principal muscle of the cheek is the Buccinator, but numerous other muscles enter into its formation—viz., the Zygomatici, Risorius Santorini, and Platysma myoides.

The Buccal Glands (glandulae buccales).—The buccal glands are placed in the submucous tissue between the mucous membrane and Buccinator muscle; they are similar in structure to the labial glands, but smaller. Four or five glands of larger size than the previously mentioned glands are placed beneath the mucous membrane in the neighborhood of the last molar tooth. They are called the molar glands (glandulae molares). Their ducts open into the mouth opposite the last molar tooth.

The Gums (Gingiva).

The gums are composed of a dense fibrous tissue closely connected to the periosteum of the alveolar processes and surrounding the necks of the teeth. They are covered by smooth and vascular mucous membrane, which is remarkable for its limited sensibility. Around the necks of the teeth this membrane presents numerous fine papillae; and from this point it is reflected into the alveolus, where it is continuous with the periosteal membrane lining that cavity.

The Teeth (Dentes).

The human subject is provided with two sets of teeth, which make their appearance at different periods of life. The first set appear in childhood, and are called the temporary, deciduous or milk teeth. The second set are named permanent.

The temporary teeth are twenty in number—four incisors, two canine, and four molars in each jaw (Figs. 813 and 830).

The permanent teeth are thirty-two in number—four incisors (two central and two lateral), two canines, four bicuspids, and six molars in each jaw (Figs. 815 and 819).

General Characters (Fig. 820).—Each tooth consists of three portions; the crown or body (corona dentis), projecting above the gum; the root or fang (radix dentis), entirely concealed within the alveolus; and the neck (collum dentis), the constricted portion, between the root and crown.

Surfaces.—The surfaces of a tooth are named thus: that which comes in contact with the teeth of the opposite jaw is the grinding or masticating surface (facies masticatoria); that which touches the next tooth in the same row is the contact surface (facies contactus). That surface which is toward its predecessor is called the proximal surface (in incisors and canines, facies medialis; in molars and premolars, facies anterior). That surface which is toward its successor is called the distal surface (in incisors and canines, facies lateralis; in molars and premolars, facies posterior). That which looks toward the lips and cheek is the labial or buccal surface (facies labialis). That toward the tongue is the lingual surface (facies lingualis). In part this method of designation applies to the roots as well as to the crowns of teeth.
The Roots of the Teeth.—The roots of the teeth are firmly implanted within the sockets or alveoli of the jaws (alveoli dentales) (see pp. 109 and 124). These depressions are lined with periosteum, called the pericementum, which is reflected on to the tooth at the point of the root and covers it as far as the neck. This is the root membrane (periostea alveolare). At the margin of the alveolus the periosteum becomes continuous with the fibrous structure of the gums.

Temporary, Deciduous or Milk Teeth (dentes decidui) (Figs. 813, 814, and 830).—The temporary or milk teeth are smaller, but resemble in form those of the permanent set. The neck is more marked, owing to the greater degree of convexity of the labial and lingual surfaces of the crown. The hinder of the two temporary molars is the largest of all the deciduous teeth, and is succeeded by the second bicuspid. The first upper molar has only three cusps—two labial, one lingual; the second upper molar has four cusps. The first lower molar has four cusps; the second lower molar has five. The roots of the temporary molar teeth are smaller and more diverging than those of the permanent set, but in other respects bear a strong resemblance to them.

Permanent Teeth (dentes permanentes) (Figs. 815, 816, 817, and 819). The Incisors (dentes incisivi).—The incisors or cutting teeth are so named from their presenting a sharp cutting edge, adapted for incising the food. They are eight in number, and comprise the four front teeth in each jaw.

The crown is directed almost vertically and is spade-like in form; it has the form of a truncated cone whose top has been compressed into a sharp horizontal cutting
edge. Before being subjected to attrition this edge presents three small elevations. The labial surface is convex, and marked by free longitudinal ridges extending from the edge tubercles toward the neck of the tooth. The lingual surface is concave, and is marked by two marginal ridges extending from an encircling ridge at the neck to the angles of the cutting edge of the tooth. The ridge at the neck is termed the cingulum or basal ridge. The mesal and distal surfaces are triangular, the apex of the triangle being at the cutting edge. The neck of the tooth is constricted. The root is long, single, and has the form of a transversely flattened cone, thicker before than behind. The root may be curved.

The Incisors of the Upper Jaw are altogether larger and stronger than those of the lower jaw, the central incisors being larger and flatter than the lateral incisors. They are directed obliquely downward and forward.

The Incisors of the Lower Jaw are smaller and flatter than the upper, and the elevations upon their lingual faces are not marked. The two central are smaller than the two lateral incisors, being the smallest of all the teeth. The roots of these teeth are flattened laterally.

The Canine Teeth or Cuspidati (dentes canini).—The canine teeth are four in number, two in the upper, two in the lower jaw—one being placed distal to each lateral incisor. They are larger and stronger than the incisors, especially in the roots, which are deeply implanted and each causes a well-marked prominence of the process at the place of insertion.

The crown is large, of spear-head form, and its very convex labial surface is marked by three longitudinal ridges. The concave lingual surface is also marked by three ridges which unite at a basal ridge. The point or cusp is longer than in the other teeth, and is the point of division between a short mesal and a long distal cutting edge. These two edges form an obtuse angle with each other.

The root is single, oval, or elliptical on transverse section, and is longer and more prominent than the roots of the incisors.

The Upper Canines or cuspids, vulgarly called the eye teeth, are larger and longer than the two lower, and in occlusion are distal to them to the extent of half the width of the crown.

The Lower Canines, vulgarly called the stomach teeth, have the general form of the upper cuspids, but their lingual surfaces are much more flattened, owing to
the absence of the elevations marking the upper. Their roots are more flattened and may be bifid at their apices.

The Bicuspid Teeth or the Premolars (*dentes premolares*).—The bicuspid teeth are eight in number, four in each jaw; they are placed distal to the cuspid teeth, two upon each side of the jaw. They are double cuspids in form. The crown is surmounted by two cusps, one buccal and one lingual, separated by a groove, the buccal being more prominent and larger than the lingual. The lower bicuspids are not truly bicuspid, the first having but a primitive lingual cusp, the second having the lingual cusp divided into two sections—*i. e.*, it is usually tricuspid. The necks of the teeth are oval; the roots are single and laterally compressed, that of the first upper bicuspid being frequently bifid. The first upper bicuspid is usually the largest of the series. The roots of the lower bicuspid are less compressed and more rounded.

The Molar Teeth, the Multicuspidati or Grinders (*dentes molares*).—The molar teeth are the largest and strongest teeth of the denture. They are adapted by their forms for the crushing and grinding of the food. They are twelve in number, six in each jaw, three being placed posterior to each second bicuspid.

The crowns are cuboidal in form, are convex buccally and lingually; they are flattened mesially and distally. They are formed by the fusion of three primitive cusps in the upper and four in the lower. To these are added in the first and second upper molars a *disto-lingual tubercle*, and in the first and third molars of the lower jaw a *disto-buccal tubercle*. The unions of the primitive forms are marked by sulci. The necks of these teeth are large and rhomboidal in form. The roots of the upper molars are three in number—one large *lingual* or *palatal root*, and two smaller *buccal roots*. In the lower molars, two roots are found, a mesial and a distal, each of which is much flattened from before backward.

The First Molar Teeth are the largest of the dental series; they have four cusps on the upper and five in the lower—three buccal and two lingual.

The Second Molars are smaller; the crowns of the upper are compressed until the disto-lingual cusp is reduced. The crowns of the lower are almost rectangular, with a cusp at each angle.

The Third Molars are called the wisdom teeth or *dentes sapientae* (*dentes serotini*), from their late eruption; they have three cusps upon the upper and five upon the lower. The three roots of the upper are frequently fused together, forming a grooved cone, which is usually curved backward. The roots of the lower, two in number, are compressed together, and curve backward.

**Arrangement of the Teeth.**—The human teeth are arranged in two parabolic arches, the upper row or arch (*arcus dentalis superior*) being larger, its teeth overlapping the lower row or arch (*arcus dentalis inferior*). The average distance between the centres of the condyles of the inferior maxillary bones is about four inches, which is also the distance from either of these points to the line of junction between the lower incisor teeth. Whether the jaw be large or small, the equilateral triangle indicated is included in it; the range of size is between three and one-half and four and one-half inches.

Owing to the smaller sizes of the lower incisors, the teeth of the lower jaw are each one-half a tooth in advance of its upper fellow, so that each tooth of the dental series has two antagonists, with the exception of the lower central incisors and upper third molars (Figs. 818 and 819).

The grinding faces of the upper bicuspid and molars curve progressively upward and point outward, the first molar being at the lowest point of the curve, the third molar at the highest. The curve of the lower dental arch is the reverse, the first molar at its deepest part, the third molar at its extremity. The greater the depth
to which the upper incisors overlap the lower, the more marked this curve and the more pointed are the cusps of the grinding teeth.

The movement of the human mandible is forward and downward, the resultant of these directions being an oblique line, upon an average of 35 degrees from the horizontal plane.¹ When the lower jaw is advanced until the cutting edges of

¹ W. E. Walker, Dental Cosmos, 1896.
the incisors are in contact, the jaws are separated, but at the highest point of the lower arch its third molar advances, and meets and rests upon a high point, the second molar of the upper arch, and thus undue strain upon the incisors is obviated.

In the lateral movements of the mandible but one side is in effective action at one time; the oblique positions of the cusps of the opposite teeth are such that when either side is in action the other is balanced at two or more points.

There is an anatomical correspondence between the forms and arrangement of the teeth, the form of the condyle of the mandible, and the muscular arrangement. Individuals who have teeth with long cusps have the head of the bone much rounded from before backward, and have a preponderance of the direct over the oblique muscles of mastication, and vice versa; teeth with short or no cusps are associated with a flattened condyle and strong oblique muscles.

Very great aberrations in the dental arrangement are frequently followed by accommodative changes in the heads of the mandible.

Structure of the Teeth. The Dental Pulp (pulpa dentis).—A longitudinal section of a tooth will show the presence of a central chamber having the general form of the crown of the tooth. Processes of the chamber pass from its body, one for each root and down each root, and open at the apex by a minute orifice. This cavity is known as the pulp-chamber or pulp-cavity (carum dentis) (Figs. 820 and 821). The minute canal in each root is called the pulp-canal or root-canal (canalis radicis dentis). The foramen at the apex of the root is the apical foramen (foramen apicis dentis). The cavity contains a soft, vascular, and sensitive organ called the dental pulp (pulpa dentis). It is made up of fibrous cellular connective tissue, the fibres of which are extremely fine, and contains numerous blood-vessels and nerves, which enter by way of the apical foramina. It has not been proved that there are lymphatics in the dental pulp, although some authors assert that they exist (Wangemann and others). It seems to have been proved that the spaces between the fibres of the pulp communicate with the lymphatic system. The periphery of the pulp is bounded by a layer of cells arranged like columnar epithelium, each cell sending one or more branched processes through the basic substance

---

of the dentine. These processes constitute the dentine fibres. Other processes come off from the cells which pass in the direction of the pulp and surround it. The cells at the periphery of the pulp are the dentine-forming cells, the odontoblasts of Waldeyer. The blood-vessels break up into innumerable capillary loops which lie beneath the layer of odontoblasts. The nerve-fibrils break up into numberless amyleinic filaments, which spread out beneath the odontoblasts, and probably send terminal filaments to the extreme periphery of the pulp outside the odontoblasts.

The matrix cells and their processes are irregularly arranged in the body of the pulp, but in the canal portion the fibrillae are in the direction of the axis of the root.

**The Solid Portion of the Tooth.**—The section will exhibit three hard tissues in a tooth: one, the proper dental substance, forming the greater mass of the tooth; hence its name dentine or ivory. The dentine upon the exposed crown is sheathed by a layer called the enamel; the dentine of the root is enclosed in a distinct tissue, the cementum or crista petrosa; both cementum and enamel are thinnest at the neck and thickest upon their distal portions.

*Fig. 823.*—Longitudinal ground-section through the apex of a canine tooth from a three-and-a-half-year-old boy. The entrance of the dental canaliculi between the enamel prisms and the course taken by the latter are shown. × 135. (Szymonowicz.)
The Ivory or Dentine (substantiae eburnea) (Figs. 821, 822, 823, and 824) forms the principal mass of a tooth; in its central part is the cavity enclosing the pulp. It is a modification of osseous tissue, from which it differs, however, in the fact that it does not contain cells placed in cavities, but the cells lie in the periphery of the pulp, against but not in the dentine. The dentine contains the processes of the cells, which are known as dental or dentinal fibres. On microscopic examination it is seen to consist of a number of minute wavy and branching tubes having distinct parietes. They are called the dentinal tubuli or dental canals, and are embedded in a dense homogeneous substance, the intertubular tissue.

The dentinal tubuli (canaliculi dentales) (Fig. 824) are placed parallel with one another, and open at their inner ends into the pulp-cavity. In their course to the periphery they present two or three curves, and are twisted on themselves in a spiral direction. The direction of these tubes varies; they are vertical in the upper portion of the crown, oblique in the neck and upper part of the root, and toward the lower part of the root they are inclined downward. The tubuli, at their commencement, are about \( \frac{1}{40} \) of an inch in diameter; in their course they divide and subdivide dichotomously, so as to give to the cut surface of the dentine a striated appearance. From the sides of the tubes, especially in the root, ramifications of extreme minuteness are given off, which join together in loops in the intertubular substance, or terminate in small dilatations, from which branches are given off. Near the pulp the lateral branches are few and are almost at right angles to the canals. Nearer the periphery the lateral branches are more numerous, and they come off at acute angles. The terminations of the chief canals at the periphery vary. In the crown they break up into branches like fingers just beneath the enamel. Some of these finger-like branches leave the dentine and enter the cement substance between enamel prisms. The majority of the chief canals end in blind extremities at the margin of the enamel and do not enter this structure. In the lower portion of the tooth the chief canals do not emerge from the dentine, but end at the margin of the cement in blind extremities. They may reach the spaces of the granular sheath. Near the periphery of the dentine of the crown the finer ramifications of the tubuli pass through a layer of irregular branched spaces which communicate with each other. These are called the interglobular spaces of Czermak (spatia interglobularia) (Fig. 824, J). These spaces are gaps in the dentine due to failure of calcification and are filled with uncalcified dentine. The outer part of the dentine in the lower portion of the tooth contains a layer of interglobular spaces known as the granular layer or granular sheath of Tomes. The dentinal tubuli have comparatively thick walls, and contain slender cylindrical prolongations from the processes of the cells of
the pulp-tissue already mentioned, and first described by Mr. Tomes and named Tomes's fibres or dentinal fibres. These dentinal fibres are analogous to the soft contents of the canaliculi of bone. Between Tomes's fibres and the ivory around the canals there is a tissue which is markedly resistant to the action of acids—the dentinal sheath of Neumann.

The intertubular substance or tissue is translucent and contains the chief part of the earthy matter of the dentine. After the earthy matter has been removed by steeping a tooth in weak acid the animal basis remaining may be torn into laminae which run parallel with the pulp-cavity across the direction of the tubules. These laminae show the method of growth to be by deposition of successive strata of dentine. Fibrils have been found in the matrix of the intertubular substance, and are probably continuous with the dentinal fibres of Tomes. In a dry tooth a section of dentine often displays a series of lines—the incremental lines of Salter—which are parallel with the laminae above mentioned. These lines are caused by two facts: (1) The imperfect calcification of the dentinal laminae immediately adjacent to the line. (2) The drying process, which reveals these defects in the calcification. These lines are wide or narrow according to the number of laminae involved, and along their course, in consequence of the imperfection in the calcifying process, little irregular cavities are left, which are the interglobular spaces already referred to. They have received their name from the fact that they are surrounded by minute nodules or globules of dentine. Other curved lines may be seen parallel to the surface. These are the concentric lines of Schreger, and are due to the optical effect of simultaneous curvature of the dentinal tubules.

![Diagram](https://via.placeholder.com/150)

**Fig. 825.**—Enamel prisms (350 diameters). A, fragments and single fibres of the enamel isolated by the action of hydrochloric acid. B, surface of a small fragment of enamel, showing the hexagonal ends of the fibres.

**Chemical Composition.**—According to Berzelius and Bibra, dentine consists of twenty-eight parts of animal and seventy-two of earthy matter. The animal matter is resolvable by boiling into gelatin. The earthy matter consists of phosphate and carbonate of calcium, with a trace of fluoride of calcium, phosphate of magnesia, and other salts.

The Enamel (substantia adamantina) (Figs. 821, 823, and 825) is the hardest and most compact part of a tooth, and forms a thin crust over the exposed part of the crown as far as the commencement of the root. It is thickest on the grinding surface of the crown until worn away by attrition, and becomes thinner toward the neck. It consists of a congeries of minute hexagonal rods, columns, or prisms known as enamel fibres or enamel prisms (prismata adamantina) (Fig. 825). In general, they lie parallel with one another, resting by one extremity upon the dentine, which presents a number of minute depressions for their reception, and
forming the free surface of the crown by the other extremity. There are occasional collections of prisms which run diagonally. The prisms are directed vertically on the summit of the crown, horizontally at the sides; they are about the \( \frac{1}{3000} \) of an inch in diameter, and pursue a more or less wavy course. By reflected light radial striations are visible. These are Schreger's lines, and are due to the fact that the prisms take an undulatory course and those of two layers may have opposite directions. Another series of lines, having a brown appearance from pigmentation, and denominated the parallel striae or brown striae of Retzius or the colored lines, are seen on a section of the enamel. These lines are concentric and cross the enamel rods. They are caused by the mode of enamel deposition. Inasmuch as the enamel columns, when near the dentine, cross each other and only become parallel farther away, a series of radial markings, light and dark alternately, is obtained (Fig. 821). The enamel prisms are themselves calcified and are fixed to each other by a very small amount of cement substance. Numerous minute interstices intervene between the enamel-fibres near their dentinal surface. It is noted that some of the dentinal canals at the crown penetrate a certain distance between the rods of the enamel (Fig. 823). No nutritive canals exist in the enamel, except the very few dentinal canals which at the crown penetrate a short distance, and these are found only in a small area.

Chemical Composition.—According to Bibra, enamel consists of 96.5 per cent. of earthy matter and 3.5 per cent. of animal matter. The earthy matter consists of the phosphate and the carbonate of calcium, with traces of fluoride of calcium, phosphate of magnesia, and other salts.

The enamel of a recently erupted tooth is covered by a membrane, the thickness of which is \( \frac{1}{3000} \) of an inch. It is known as enamel cuticle or Nasmyth's membrane (cuticula dentis). It is probably the most recent, and hence an uncalcified, or partly calcified enamel layer. Some believe it to be a product of the outer layer of the cells of the enamel organ.

The Cortical Substance, Cementum or Crusta Petrosa (substantia ossea) (Figs. 808 and 811) is disposed as a thin layer on the roots and neck of a tooth, from the termination of the enamel as far as the apex of the root, where it is usually very thick. At the neck it overlies a slight margin of enamel. In structure and chemical composition it is true bone. It contains, sparingly, the lacunae and canaliculi which characterize true bone; the lacunae placed near the surface have the canaliculi radiating from the side of the lacunae toward the periodontal membrane or dental periosteum, and those more deeply placed join with adjacent dentinal tubuli. The teeth of the young usually contain Haversian systems in the thicker portions of the cementum. The neck of the tooth does not contain lacunae. The cementum is occasionally laminated. Sharpey's fibres (p. 37) are very numerous. Some of the lacunae of the cementum receive dentinal tubes from the dentine.

As age advances the cement increases in thickness, and gives rise to those bony growths, or exostoses, so common in the teeth of the aged; the pulp-cavity becomes also partially filled up by a hard substance intermediate in structure between dentine and bone (the osteo-dentine of Owen; the secondary dentine of Tomes). It is formed by the odontoblasts, the dental pulp lessening in volume.

Development of the Teeth (Figs. 826, 827, 828, and 829).—The teeth are an evolution from the dermoid system, and not of the bony skeleton; they are developed from two of the blastodermic layers, the epiblast and mesoblast. From the former the enamel is developed; from the latter the dentinal pulp, dentine, cementum, and pericementum. It is customary to view the development of the permanent and temporary teeth as separate studies.

The earliest evidence of tooth-formation in the human embryo is observed about the seventh week. The mucous membrane covering the embryonic jaws is seen to rise as a longitudinal ridge along the summit of each jaw. This ridge is
the maxillary rampart of Kölliker and Waldeyer. A transverse section through the jaw will show the elevation to be due to a linear and outlined activity of the germinal epithelial layer; a corresponding epithelial growth is seen to sink as a band into the mesoblastic tissue beneath. This band is called the dental lamina or dental band. The local cell-activity continues, and in its descent the band appears to meet with a resistance which causes a flattening of its extremity into a continuous lamina. From the inner (toward the tongue) edge of the lamina epithelial cords are given off, ten in number, one for each temporary tooth.

![Diagram of method of development of the teeth.](image)

The growth of each cord continues, and each expands into a flask-like form, the walls covered by a layer of germinal cells, its interior by swollen mature cells. The ingrowing bulb is now seen to flatten upon its lower surface, as though it had met with an outlined resistance from the mesoblastic tissue beneath. The epithelial ingrowth assumes the general form of the several teeth; it is the enamel-organ of the tooth (Fig. 826). The cellular tissue of the jaw beneath the cap of the enamel-organ grows and projects into the cap. This projection is the dentine papilla (papilla dentis). At this period the mesoblastic tissue around each enamel-organ is seen to become differentiated into fibrous tissue surrounding the enamel-organs,

![Vertical section of the inferior maxilla of an early human foetus.](image)

but at some distance from them. Islets of bone are also seen to be forming the beginning of the bony maxillae.

The indentation of the base of the enamel-organ continues until it assumes the form of the future teeth. The cells bounding the organ assumes a cylindrical form; the cells of the interior become much expanded, and irregular in size and form.

The mesoblastic tissue underlying the enamel-organ is much condensed; evidences of cellular differentiation and a vascular system appear. Bone continues to
develop until all of the tooth-follicles are embraced in a gutter of bone. From the lingual side of the cords of the temporary teeth epithelial buds are given off, which sink into the mesoblastic tissue and form the enamel-organs of the permanent teeth. The condensation of fibrous tissue continues until each embryonic tooth is enveloped in a sac, the dental sac (Fig. 827); this, together with all of its contents, is called the dental follicle.

The tooth which is undergoing development with its enamel-organ and dentine papilla is known as the tooth germ. This tooth germ is encompassed and shut off from surrounding structures by the bag of membranous structure known as the dental sac.

The cells of the enamel-organ now undergo a series of differentiations: the inner layer, arranged as columnar epithelium, are the enamel cells, or ameloblasts. The layer is called the ameloblastic or enamel-forming layer (Figs. 827 and 828). The cells of the outer wall remain cuboidal; the cells which lie between become much distended, and on account of their appearance when seen in section this portion of the organ is called the enamel jelly or the stellate reticulum. The layer of cells immediately contiguous to the ameloblasts form a layer called the stratum intermedium (Fig. 828 A, D).

![Fig. 828](image_url)

The enclosed mesoblastic papilla (the future dental pulp) has its peripheral cells, which are called odontoblasts, differentiated into columnar bodies disposed as a layer, each cell having a large nucleus. The vascular supply of the pulp is now well marked. A section of a follicle at this period will exhibit the follicular wall springing from the base of the dental papilla and having a well-marked blood-supply. The bony alveolar walls are well outlined, and evidences of a periosteum appear (Figs. 827 and 828).

**Development of Enamel** (Fig. 828 B).—In point of time, the deposition of dentine actually begins before that of enamel, so that the first-formed layer of enamel is deposited against a layer of immature dentine. The enamel is built up of two distinct substances—globules of uniform size which are formed by the ameloblasts, and a cementing substance, probably an albuminate of calcium (calcoglobulin), the basis of all the calcified tissues. At the ends of the ameloblasts,
next to the dentine, the secretion of calco-globulin is deposited, and into the plastic mass the enamel-globules are extruded, each globule remaining connected with the ameloblasts by plasmic strings, which also join the globules laterally.

The first deposit of enamel begins in the tips of the cusps, and is quickly followed by a disappearance of the stellate reticulum at that point; the stellate reticulum appears to atrophy, so that the vascular follicular wall is brought into direct apposition with the stratum intermedium, which becomes differentiated into a glandular (secreting) tissue which elaborates the calcic albuminous basis of the enamel. The secretion passes from the cells of the stratum intermedium through a membrane into the ameloblasts, where it is in part combined with the cellular globules, and irregular masses of it are extruded as cementing substance. The deposition continues until the enamel-cap has its typical form. The deposition of the layers of globules is indicated by parallel lines transverse to the axes of the enamel-rods. At the completion of amelification the ameloblasts are partially calcified and form the enamel cuticle or Nasmyth's membrane (cuticula dentis).

Formation of Dentine.—The layer of columnar cells bounding the periphery of the pulp, the odontoblasts, are in apposition with a plexus of capillary vessels (Fig. 829). Each cell is a secreting body which selects the material for dentine-building. Against the layer of ameloblasts covering the dental papilla the odontoblasts deposit globules, of the calcium albuminate, and receding as the deposits are made, leave one or more protoplasmic processes in the calcic deposit. These are known as Tomes's fibres. The process continues until the normal dentine thickness is formed. The deposit is laid down in a scaffolding of finely fibrillated tissue. The layer of formative cells remains constant. The remains of the dentine papilla constitute the pulp and lie in the pulp-cavity (p. 1210).

Formation of Cementum.—Hertwig asserts that the epithelial edge of the enamel organ formed by the inner and outer epithelial layers of the organ grows downward, or rather the developing tooth grows upward until the future root-form of the tooth is outlined by a double layer of epithelial cells, constituting the root-sheath of Hertwig. The growth of the alveolar process is synchronous.

Upon the pulp side of the sheath a layer of odontoblasts is developed; upon the outer side the fibrous encasement becomes closely attached to the sheath and a layer of osteogenetic cells is differentiated. These cells are called cementoblasts. The growth of the dentine of the root is exactly similar to the growth of that of the crown. The epithelial sheath undergoes atrophic changes, leaving the epithelial whors which remain in the pericementum. The cementum is developed as subperiosteal bone. The cementum over the apex of the root is not formed until after the eruption of the tooth.

Formation of Alveoli.—By the time the crowns of the teeth have formed, each is enclosed in a loculus of bone which has developed around it and at some distance from it; the loculus is open at the top toward the gums, where it is closed by fibrous tissue; the developing permanent tooth is contained in the same loculus, but is later separated from the temporary tooth by a growth of bone. The alveolar

---

1 J. L. Williams, Dental Cosmos, 1896.
process is not completed until after the eruption of the teeth. During eruption that portion of the process overlying the crown undergoes absorption, and as soon as the immature tooth has erupted the alveolar process is developed about the root, whose formation is also completed after eruption.

Development of the Permanent Teeth.—The permanent teeth as regards their development may be divided into two sets: (1) those which replace the temporary teeth, and which, like them, are ten in number; these are the \textit{successional permanent teeth}; and (2) those which have no temporary predecessors, but are superadded at the back of the dental series. These are three in number on either side in each jaw, and are termed the \textit{superadded permanent teeth}. They are the three molars of the permanent set, the molars of the temporary set being replaced by the premolars or bicuspids of the permanent set.

The \textit{Development of the Successional Permanent Teeth}—the ten anterior ones in either jaw—will be first considered. As already stated, the germ of each milk tooth is a special thickening of the “free” edge of the common dental germ or dental lamina. In like manner is formed the special dental germ of each of the successional permanent teeth. But these thickenings are not at the “free” edge of the dental lamina, but occur behind and lateral to each of the milk-tooth germs (Fig. 826). There are ten of these, and they appear in order, about the sixteenth week, on each side, the central incisor germs being the first.

These special dental germs now go through the same transformations as were described in connection with those of the milk teeth, and the changes also eventuate in the germs becoming enamel organs; that is, they recede into the substance of the gum behind the germs of the temporary teeth. As they recede they become flask-shaped, form an expansion of their distal extremity, and finally meet a papilla, which has been formed in the mesoblast, just in the same manner as was the case in the temporary teeth. The apex of the papilla indents the dental germ, which encloses it, and forming a cap for it, undergoes analogous changes to those described in the development of the milk teeth, and becomes converted into the enamel, whilst the papilla forms the dentine of the permanent tooth. In its development it becomes enclosed in a dentinal sac which adheres to the back of the sac of the temporary tooth. The sac of each permanent tooth is also connected with the fibrous tissue of the gum by a slender band of the \textit{gubernaculum}, which passes to the margin of the jaw behind the corresponding milk tooth (see above).

The \textit{Superadded Permanent Teeth}—three on each side in each jaw—arise from successive extensions backward—\textit{i.e.}, along the line of the jaw—of the common dental germ from the back of the special dental germ of the immediately preceding tooth. During the fourth month or seventeenth week, in that portion of the common dental germ which lies behind—\textit{i.e.}, lateral to the special dental germ of the last temporary molar tooth, and which has hitherto remained unaltered—there is developed the special dental germ of the first permanent molar into which a papilla projects. In a similar manner, about the fourth month after birth the second molar is formed, and about the third year the third molar.

Eruption.—When the calcification of the different tissues of the \textit{milk} tooth is sufficiently advanced to enable it to bear the pressure to which it will be afterward subjected, its eruption takes place, the tooth making its way through the gum. The gum is absorbed by the pressure of the crown of the tooth against it, which is itself pressed up by the increasing size of the fang. At the same time the septa between the dentinal sacs, at first fibrous in structure, ossify and thus form the \textit{loculi} or \textit{alveoli}; these firmly embrace the necks of the teeth and afford them a solid basis.

Previous to the permanent teeth penetrating the gum, the bony partitions which separate their sacs from the deciduous teeth are absorbed, the roots of
the temporary teeth disappear by absorption through the agency of particular multinucleated cells, called **odontoclasts**, which are developed at the time in the neighborhood of the root, and the permanent teeth become placed under the loose crown of the deciduous teeth; the latter finally become detached, and the permanent teeth take their place in the mouth (Fig. 830).

**Calcification** of the permanent teeth proceeds in the following order: First molar, soon after birth; the central incisor, lateral incisor, and cuspids, about six months after birth; the bicuspid, at the second year or later; second molar, end of second year; third molar, about the twelfth year.

The **Eruption of the Temporary Teeth** commences at the seventh month, and is complete about the end of the second year.

The periods for the eruption of the temporary set are (C. S. Tomes)—

The **Eruption of the Permanent Teeth** takes place at the following periods, the teeth of the lower jaw preceding those of the upper by a short interval:

- 6½ years, first molars.
- 7th year, two middle incisors.
- 8th year, two lateral incisors.
- 9th year, first bicuspid.
- 10th year, second bicuspid.
- 11th to 12th year, canine.
- 12th to 13th year, second molars.
- 17th to 21st year, third molars.
The Palate (Palatum).

The palate forms the roof of the mouth; it consists of two portions, the **hard palate** in front, the **soft palate** behind.

**The Hard Palate** (*palatum durum*) (Figs. 831 and 832).—The hard palate is bounded in front and at the sides by the upper alveolar arches and gums. In front and to the sides it is continuous with the gums; behind, it is continuous with the soft palate. It is formed by the palate processes of the superior maxillary bones and the palate processes of the palate bones (Fig. 72). It is covered by a dense structure formed by the periosteum and mucous membrane of the mouth, which are intimately adherent, particularly to the front and sides, by means of a layer of fibrous tissue. Along the middle line is a **linear ridge** or **raphe** (*raphe palati*), which terminates anteriorly in a small papilla, the **incisive papilla** (*papilla incisiva*), corresponding with the inferior opening of the anterior palatine fossa. This papilla receives filaments from the naso-palatine and anterior palatine nerves. The incisive papilla in a recently born child is continuous with the gum and the frenulum of the upper lip. On either side and in front of the raphe the mucous membrane is thick, pale in color, and corrugated; these corrugations, which are composed of fibrous tissue, are the **palatine rugae** (*plicae palatinae transversae*). In very young children the rugae are distinct and definite. In the aged they are indistinct. Behind, it is thin, smooth, and of a deeper color; it is covered with squamous epithelium, and the fibrous tissue beneath it...
contains many mucous glands, the **palatine glands** (*glandulae palatinae*). The palatine vessels and nerves lie in the fibrous tissue beneath the mucous membrane.

**The Soft Palate or Velum Pendulum Palati** (*palatum molle*) (Figs. 831, 832, and 837).—The soft palate is a movable fold suspended from the posterior border of the hard palate, and forming an incomplete septum between the mouth and pharynx. It consists of a fold of mucous membrane enclosing muscular fibres, an aponeurosis, vessels, nerves, adenoid tissue, and mucous glands. When occupying its usual position it is relaxed and pendent and its oral surface is concave, continuous with the roof of the mouth, and marked by a **median ridge** or **raphé**, which indicates its original separation into two lateral halves. Its pharyngeal surface is convex, and continuous with the mucous membrane covering the floor of the posterior nares. Its anterior or upper border is attached to the posterior margin of the hard palate, and its sides are blended with the pharynx. Its posterior or lower border is free. The posterior portion of the soft palate is known as the **vail of the palate** (*velum palatinum*) and terminates posteriorly and externally on each side in a free margin, the posterior arch of the palate.

Hanging from the middle of its lower border is a small, conical-shaped, pendulous process, the **uvula** (*uvula palatina*). The uvula varies greatly in length in different individuals. It is composed of glands and connective tissue, contains a prolongation of the Azygos uvulae muscle and is covered with mucous membrane, and arching outward and downward from the base of the uvula on each side are two curved folds of mucous membrane, containing muscular fibres, called the **arches or pillars of the soft palate** or **pillars of the fauces** (*arcus palatini*).
The Anterior Pillar (*arcus glossopalatinus*) (Figs. 831 and 837).—The anterior pillar on each side runs downward, outward, and forward to the side of the base of the tongue. These pillars are formed by the projection of the Palato-glossi muscles, covered by mucous membrane.

The Posterior Pillar (*arcus pharyngopalatinus*) (Figs. 831 and 837).—The posterior pillar on each side is nearer to its opposite arch than is the anterior pillar to its opposite. These pillars are larger than the anterior; they run downward, outward, and backward to the sides of the pharynx, and are formed by the projection of the Palato-pharyngei muscles, covered by mucous membrane. The anterior and posterior pillars are separated below by a triangular interval in which the tonsils is lodged.

The space left between the arches of the palate on the two sides is called the *isthmus of the fauces (isthmus faecium).* It is bounded, above, by the free margin of the soft palate; below, by the back of the tongue; and on each side by the pillars of the fauces and the tonsils. Through this isthmus the mouth communicates with the pharynx.

The Mucous Membrane of the Soft Palate.—The mucous membrane of the soft palate is thin, and covered with squamous epithelium on both surfaces, excepting near the orifice of the Eustachian tube, where its epithelium is columnar and ciliated. Beneath the mucous membrane on the oral surface of the soft palate is a considerable amount of adenoid tissue. The palatine glands form a continuous layer on the pharyngeal surface and around the uvula.

The Aponeurosis of the Soft Palate.—The aponeurosis of the soft palate is a thin but firm fibrous layer attached above to the posterior border of the hard palate, and becoming thinner toward the free margin of the velum. Laterally, it is continuous with the pharyngeal aponeurosis. It forms the framework of the soft palate, and is joined by the tendons of the Tensor palati muscles.

The Muscles of the Soft Palate.—The muscles of the soft palate are six on each side: the Levator palati, Tensor palati, Azygos uvulae, Palato-glossus, Palato-pharyngeus and Salpingo-pharyngeus (see p. 407). The following is the relative position of these structures in a dissection of the soft palate from the posterior or naso-pharyngeal to the anterior or oral surface: Immediately beneath the pharyngeal mucous membrane is a thin stratum of muscular fibres, the posterior fasciculus of the Palato-pharyngeus muscle, joining with its fellow of the opposite side in the middle line. This posterior fasciculus is joined by the Salpingo-pharyngeus muscle. Beneath this are the Azygos uvulae and Salpingo-pharyngeus muscles, consisting of two rounded fleshy fasciculi, placed side by side in the median line of the soft palate. Next comes the aponeurosis of the Levator palati, joining with the muscle of the opposite side in the middle line. Fourthly, the anterior fasciculus of the Palato-pharyngeus, thicker than the posterior, and separating the Levator palati from the next muscle, the Tensor palati. This muscle terminates in a tendon which, after winding around the hamular process of the internal pterygoid plate of the sphenoid bone, expands into a broad aponeurosis in the soft palate, anterior to the other muscles, which have been enumerated. Finally, we have a thin muscular stratum, the Palato-glossus muscle, placed in front of the aponeurosis of the Tensor palati, and separated from the oral mucous membrane by adenoid tissue.

The Blood-vessels of the Palate (Fig. 832).—The palate is supplied with blood by branches of the posterior or descending palatine branch of the internal maxillary artery (*a. palatina descendens*) and of the ascending or anterior palatine branch of the facial artery (*a. palatina ascendens*). The posterior palatine artery divides into the great and small palatine arteries (*aa. palatinae major et minor*), which run through the

---

1 According to Klein, the mucous membrane on the nasal surface of the soft palate in the fetus is covered throughout by columnar ciliated epithelium, which subsequently becomes squamous; and some anatomists state that it is covered with columnar ciliated epithelium, except at its free margin, throughout life. —Ed. of 15th English edition.
palatine canals and after emerging give off branches. Branches from the small palatine go to the soft palate, the large branch passes forward on the hard palate near the alveolar margin. The ascending palatine branch of the facial lies upon the medial surface of the Tensor palati muscle and is distributed to the soft palate and pharynx. A palatine vein corresponding to the descending palatine artery opens into the anterior facial vein. The pharyngeal veins also receive palatine veins.

The Nerves of the Palate.—The large posterior palatine nerve emerges from the posterior palatine canal and accompanies the posterior palatine artery. The naso-palatine nerve emerges from the foramen of Scarpa and is distributed to the anterior portion of the hard palate. The soft palate is supplied by the small posterior palatine and the accessory palatine nerves.

The Tonsil or Amygdala (tonsilla palatina) (Figs. 818 and 824).—The tonsils or amygdalae are two prominent bodies situated one on each side of the fauces, between the anterior and posterior pillars of the soft palate. They are of a rounded form, and vary considerably in size in different individuals. A recess, the supra-tonsillar fossa (fossa supratonsillaris), may be seen, directed upward and backward above the tonsil. His regards this as the remains of the lower part of the second visceral cleft. The recess is covered by a fold of mucous membrane termed the plica triangularis. Externally the tonsil is covered with a fibrous capsule which joins the aponeurosis of the pharynx. The outer surface of the capsule is in relation with the inner surface of the Superior constrictor muscle of the pharynx, to the outer side of which is the Internal pterygoid muscle. The ascending palatine artery is close to the outer surface of the tonsil, the Superior constrictor muscle of the pharynx and the tonsillar capsule intervening. The tonsillar artery, which is sometimes a branch of the ascending palatine, is also close to the outer surface of the tonsil. The internal carotid artery lies behind and to the outer side of the tonsil, and nearly an inch (20 to 25 mm.) distant from it. It corresponds to the angle of the lower jaw. The surface of the tonsil which looks toward the pharynx presents from twelve to fifteen orifices, each leading into a small recess or crypt (fossula tonsillaris). From the crypts numerous follicles branch out into the substance of the tonsil by means of very irregular channels. The crypts are lined with stratified pavement epithelium. The epithelium of the crypts exhibits marked degenerative changes. The degeneration causes the formation of numerous communicating spaces, which contain leukocytes and lymphocytes. The crypts are surrounded with lymphoid tissue. In this are numerous lymphoid follicles (noduli lymphatici), which are placed in the submucous tissue. These follicles are analogous to those of Peyer's glands and consist of adenoid tissue. No openings from the capsules into the follicles can be recognized. They contain a thick grayish secretion.

The Blood-vessels of the Tonsil.—The arteries supplying the tonsils are the dorsalis linguae from the lingual, the ascending palatine and tonsillar from the facial, the ascending pharyngeal from the external carotid, the descending palatine branch of the internal maxillary, and a twig from the parvadural. The veins terminate in the tonsillar plexus, on the outer side of the tonsil, and the tonsillar plexus joins the pharyngeal plexus, which communicates with the pterygoid plexus of the internal jugular or facial vein.

Lymphatics of the Tonsil.—Surrounding each follicle is a close plexus of lymphatic vessels. From these plexuses the lymphatic vessels pass to the submaxillary lymph glands below the angle of the jaw. From the submaxillary glands lymph passes to the deep cervical glands.

The Nerves of the Tonsil.—A branch from the glossopharyngeal nerve by uniting with branches of the pharyngeal plexus forms the tonsillar plexus. The pharyngeal plexus is formed by the pharyngeal branches of the glossopharyngeal and superior cervical ganglia of the sympathetic and the pharyngeal branch of the vagus.
The Salivary Glands (Fig. 833).

Numerous glands exist in the lips, cheeks, palate, and tongue, but by the term salivary glands are usually understood the three chief glandular masses on each side of the face. These are the principal salivary glands. They communicate with the mouth, pour their secretion into its cavity, and are named respectively the parotid, submaxillary, and sublingual.

The Parotid Gland (glandulae parotis).—The parotid gland, so called from being placed near the ear (παρόδ, near; ὄς, ὄς, the ear), is the largest of the three salivary glands, varying in weight from half an ounce to an ounce. It lies upon the side of the face immediately below and in front of the external ear. It is limited above by the zygoma; below, by the angle of the jaw and by a line drawn between the angle and the mastoid process: anteriorly, it extends to a variable extent over the Masseter muscle; posteriorly, it is bounded by the external meatus, the mastoid process, and the Sterno-mastoid and Digastric muscles, slightly overlapping the two muscles.

![Fig. 833.—The salivary glands.](image)

Its anterior surface is grooved to embrace the posterior margin of the ramus of the lower jaw, and advances forward beneath the ramus, between the two Pterygoid muscles and superficial to the ramus over the Masseter muscle. Its outer surface is triangular and convex, slightly lobulated, is covered by the integument and parotid fascia, and has one or two lymphatic glands resting on it. Its inner surface (processus retromandibularis) extends deeply into the neck by means of two large processes, one of which dips behind the styloid process and projects beneath the mastoid process and the Sterno-mastoid muscle; the other is situated in front of the styloid process, and passes into the back part of the glenoid fossa, behind the articulation of the lower jaw. The structures passing through the parotid gland are—the external carotid artery, giving off its three terminal
branches: the posterior auricular artery emerges from the gland behind; the superficial temporal artery above; the transverse facial, a branch of the temporal, in front; and the internal maxillary winds through it as it passes inward, behind the neck of the jaw. Superficial to the external carotid is the trunk formed by the union of the temporal and internal maxillary veins; a branch, connecting this trunk with the internal jugular, also passes through the gland. The gland is also traversed by the facial nerve and its branches, which emerge at its anterior border; branches of the great auricular nerve pierce the gland to join the facial, and the auriculo-temporal branch of the inferior maxillary nerve emerges from the upper part of the gland. The internal carotid artery and internal jugular vein lie close to its deep surface. The triangular space occupied by the greater part of the gland is bounded in front by the posterior margin of the ramus of the jaw and the internal pterygoid muscle, and behind by the anterior edge of the Sternocleido-mastoid muscle, the tympanic portion of the temporal bone and the cartilaginous portion of the external auditory meatus. Its floor is formed by the anterior and posterior walls of the space which meet about the styloid process. These walls are composed of fascia derived from the deep cervical fascia. The remaining side of the space is external and is formed by fascia, derived from the deep cervical fascia and called the parotid fascia. This space is called the parotid recess. Sir Frederick Treves\(^1\) denies that the fascial covering of the space is complete. He says it is deficient above between the anterior edge of the styloid process and the posterior border of the external pterygoid muscle. A portion of the gland does not occupy the space, but projects forward over the Masseter muscle. This projecting portion is the facial process.

Lymph-glands, known as the parotid lymph-glands, are in and about the parotid gland, some being embedded in the outer surface of the parotid fascia, others being in the inner surface of the fascia, others in the gland itself, particularly along the temporo-maxillary vein and external carotid artery. They receive lymph from the anterior and lateral portions of the scalp, both eyelids, a portion of the cheek, the root of the nose, the outer portion of the external ear, the soft palate, the posterior nares, and the external auditory meatus. The vessels from them empty into the superficial cervical glands and the superior deep cervical glands. Between the parotid gland and the pharynx are the subparotid glands. They receive lymph from the nasal fossae, naso-pharynx, and Eustachian tube, and vessels from the glands take lymph to the deep cervical glands.\(^2\)

The Duct of the Parotid Gland, called the Parotid Duct or Stenson’s Duct (ductus parotideus [Stenonis]) (Fig. 833).—The duct of the parotid gland is about two inches and a half in length. It commences by numerous branches from the anterior part of the gland, crosses the Masseter muscle, and at its anterior border dips down into the substance of the Buccinator muscle, which it pierces; it then runs for a short distance obliquely forward between the Buccinator muscle and the mucous membrane of the mouth, and opens upon the inner surface of the cheek by a small orifice opposite the second molar tooth of the upper jaw (Fig. 824). Upon the beginning of Stenson’s duct there is often an accessory parotid gland (glandulae parotis accessorium), which is often called the socia parotidis. It is a portion of the facial process. It is a detached portion of gland, and has a duct which opens into Stenson’s duct. This accessory gland occasionally exists as a separate lobe, just beneath the zygomatic arch. In this position it has the transverse facial artery above it and some branches of the facial nerve below it.

Surface Form.—The direction of the duct corresponds to a line drawn across the face about a finger’s breadth below the zygoma; that is, from the lower margin of the concha to midway between the free margin of the upper lip and the ala of the nose.

---

\(^1\) Applied Anatomy.

\(^2\) Poirier and Cunéo, Human Anatomy.
Structure of the Parotid Duct.—The parotid duct is dense, it is of considerable thickness, and its canal is about the size of a crowquill; but at its orifice on the inner aspect of the cheek its lumen is greatly reduced in size. The duct consists of an external or fibrous coat, of considerable density, containing contractile fibres, and of an internal or mucous coat lined with short columnar epithelium.

Vessels and Nerves.—The arteries supplying the parotid gland are derived from the external carotid, and from the branches given off by that vessel in or near its substance. The veins empty themselves into the external jugular through some of its tributaries. The lymphatics terminate in the superficial cervical and the deep cervical glands, passing in their course through several lymphatic glands placed on the surface and in the substance of the parotid. The nerves are derived from the plexus of the sympathetic on the external carotid artery, the facial, the auriculo-temporal, and great auricular nerves. It is probable that the branch from the auriculo-temporal nerve is derived from the glosso-pharyngeal through the otic ganglion. At all events, in some of the lower animals this has been proved experimentally to be the case.

The Parotid Capsule.—The parotid gland is enclosed by two layers of the parotid fascia (fascia parotideomasseterica), which almost completely encompass the gland. The sheath is incomplete at one area toward the pharyngeal wall (see p. 1225).

The parotid fascia comes from the deep cervical fascia. The external layer covers the gland. The internal layer lines the parotid recess. The external layer is the structure usually spoken of as the parotid fascia. Anteriorly it joins the fascia of the masseter; below it is continuous with the deep cervical fascia; above it is attached to the zygoma; behind it is adherent to the external auditory meatus and sheath of the Sternomastoid. The deep layer is adherent above to the external auditory meatus and back of the glenoid fossa; internally to the styloid process; below it is continuous with the deep cervical fascia. The stylomaxillary or stylomandibular ligament comes off from the parotid fascia.

The Submaxillary Gland (glandula submaxillaris) (Fig. S33).—The submaxillary gland is situated below the jaw, in the anterior part of the submaxillary triangle of the neck. It is irregular in form and weighs about two drachms (8 to 10 grammes). It is covered by the integument, Platysma, deep cervical fascia, and the body of the lower jaw, corresponding to a depression on the inner surface of the body of the mandible, and lies upon the Mylo-hyoid, Hypoglossus, and Stylo-glossus muscles, a portion of the gland passing beneath the posterior border of the Mylo-hyoid. In front of it is the anterior belly of the Digastric muscle; behind, it is separated from the parotid gland by the stylomaxillary ligament, and from the sublingual gland in front by the Mylo-hyoid muscle. The facial artery lies embedded in a groove in its posterior and upper border. A process is given off from the deep surface of the anterior portion of the gland. This is the deep process (Cunningham), and it passes with the duct beneath the Mylo-hyoid muscle.

The Duct of the Submaxillary Gland or Wharton's Duct (ductus submaxillaris Whartoni).—The duct of the submaxillary gland is about two inches in length, and its walls are much thinner than those of the parotid duct. It commences by numerous branches from the deep portion of the gland which lies on the upper surface of the Mylo-hyoid muscle, and passes forward and inward between the Mylo-hyoid and the Hyo-glossus and Genio-hyo-glossus muscles, then between the sublingual gland and the Genio-hyo-glossus muscle, and opens by a narrow orifice on the summit of a small papilla (carinaula sublingualis) at the side of the f r a c c u m linguae. On the Hyo-glossus muscle it lies between the lingual and hypoglossal nerves, but at the anterior border of the muscle it crosses under the lingual nerve, and is then placed above it.
Vessels and Nerves.—The arteries supplying the submaxillary gland are branches of the facial and lingual. Its veins follow the course of the arteries. The lymphatics drain into the submaxillary lymph-glands. There are no lymphatic glands in this salivary gland. The nerves are derived from the submaxillary ganglion, through which it receives filaments from the chorda tympani and from the lingual branch of the inferior maxillary, sometimes from the mylo-hyoid branch of the inferior dental and from the sympathetic.

The Sublingual Gland (*glandula sublingualis*) (Fig. 833).—The sublingual gland is the smallest of the salivary glands. It is situated beneath the mucous membrane of the floor of the mouth, at the side of the fraenum linguae, in contact with the inner surface of the lower jaw, close to the symphysis. It is narrow, flattened, in shape somewhat like an almond, and weighs about a drachm. It is in relation, above, with the mucous membrane; below, with the Mylo-hyoid muscle; in front, with the depression on the side of the symphysis of the lower jaw, and with its fellow of the opposite side; behind, with the deep part of the submaxillary gland; and internally, with the Genio-hyo-glossus, from which it is separated by the lingual nerve and Wharton’s duct. Its excretory ducts or ducts of Rivinus (*ductus sublingualis minores*) are from eight to twenty in number.

![Diagram](image)

Fig. 834.—A highly magnified section of the submaxillary gland of the dog, stained with carmine. (Kölliker.)

They open separately into the mouth back of Wharton’s duct and upon a fold of mucous membrane known as the *plica sublingualis*. The plica sublingualis is an elevated crest of mucous membrane caused by the projection of the gland on either side of the fraenum linguae. One or more ducts sometimes join to form a tube which opens into the Whartonian duct or remains independent, opening close to Wharton’s duct on the sublingual papilla. This single duct is called the duct of Bartholin (*ductus sublingualis major*).

Vessels and Nerves.—The sublingual gland is supplied with blood from the sublingual and submental arteries. Its nerves are derived from the lingual.

Structure of Salivary Glands (Fig. 834).—The salivary glands are compound racemose glands, consisting of numerous lobes, which are made up of smaller lobules connected together by dense areolar tissue, vessels, and ducts. Each lobule consists of the ramifications of a single duct, dividing frequently like the branches of a tree, the branches terminating in dilated ends or alveoli, on which the capillaries are distributed. These alveoli, however, as Pflüger points out, are not necessarily spherical, though sometimes they assume that form; sometimes they are perfectly cylindrical, and very often they are mutually compressed. The alveoli are enclosed by a basement membrane which is continuous with the membrana propria of the duct. It presents a peculiar reticulated
structure, having the appearance of a basket with open meshes, and consisting of a network of branched and flattened nucleated cells.

The alveoli of the salivary glands are of two kinds, which differ both in the appearance of their secreting cells, in their size, and in the nature of their secretion. The one variety secretes aropy fluid which contains mucin, and such alveoli have therefore been named the mucous alveoli, whilst the other secretes a thinner and more watery fluid, which contains serum-albumin, and alveoli of this variety have been named serous or albuminous alveoli. The sublingual gland may be regarded as an example of the former variety, the parotid of the latter. The submaxillary is of the mixed variety, containing both mucous and serous alveoli, the latter, however, preponderating.

Both varieties of alveoli are lined by cells, and it is by the character of these cells that the nature of the gland is chiefly to be determined. In addition, however, the alveoli of the serous glands are smaller than those of the mucous ones.

The Mucous Alveoli.—The cells in the mucous alveoli are spheroidal in shape, glassy, transparent, and dimly striated in appearance. The nucleus is usually situated in the part of the cell which is next the basement membrane, against which it is sometimes flattened. The most remarkable peculiarity presented by these cells is, that they give off an extremely fine process which is curved in a direction parallel to the surface of the alveolus, lies in contact with the membrana propria, and overlaps the process of neighboring cells. The cells contain a quantity of mucin, to which their clear, transparent appearance is due.

Here and there in the alveoli are seen peculiar half-moon-shaped bodies lying between the cells and the membrana propria of the alveolus. They are termed the crescents of Gianuzzi or the demilunes of Heidenhain (Fig. 834), and are composed of polyhedral granular cells, which Heidenhain regards as young epithelial cells destined to supply the place of those salivary cells which have undergone disintegration. This view, however, is not accepted by Klein.

Serous Alveoli.—In the serous alveoli the cells almost completely fill the cavity, so that there is hardly any lumen perceptible. Instead of presenting the clear, transparent appearance of the cells of the mucous alveoli, they present a granular appearance, due to distinct granules of an albuminous nature embedded in a closely reticulated protoplasm. The ducts which originate from the alveoli are lined at their commencement by epithelium which differs little from the pavement type. As the ducts enlarge, the epithelial cells change to the columnar type, and the part of the cells next the basement-membrane is finely striated. The lobules of the salivary glands are richly supplied with blood-vessels which form a dense network in the interalveolar spaces. Fine plexuses of nerves are also found in the interlobular tissue. The nerve-fibrils pierce the basement-membrane of the alveoli, and end in branched varicose filaments between the secreting cells. There is no doubt that ganglia are to be found in some salivary glands in connection with the nerve-plexuses in the interlobular tissue; they are to be found in the submaxillary, but not in the parotid.

In the submaxillary and sublingual glands the lobes are larger and more loosely united than in the parotid.

Mucous Glands.—Besides the salivary glands proper, numerous other glands are found in the mouth. They appear to secrete mucus only, which serves to keep the mouth moist during the intervals of the salivary secretion, and which is mixed with that secretion in swallowing. Many of these glands are found at the posterior part of the dorsum of the tongue, behind the circumvallate papillae, and also along its margins as far forward as the apex. Others lie around and in the tonsil

---

1 It has been shown by Elsner that many of these glands open into the trenches around the circumvallate papillae, and that their secretion is more watery than that of ordinary mucous glands. He supposes that they assist in the more rapid distribution of the substance to be tasted over the region where the special apparatus of the sense of taste is situated.—Ed. of 15th English edition.
between its crypts, and a large number are present in the soft palate. These glands are of the ordinary compound racemose type. Behind the tip of the tongue on each side, external to the anterior extremity of the genio-glossus muscle, is a mucous gland, the **gland of Nuhn and Blandin** (*glandula lingualis anterior*). Its lower surface is partly covered by muscular fibres from the inferior lingualis and styloglossus muscles, and it opens by several ducts.

**Surface Form.**—The orifice of the mouth is bounded by the lips, two thick, fleshy folds covered externally by integument and internally by mucous membrane, and consisting of muscles, vessels, nerves, arcual tissue, and numerous small glands. The size of the orifice of the mouth varies considerably in different individuals, but seems to bear a close relation to the size and prominence of the teeth. Its corners correspond pretty accurately to the outer border of the canine teeth. In the Ethiopian tribes the front teeth are large and inclined forward, the mouth is large; and this, combined with the thick and everted lips which appear to be associated with prominent teeth, gives to the negro's face much of the peculiarity by which it is characterized. The smaller teeth and the slighter prominence of the alveolar arch of the more highly civilized races render the orifice of the mouth much smaller, and thus a small mouth is an indication of intelligence, and is regarded as an evidence of the higher civilization of the individual.

Upon looking into the mouth, the first thing we may note is the tongue, the upper surface of which will be seen occupying the floor of the cavity. This surface is convex, and is marked along the middle line by a raphé which divides it into two symmetrical portions. The anterior two-thirds is rough and studded with papillae; the posterior third smooth and tuberculated, and covered by numerous glands which project from the surface. Upon raising the tongue the mucous membrane which invests the upper surface may be traced covering the sides of the under surface, and then reflected over the floor of the mouth on to the inner surface of the lower jaw, a part of which it covers. As it passes over the borders of the tongue it changes its character, becoming thin and smooth and losing the papillae which are to be seen on the upper surface. In the middle line the mucous membrane on the under surface of the tip of the tongue forms a distinct fold, the **fraenum linguae**, by which this organ is connected to the symphysis of the jaw. Occasionally it is found that this fraenum is rather shorter than natural, and, acting as a bridle, prevents the complete protrusion of the tongue. When this condition exists and an attempt is made to protrude the organ, the tip will be seen to remain buried in the floor of the mouth, and the dorsum of the tongue is rendered very convex, and more or less extruded from the mouth; at the same time a deep furrow will be noticed to appear in the middle line of the anterior part of the dorsum. Sometimes, a little external to the fraenum, the canine vein may be seen immediately beneath the mucous membrane. The corresponding artery, being more deeply placed, does not come into view, nor can its pulsation be felt with the finger. On either side of the fraenum, in the floor of the mouth, is a longitudinally elevation or ridge, produced by the projection of the sublingual gland, which lies immediately beneath the mucous membrane. And close to the attachment of the fraenum to the tip of the tongue may be seen on either side the slit-like orifices of Wharton's ducts, into which a fine probe may be passed without much difficulty. By everting the lips the smooth mucous membrane lining them may be examined, and may be traced from them on to the outer surface of the alveolar arch. In the middle line, both of the upper and lower lip, a small fold of mucous membrane passes from the lip to the bone, constituting the fraena; these are not so large as the fraenum linguae. By pulling outward the angle of the mouth, the mucous membrane lining the cheeks can be seen, and on it may be perceived a little papilla which marks the position of the orifice of Stenson's duct—the duct of the parotid gland. The exact position of the orifice of the duct will be found to be opposite the second molar tooth of the upper jaw. The introduction of a probe into this duct is attended with considerable difficulty. The teeth are the next objects which claim our attention upon looking into the mouth. These are, as stated above, ten in either jaw in the temporary set, and sixteen in the permanent set. The gums, in which they are implanted, are dense, firm, and vascular.

At the back of the mouth is seen the **isthmus of the fauces**, or, as it is popularly called, "the throat:" this is the space between the pillars of the fauces on either side, and is the means by which the mouth communicates with the pharynx. Above, it is bounded by the soft palate, the anterior surface of which is concave and covered with mucous membrane, which is continuous with that lining the roof of the mouth. Projecting downward from the middle of its lower border is a conical-shaped projection, the uvula. On either side of the isthmus of the fauces are the anterior and posterior pillars, formed by the Palato-glossus and Palato-pharyngeus muscles respectively, covered over by mucous membrane. Between the two pillars on either side is situated the **tonsil**. The extirpation of this body is not unattended with danger of hemorrhage. Dr. Weir has stated that he believes that when hemorrhage occurs after their removal it arises from one of the palatine arteries having been wounded. These vessels are
THE ORGANS OF DIGESTION

large: they lie in the muscular tissue of the palate, and when wounded are constantly exposed to disturbance from the contraction of the palatine muscles. The vessels of the tonsil, Dr. Weir states, are small and lie in the soft tissue, and readily contract when wounded.

When the mouth is wide open a prominent tense fold of mucous membrane may be seen and felt, extending upward and backward from the position of the fang of the last molar tooth to the posterior part of the hard palate. This is caused by the pterygo-maxillary ligament, which is attached by one extremity to the apex of the internal pterygoid plate, and by the other to the posterior extremity of the mylo-hyoid ridge of the lower jaw. It connects the Buccinator with the Superior constrictor of the pharynx. The fang of the last molar tooth indicates the position of the lingual (gustatory) nerve where it is easily accessible, and can with readiness be divided in cases of cancer of the tongue (see page 1043). On the inner side of the last molar tooth we can feel the hamular process of the internal pterygoid plate of the sphenoid bone, around which the tendon of the Tensor palati plays. The exact position of this process is of importance in performing the operation of staphylorrhaphy. About one-third of an inch in front of the hamular process, and the same distance directly inward from the last molar tooth, is the situation of the opening of the posterior palatine canal, through which emerges the posterior or descending palatine branch of the internal maxillary artery and one of the descending palatine nerves from Meckel's ganglion. The exact position of the opening on the subject may be ascertained by driving a needle through the tissues of the palate in this situation, when it will be at once felt to enter the canal. The artery emerging from the opening runs forward in a groove in the bone just internal to the alveolar border of the hard palate, and may be wounded in the operation for the cure of cleft palate. Under these circumstances the palatine canal may require plugging. By introducing the finger into the mouth the anterior border of the coronoid process of the jaw can be felt, and it is especially prominent when the jaw is dislocated. By throwing the head well back a considerable portion of the posterior wall of the pharynx may be seen through the isthmus faucium, and on introducing the finger the anterior surface of the bodies of the upper cervical vertebrae may be felt immediately beneath the thin muscular stratum forming the wall of the pharynx. The finger can be hooked around the posterior border of the soft palate, and by turning it forward the posterior nare, separated by the septum, can be felt, or the presence of any adenoid or other growths in the naso-pharynx can be ascertained.

THE PHARYNX (Figs. 831, 837, 838).

The pharynx (from "phary̑n̑x, the throat") is that part of the alimentary canal which is placed behind and communicates with the nose, mouth, and larynx. It is a musculo-membranous tube, somewhat conical in form, with the base upward and the apex downward, extending from the under surface of the skull to the level of the crioid cartilage in front and that of the intervertebral disk between the fifth and sixth cervical vertebrae behind.

The pharynx is about four inches and a half in length, and broader in the transverse than in the antero-posterior diameter. Its greatest breadth is opposite the cornua of the hyoid bone; its narrowest point, at its termination in the oesophagus. It is attached, above, to the peristome of the petrous portion of the temporal bone and of the basilar process of the occipital bone. To the pharyngeal tubercle of the basilar process of the occipital bone the raphé of the Constrictor muscles is attached. It is bounded above by the body of the sphenoid as well as by the basilar process of the occipital; below, it is continuous with the oesophagus; posteriorly, it is connected by loose areolar tissue with the cervical portion of the vertebral column and the Longi colli and Recti capitis antici muscles; this areolar tissue is contained in what is called the retro-pharyngeal space (spatia retropharyngea); anteriorly, it is incomplete, the gap being occupied by the cavities of the nose, mouth, and larynx. Anteriorly, it is attached in succession to the Eustachian tube, the internal pterygoid plate, the pterygo-maxillary ligament, the posterior termination of the mylo-hyoid ridge of the lower jaw, the mucous membrane of the mouth, the base of the tongue, hyoid bone, the thyroid and criocid cartilages; laterally, it is connected to the styloid processes and their muscles, and is in contact with the common and internal carotid arteries, the internal jugular veins, and the glosso-pharyngeal, vagus, hypoglossal, and sympathetic nerves, and above with a small part of the Internal pterygoid muscles. When the pharynx
is at rest the anterior and posterior walls are near together. Above the larynx they do not come in contact, but leave a channel for air; below the larynx they lie in contact, but open for the passage of food. It has seven openings communicating with it—the two posterior nares, the two Eustachian tubes, the mouth, larynx, and oesophagus. The pharynx may be subdivided from above downward into three parts, nasal, oral, and laryngeal.

The Nasal Part (pars nasalis pharyngis) (Fig. 837).—The nasal part of the pharynx or *naso-pharynx* lies behind the nose and above the level of the soft palate; it differs from the two lower parts of the tube in that its cavity always remains patent. In front it communicates through the *posterior nares* (choanæ) (Fig. 838) with the nasal fossae. On its lateral wall is the *pharyngeal orifice of the Eustachian tube* (ostium pharyngeum tubae auditīvae) (Figs. 835 and 836), which presents the appearance of a vertical or triangular cleft bounded above and behind by a firm prominence. The anterior portion of the prominence (*labium anterius*) is the smaller portion. The posterior portion (*labium posterius*) is large and thick, is called the *Eustachian cushion* (*torus tubarius*), and is caused by the inner extremity of the cartilage of the tube impinging on the deep surface of the mucous membrane (Fig. 836). A vertical fold of mucous membrane, the *salpingo-pharyngeal fold* (*plica salpingo-pharyngea*) (Fig. 836), stretches from the lower part of the cushion to the pharynx; it contains the Salpingo-pharyngeus muscle. A second and smaller mucous fold may be seen stretching from the upper part of the cushion to the palate, the *salpingo-palatine fold* (*plica salpingopalatina*) (Fig. 836). Behind the orifice of the Eustachian tube is a deep recess, the *lateral recess* or fossa of Rosenmüller (*recessus pharyngeus*) (Fig. 836), which represents the remains of the upper part of the second *branchial cleft*. The posterior wall of the naso-pharynx is directed upward and forward, and it meets the superior wall at an angle. This rounded area meeting is the *vault of the pharynx* (*fornix pharyngis*). On the posterior wall, at the level and above the level of the orifices of the Eustachian tubes, there is a collection of lymphoid tissue. This is particularly marked in children, and almost or quite disappears in the aged. Over it the mucous membrane is thick and in folds. This collection of lymphoid tissue is the *pharyngeal tonsil* (*tonsilla pharyngea*) (Fig. 835). The naso-pharynx communicates with the oral pharynx through an aperture between the soft palate and the posterior pharyngeal wall. This aperture is the *isthmus of the pharynx* (*isthmus pharyngonasalis*).

The Oral Part (pars oralis pharyngis).—The oral part of the pharynx reaches from the soft palate to the level of the hyoid bone. It opens anteriorly, through the *isthmus faucium*, into the mouth, while in its lateral wall, between the two
pillars of the fauces, is the tonsil. A triangular area on the lateral wall is known as the **sinus tonsillaris** (Fig. 837). It is bounded anteriorly by the anterior palatine arch, posteriorly by the posterior palatine arch, and below by the side of the pharyngeal portion of the tongue.

**The Laryngeal Part (pars larynea pharyngis).**—The laryngeal part of the pharynx is that division which lies behind the larynx; it is wide above where it is continuous with the oral portion while below at the lower border of the cricoid cartilage it becomes continuous with the oesophagus. In front it presents the triangular aperture of the larynx, the base of which is directed forward and is formed by the epiglottis, while its lateral boundaries are constituted by the aryteno-epiglottidean folds. On either side of the laryngeal orifice is a recess, termed the **sinus pyri-formis** (*recessus piriformis*) (Fig. 837); it is bounded internally by the aryteno-epiglottidean fold, externally by the thyroid cartilage and thyro-hyoid membrane. In the anterior part of the sinus pyriformis is a fold (*plica nervi laryngei*), which passes downward and inward. Extending outward from the epiglottis on each side is a fold, the **pharyngo-epiglottic fold** (*plica pharyngoepiglottica*). This ascends in the lateral wall of the pharynx, nearly to the posterior arch of the fauces.

**Structure.**—The constrictors of the pharynx (see p. 402) are surrounded by a sheath of thin fascia, the **bucco-pharyngeal fascia** (Cunningham). Forward pro-
longations of this fascia overlay the Buccinator muscles. The connective tissue of the retro-pharyngeal space joins the bucco-pharyngeal fascia to the prevertebral fascia, and it is attached by areolar tissue to the other structures to which the pharynx is in contact (Cunningham). The pharynx is composed of three coats — fibrous, mucous and muscular.

The **Pharyngeal Aponeurosis** or **Fibrous Coat** is situated between the mucous and muscular layers. It is thick above, where the muscular fibres are wanting, and is firmly connected to the periosteum of the basilar process of the occipital and petrous portion of the temporal bones. It is united to the Eustachian tube, posterior nares, and other points which the pharynx joins. It is thicker above than below, and above the sinuses of Morgagni there is no muscular coat, and the wall of the pharynx is composed of aponeurosis and mucous membrane. As it descends it diminishes in thickness, and is gradually lost. It is strengthened posteriorly by a strong fibrous band which is attached above to the pharyngeal spine on the under surface of the basilar portion of the occipital bone, and passes downward, forming a **median raphé**, which gives attachment to the Constrictor muscles of the pharynx.

The **Mucous Coat** (*tunica mucosa*).—The mucous coat is continuous with that lining the Eustachian tubes, the nares, the mouth, and the larynx. In the nasopharynx it is covered by columnar ciliated epithelium; in the buccal and laryngeal portions the epithelium is of the squamous variety. Beneath the mucous membrane are found racemose **mucous glands** (*glandulae pharyngeae*); they are especially numerous at the upper part of the pharynx around the orifices of the Eustachian tubes. Throughout the pharynx are also numerous crypts or recesses, the walls.

![Figure 838: The anterior surface of the pharynx. (Sappey.)](image-url)
of which are surrounded by lymphoid tissue similar to that found in the tonsils. Across the back part of the pharyngeal cavity, between the two Eustachian tubes, a considerable mass of this tissue exists, and has been named the pharyngeal tonsil (Fig. 835). Above this in the middle line is an irregular, flask-shaped depression of the mucous membrane, extending up as far as the basilar process of the occipital bone. It is known as the pharyngeal bursa (bursa pharyngea), and was regarded by Luschka as the remains of the diverticulum, which is concerned in the development of the anterior lobe of the pituitary body. Other anatomists believe that it is connected with the formation of the pharyngeal tonsils. The muscular coat (tunica muscularis pharyngis) has been already described (p. 402). The sinuses of Morgagni, referred to on a previous page (p. 404), are intervals between the Superior constrictor muscles and the basilar process of the occipital bone.

The Lymphatic Pharyngeal Ring.—This name was applied by Waldayer to the lymphatic structure gathered into a sort of ring about the pharynx. There are three chief collections of this tissue on each side. The first is known as the lingual tonsil (p. 1098); the second as the palatine tonsil (p. 1222); and the third as the pharyngeal tonsil (p. 1231).

Surgical Anatomy of the Mouth, Cheeks, Lips, Gums, Tonsils, Palate, Salivary Glands, and Pharynx.—The duct of a salivary gland may be blocked by a calculi, and the condition is often productive of severe pain.

A wound of Stenson's duct or of the parotid gland may be followed by a salivary fistula.

The parotid recess is completely lined by fascia, except above. "Between the anterior edge of the styloid process and the posterior border of the external pterygoid muscle there is a gap in the fascia, through which the parotid space communicates with the connective tissue about the pharynx." This explains why there is frequently swelling of the parotid region in post-pharyngeal abscess. A parotid abscess rarely bursts through the skin; it may pass into the temporal fossa, may enter the zygomatic fossa, may advance toward the mouth, pharynx, or neck. Because of the situation of the gland, a parotid abscess may cause inflammation of the temporo-mandibular joint or periostitis of the bone about the meatus, and may even burst into the external auditory meatus (Treves).

The facial nerve passes through the gland, and inflammation or tuberculosis of the gland may cause facial palsy. Some enlargements of the parotid region are due to inflammation of the parotid lymph-glands, and these glands may become tuberculous.

Mumps is characterized by acute inflammation of the parotid gland.

Various tumors occur in the parotid (fibroma, sarcoma, carcinoma, enchondroma, etc.). Most parotid tumors contain more or less cartilage. Complete extirpation of the parotid gland surgically is certainly extremely difficult, and Treves and others maintain that it is impossible.

Ranula is a salivary cyst of the floor of the mouth, due to occlusion of ducts of the sublingual gland or the duct of the submaxillary gland. Mucous cysts occur in the mouth. A mucous cyst of the gland of Nuhn and Blandin is on the under surface of the tongue near the apex. A dermoid cyst of the base of the tongue is occasionally encountered. It is of congenital origin.

What is known as the sublingual bursa is an epithelial-lined space, said to exist between the mucous membrane of the floor of the mouth and the Genio-hyo-glossus muscle. When acutely inflamed, it produces rapidly a marked swelling called acute ranula. Incomplete closure of the oral end of the thyro-glossal duct causes thyro-glossal fistula. If the oral end closes, but a portion of the duct below remains unobliterated, a thyro-glossal cyst forms. Such a cyst or fistula is always in the median line. The reader will remember that this duct runs from the foramen caecum to the isthmus of the thyroid gland.

Harelip is considered on pp. 110 and 111.

The lower lip, more commonly than any other structure, gives origin to cancer. The upper lip is not nearly so often affected. Blocking of mucous glands of the lips causes mucous cysts. A scar of the lip or about the lip disturbs this structure and pulls it far out of place. Thus great deformity is produced. Burns particularly induce hideous cicatrical contraction.

Plastic operations in this region are often successful, because of the great vascularity of the parts, and because adjacent parts admit of being stretched and pulled in.

Cleft palate is a by no means rare congenital deformity. The cleft is in the middle line. It may be a mere cleft of the uvula, it may be limited to the soft palate, or it may involve

1 Applied Anatomy. By Sir Frederick Treves.
the hard palate to but not including the alveolus. It may pass through the alveolus, but if it does so it ceases to be median at this point, and follows the line of suture between the incisive bone and the superior maxillary (pp. 110 and 111). In a complete cleft palate there is apt to be hare-lip at the end of the palate cleft. This cleft in the lip is not median, but is at the termination of the palate cleft. If the cleft of a cleft palate runs along each side of the incisive bone, the bone is isolated from the superior maxillary. In such a case double hare-lip results.

When a tonsil enlarges it projects inward. The deafness which so often attends hypertrophy of the tonsil is not due to blocking of the Eustachian orifice by the tonsil, but is due to thickening of the mucous membrane lining the tube itself. The profuse bleeding which sometimes follows an operation for the removal of the tonsil is very seldom due to injury of the internal carotid artery, but is due to injury of the ascending pharyngeal artery (p. 623) or one of the palatine arteries.

The internal carotid artery is in close relation with the pharynx, so that its pulsations can be felt through the mouth. It has been occasionally wounded by sharp-pointed instruments introduced into the mouth and thrust through the wall of the pharynx. In aneurism of this vessel in the neck the tumor necessarily bulges into the pharynx, as this is the direction in which it meets with the least resistance, nothing lying between the vessel and the mucous membrane except the thin Constrictor muscle, whereas on the outer side there is the dense cervical fascia, the muscles descending from the styloid process, and the margin of the Sterno-mastoid muscle.

The mucous membrane of the pharynx is very vascular, and is often the seat of inflammation, frequently of a septic character, and dangerous on account of its tendency to spread to the larynx. On account of the tissue which surrounds the pharyngeal wall being loose and lax, the inflammation is liable to spread through it far and wide, extending downward into the posterior mediastinum along the oesophagus. Abscess may form in the connective tissue behind the pharynx, between it and the vertebral column, constituting what is known as retro-pharyngeal abscess. This is most commonly due to caries of the cervical vertebrae, but may also be caused by suppuratiion of a lymphatic gland which is situated in this position opposite the axis, and which receives lymphatics from the nares, or by gummi or by acute pharyngitis. In these cases the pus may be easily evacuated by an incision, with a guarded bistoury, through the mouth, but, for aseptic reasons, it is desirable that the abscess should be opened from the neck. In some instances this is perfectly easy; the abscess can be felt bulging at the side of the neck and merely requires an incision for its relief; but this is not always so, and then an incision should be made along the posterior border of the Sterno-mastoid and the deep fascia should be divided. A director is now to be inserted into the wound, the forefinger of the left hand being introduced into the mouth and pressure made upon the swelling. This acts as a guide, and the director is to be pushed onward until pus appears in the groove. A pair of forceps are now inserted along the director and the opening into the cavity dilated.

Foreign bodies not infrequently become lodged in the pharynx and most usually at its termination at about the level of the cricoid cartilage, just beyond the reach of the finger, as the distance from the arch of the teeth to the commencement of the oesophagus is about six inches.

Hypertrophy of the adenoid tissue of the naso-pharynx produces groups of hypertrophic masses known as adenoids. A child with adenoids has a cough, and when awake or asleep, breathes noisily and with the mouth open. The voice is muffled, the hearing is impaired, the expression is vacant, the mind is dull, and the tonsils are enlarged.

THE OESOPHAGUS (Figs. 839, 840, 841, 842).

The oesophagus (oșo, oșo, I carry; qarenu to eat) or gullet is a muscular canal, averaging about nine or ten inches in length, extending from the pharynx to the stomach. It commences at the upper border of the cricoid cartilage, opposite the intervertebral disk between the fifth and sixth cervical vertebrae, descends along the front of the spine through the posterior mediastinum, passes through the Diaphragm, and, entering the abdomen, terminates in the stomach wall at the point known as the cardia opposite the tenth thoracic vertebra or possibly opposite the intervertebral disk between the tenth and eleventh thoracic vertebrae. The general direction of the oesophagus is vertical, but it presents two or three slight curves in its course. At its commencement it is placed in the median line, but it inclines to the left side as far as the root of the neck, gradually passes to the middle line again, and finally again deviates to the left as it passes forward to
the oesophageal opening of the Diaphragm (*hiatus oesophageus*). The oesophagus also presents an antero-posterior flexure, corresponding to the curvature of the cervical and thoracic portions of the spine. It is the narrowest part of the alimentary canal, being most contracted at its commencement and at the point where it passes through the Diaphragm.

The diameter of the largest portion of the oesophagus where it is contracted is about half an inch; when it is fully dilated, an inch or even more.

In the neck the oesophagus, when at rest, is flattened, the anterior and posterior walls approaching each other. The canal in the neck is round or oval, and the lumen is stellate (Cunningham). The oesophagus is somewhat constricted at three points. One constriction is at the very beginning of the tube; another is where the left bronchus crosses it; another is at the point where the oesophagus passes through the Diaphragm. The tube at each constricted point is distinctly flattened. The diameter of each of these constricted parts is slightly under one-half inch, the diameter of the rest of the tube when contracted is one-half inch, but when dilated may reach or exceed one inch. The average distance from the upper incisor teeth to the beginning of the gullet is about six inches; the average distance from the incisor teeth to the cardiac opening of the stomach is fifteen or sixteen inches. The portion of the oesophagus which is in the neck is called the **cervical portion** (*pars cervicalis*); the portion in the thorax, the **thoracic portion** (*pars thoracalis*), and the portion which lies in the oesophageal opening of the Diaphragm, the **diaphragmatic portion**. The margin of the oesophageal orifice in the Diaphragm is narrow in front, thicker behind and to the sides. Behind and to the sides the diaphragmatic portion of the oesophagus is about half an inch in length. In front there is only a thin edge of Diaphragm in contact with the gullet. The oesophagus is connected to the margins of the diaphragmatic orifice by connective tissue. The so-called **abdominal portion of the oesophagus** (*pars abdominalis*) is not over half an inch in length, and is limited to the small portion of the anterior and left lateral surface observed when a stomach which is completely empty is drawn downward with considerable force. The abdominal portion of the oesophagus is covered with peritoneum; the corresponding portions of the right lateral and posterior walls are not covered by peritoneum. This uncovered portion of the oesophagus runs downward and to the left and lies directly
behind the **oesophageal groove** on the posterior surface of the left lobe of the liver, but does not actually touch the groove, which in reality holds the thick, right edge of the oesophageal opening of the Diaphragm. When the stomach is distended the abdominal portion of the gullet ceases to exist and becomes part of the stomach wall.

**Relations.**—In the **neck** the oesophagus is in relation, **in front**, with the trachea, and it is connected to the posterior wall of the trachea by areolar tissue. At the lower part of the neck, where it projects to the left side, it is in relation in front with the thyroid gland and thoracic duct; **behind**, it rests upon the vertebral column and Longi colli muscles; **on each side**, it is in relation with the common carotid artery (especially the left, as the gullet inclines to that side) and part of the lateral lobes of the thyroid gland; the recurrent laryngeal nerves ascend between it and the trachea.

In the thorax, it is at first situated a little to the left of the median line; it then passes behind the aortic arch, being separated from it by the trachea, and descends in the posterior mediastinum, along the right side of the aorta, nearly to the Diaphragm, where it passes in front and a little to the left of the artery, previous to entering the abdomen. It is in relation, **in front**, with the trachea, the arch of the aorta, the left common carotid and left subclavian arteries, which incline toward its left side, the left bronchus, the pericardium, and the Diaphragm; **behind**, it rests upon the vertebral column, the Longi colli muscles, the right intercostal arteries, and the vena azygos minor; and **below**, near the Diaphragm, upon the front of the aorta; **laterally**, it comes in contact with both pleurae, especially with the left pleura above and the right pleura below; it overlaps the vena azygos major, which lies on its right side, while the descending aorta is placed on its left side. The vagus nerves descend in close contact with it, the right nerve passing down behind, and the left nerve in front of it, each nerve spreading out into a plexus, the **oesophageal plexus**, around the tube. The two plexuses are joined to each other. The right nerve forms the **posterior oesophageal plexus** (*plexus oesophageus posterior*); the left nerve the **anterior oesophageal plexus** (*plexus oesophageus anterior*).

In the lower part of the posterior mediastinum the thoracic duct lies to the right side of the oesophagus; higher up, it is placed behind it, and, crossing about the level of the fourth thoracic vertebra, is continued upward on its left side.

Above the aortic arch and the arch of the great azygos vein above the root of the right lung, the pleurae are close to but not in actual contact with the oesophagus.

Below the arch of the great azygos vein the right side of the oesophagus is covered with pleura nearly to the diaphragmatic opening. The posterior surface of the gullet also may be covered with pleura. Below the arch of the aorta on the left side the pleura covers only a small portion of the oesophagus, that is, a portion of the left wall, a little above the diaphragmatic opening.
**Anomalies.**—There may be openings of the oesophagus into the trachea. A diverticulum or pressure pouch may exist. Such a pouch is usually placed upon the posterior wall near the pharynx. There may be congenital constriction, tubular or annular.

**Structure.**—The oesophagus is fastened to adjacent structures by connective tissue called the tunica adventitia. The tube has three coats—an external or muscular, a middle or areolar, and an internal or mucous coat.

**The Muscular Coat (tunica muscularis).**—The muscular coat is composed of two planes of fibres of considerable thickness, an external plane of longitudinal and an internal plane of circular fibres.

---

**Fig. 841.**—The position and relation of the oesophagus in the cervical region and in the posterior mediastinum. Seen from behind. (Poirier and Charpy.)

The Longitudinal Fibres are arranged, at the commencement of the tube, in three fasciculi: one in front, which is attached to the vertical ridge on the posterior surface of the cricoid cartilage; and one at each side, which is continuous with the fibres of the Inferior constrictor of the pharynx; as they descend they blend together and form a uniform layer, which covers the outer surface of the tube.

Accessory slips of muscular fibres are described by Cunningham as passing between the oesophagus and the left pleura (m. pleurooesophagus), where it covers the thoracic aorta, or between the oesophagus and the root of the left bronchus (m. bronchooesophagus), or the back of the pericardium, as well as other still more...
rare accessory fibres. In Fig. 842, taken from a dissection in the Museum of the Royal College of Surgeons of England, several of these accessory slips may be seen passing from the oesophagus to the pleura, and two slips passing to the back of the trachea just above its bifurcation. These slips of muscular fibres which pass to adjacent structures give support to the oesophagus. Below, the longitudinal fibres of the oesophagus are continued into the longitudinal fibres of the stomach.

The Circular Fibres are continuous above with the Inferior constrictor of the pharynx; their direction is transverse at the upper and lower parts of the tube, but oblique in the central part. Below, the circular fibres pass into the circular and oblique fibres of the stomach.

The muscular fibres in the upper part of the oesophagus are of a red color, and consist chiefly of the striped variety, but below they consist for the most part of involuntary muscular fibre. At the cardia they act as a sphincter to solid food. Some maintain that this sphincter is closed tonically, others that it opens and closes rhythmically during gastric digestion.

The Submucous or Areolar Coat (tela submucosa).—The submucous or areolar coat connects loosely the mucous and muscular coats. It consists of dense connective tissue and contains blood-vessels, nerves, and oesophageal glands (glandulae oesophageae). The glands are mucous glands and are found throughout the length of the gullet. The ducts of the glands pass through the muscularis mucosae. These ducts are surrounded by adenoid tissue.

The Mucous Coat (tunica mucosa).—The mucous coat is thick, of a reddish color above and pale below. It is disposed in longitudinal folds, which disappear on distention of the tube. Its surface is studded with minute papillae, and is covered throughout with a thick layer of stratified pavement epithelium. The mucous coat contains glands which differ from the mucous glands of the submucous tissue. They are branched and tubular (Hewlett) and are called the superficial glands. There are two chief groups of superficial glands; one near the beginning, and the other near the termination of the oesophagus. The ducts of the superficial glands are not surrounded by lymphoid tissue (Hewlett). Beneath the mucous membrane, between it and the submucous coat, is a layer of longitudinally arranged non-striped muscular fibres. This is the muscularis mucosae (lamina muscularis mucosae). At the commencement it is absent, or only represented by a few scattered bundles; lower down it forms a considerable stratum.

Vessels of the Oesophagus.—The larger vessels are in the submucosa and send branches to the mucosa and muscularis. The arteries supplying the oesophagus are derived from the inferior thyroid branch of the thyroid axis of the subclavian, from the descending thoracic aorta and the bronchial arteries, and from the gastric branch of the coeliac axis, and from the left inferior phrenic of the abdominal aorta. They have for the most part a longitudinal direction. The veins are gathered into a plexus on the outer surface of the oesophagus. This plexus receives the venous blood from the walls of the tube. From the lower portion of the plexus branches go to the coronary vein of the stomach. Higher up branches go to the azygos veins.
and thyroid veins. In this manner a communication is opened between the portal veins and the systemic veins.

**Lymphatics of the Oesophagus.**—The lymphatics drain into the inferior deep cervical glands and the glands of the posterior mediastinum.

**Nerves of the Oesophagus.**—The nerves are derived from the vagus and from the sympathetic; they form a plexus in which are groups of ganglion-cells between the two layers of the muscular coats. From this fibres pass to supply the muscle, and others go to the submucous tissue to form a secondary plexus. It is usual to regard the plexus as consisting of two parts, a **ventral or anterior oesophageal plexus**, derived from the left vagus, and a **dorsal or posterior oesophageal plexus**, derived from the right vagus. These two plexuses are in the posterior mediastinum; they communicate with each other and contain sympathetic fibres.

**Movements and Innervation of the Oesophagus.**

**Movements.**—When liquid is swallowed it is, as pointed out by Kronecker and Meltzer, suddenly forced into the gullet by the contraction of the Mylo-hyoid muscle, the tube playing a practically passive part.1 In the passage of solid and semisolid food the oesophagus contracts. It does not contract, as was once thought, in sections, but there is a peristaltic wave. "The wave at a given point lasts in the neck region about 3.5 seconds, and from five to nine seconds in the thoracic region."2 The lower end of the oesophagus or cardia has a sphincter, the cardiac sphincter. It is usually taught that this sphincter is tonically contracted. When a mouthful of food is swallowed it rests above the sphincter for a moment and is then forced through by muscular contractions (Kronecker and Meltzer). If several acts of swallowing follow each other rapidly the sphincter relaxes so that there is no resistance to the passage of food. In cats Dr. Walter B. Cannon3 has demonstrated "rhythmic relaxations of the cardia, so that fluid food streams from the stomach into the oesophagus even above the level of the heart, then is pressed into the stomach again by a peristaltic wave, only to be released a moment later to pour into the oesophagus anew."

**Innervation.**—There is in the oesophagus a local reflex, but peristalsis is dominated by the central nerve system. "It seems probable that the peristaltic contractions of the oesophagus, to be efficient, must be supported by nervous influences from outside. In this respect the oesophagus is different from the remainder of the alimentary canal."4

**Surgical Anatomy.**—The relations of the oesophagus are of considerable practical interest to the surgeon, as he is frequently required, in cases of **stricture** of this tube, to dilate the canal by a bougie, when it is of importance that the direction of the oesophagus and its relations to surrounding parts should be remembered. In cases of **malignant disease** of the oesophagus, where its tissues have become softened from infiltration of the morbid deposit, the greatest care is requisite in directing the bougie through the strictured part, as a false passage may easily be made, and the instrument may pass into the mediastinum, or into one or the other pleural cavity, or even into the pericardium.

The student should also remember that obstruction of the oesophagus, and consequent symptoms of stricture, are occasionally produced by **aneurism** of some part of the aorta pressing upon the tube. In such a case the passage of a bougie could only hasten the fatal issue.

In passing a bougie the left forefinger should be introduced into the mouth and the epiglottis felt for, care being taken not to throw the head too far backward. The bougie is then to be passed beyond the finger until it touches the posterior wall of the pharynx. The patient is now asked to swallow, and at the moment of swallowing the bougie is passed gently downward, all violence being carefully avoided.

It occasionally happens that a **foreign body** becomes impacted in the oesophagus and can neither be brought upward nor moved downward. When all ordinary means for its removal have failed, and the body is lodged above the lower one-third of the gullet, external **oesophagotomy** is performed. If the foreign body is lodged in the lower one-third of the gullet the stomach is opened (gastroctomy) and the foreign body is extracted. If the foreign body is allowed to remain lodged in the oesophagus, extensive inflammation and ulceration may ensue. In one case the foreign body ultimately penetrated the intervertebral substance, and destroyed life by inflammation of the membranes and substance of the cord.

The operation of **oesophagotomy** is thus performed: The patient being placed upon his back, with the head and shoulders slightly elevated, an incision, about four inches in length,

THE ABDOMEN

should be made on the left side of the trachea, from the thyroid cartilage downward, dividing the skin, Platysma, and deep fascia. The edges of the wound being separated, the Omohyoid muscle should, if necessary, be divided, and the fibres of the Sternohyoid and Sternothyroid muscles drawn inward; the sheath of the carotid vessels, being exposed, must be drawn outward, and retained in that position by retractor: the oesophagus will now be exposed, and should be divided over the foreign body, which can then be removed. Great care is necessary to avoid wounding the thyroid vessels, the thyroid gland, and the laryngeal nerves.

The oesophagus may be obstructed not only by foreign bodies, but also by changes in its coats, producing stricture, or by pressure on it from without of new-growths or aneurism, etc. The different forms of stricture are: (1) the spasmoid, occurring in neurotic individuals, and intermittent in character, so that the dysphagia is not constant. Spasmoid stricture of the oesophagus sometimes occurs in cases of cancer of the stomach and cancer of the liver; (2) fibrous, due to cicatrization after injuries, such as swallowing corrosive fluids or boiling water; and (3) malignant, usually epitheliomatous, in its nature. Cancer is most common either at the upper end of the tube, opposite to the cricoid cartilage, or at its lower end at the cardiac orifice. Cicatricial stricture may be treated by gradual dilatation. If a stricture is impassible from above, the stomach may be opened, an instrument passed from below, and a string used to divide the stricture.

The operation of oesophagostomy has occasionally been performed in cases where the stricture in the oesophagus is at the upper part, with a view to making a permanent opening below the stricture through which to feed the patient, but the operation has been far from a successful one, and the risk of setting up diffuse inflammation in the loose planes of connective tissue deep in the neck is so great that it would appear to be better, if any operative interference is undertaken, with the idea of forming a mouth to introduce food, to perform gastrostomy. The operation of oesophagostomy is performed in the same manner as oesophagotomy, but the edges of the opening in the oesophagus are stitched to the skin incision. Gastrostomy is the only operation to be thought of in malignant stricture.

THE ABDOMEN.

The abdomen (from abdo, I put away or hide, or possibly from adeps, fat) is the largest cavity in the body. It is of an oval form, the extremities of the oval being directed upward and downward; the upper one being formed by the under surface of the Diaphragm, the lower by the upper concave surface of the Levati ani muscles. In order to facilitate description, it is artificially divided into two parts: an upper and larger part, the abdomen proper; and a lower and smaller part, the pelvis. These two cavities are not separated from each other, but the limit between them is marked by the brim of the true pelvis. The space is wider above than below, and measures more in the vertical than in the transverse diameter.

The abdomen proper differs from the other great cavities of the body in being bounded for the most part by muscles and fasciae, so that it can vary in capacity and shape according to the condition of the viscera which it contains; but, in addition to this, the abdomen varies in form and extent with age and sex (Fig. 844). In the adult male, with moderate distention of the viscera, it is oval or barrel-shaped, but at the same time flattened from before backward. In the adult female, with a fully developed pelvis, it is conical with the apex above, and in young children it is conical with the apex below.

Boundaries.—The boundary between the thorax and abdomen is the Diaphragm. This muscle forms a dome over the abdomen, and the cavity extends high into the bony thorax, reaching to the level of the junction of the fourth costal cartilages with the sternum. The lower end of the abdomen is limited by the structures which elute the inner surface of the bony pelvis, principally the Levatores ani and Coccygei muscles on either side. These muscles are sometimes termed the Diaphragm of the pelvis. The abdomen proper is bounded in front and at the sides by the lower ribs, the abdominal muscles, and the venter ilii; behind, by the vertebral column and the Psoas and Quadratus lumborum muscles; above, by the Diaphragm; below, by the brim of the pelvis. The muscles forming the
boundaries of the cavity are lined upon their inner surface by a layer of fascia, differently named, according to the part which it covers.
The abdomen contains (Fig. 843) the greater part of the alimentary canal; some of the accessory organs to digestion—viz., the liver and pancreas, the spleen, the kidneys, and suprarenal capsules. Most of these structures, as well as the wall of the cavity in which they are contained, are covered by an extensive and complicated serous membrane, the peritoneum (Fig. 856).

The Apertures in the Walls of the Abdomen.—The apertures found in the walls of the abdomen, for the transmission of structures to or from it, are the umbilicus, for the transmission (in the foetus) of the umbilical vessels; the caval opening in the Diaphragm, for the transmission of the postcava; the aortic opening, for the passage of the aorta, vena azygos major, and thoracic duct; and the oesophageal opening, for the oesophagus and vagus nerves. Below, there are two apertures on each side: one for the passage of the femoral vessels, and the other for the transmission of the spermatic cord in the male, and the round ligament in the female.

Regions (Fig. 846).—For convenience of description of the viscera, as well as of reference to the morbid conditions of the contained parts, the abdomen is artificially divided into nine regions. Thus, if two circular lines are drawn around the body, the one through the extremities of the ninth ribs where they join their costal cartilages, and the other through the highest points of the crests of the ilia, the abdominal cavity is divided into three zones—an upper, a middle, and a lower. If two parallel lines are drawn perpendicularly upward from the centre of Poupart's ligament, each of these zones is subdivided into three parts—a middle and two lateral.¹

The middle region of the upper zone is called the epigastric (ἐπί, over; γαστήρ, the stomach); and the two lateral regions, the right and left hypochondriac (ὑπο, under; χονδρια, the cartilages). The central region of the middle zone is the mesogastric or umbilical; and the two lateral regions, the right and left lumbar. The middle region of the lower zone is the hypogastric or pubic region; and the lateral regions are the right and left inguinal or iliac. The viscera contained in these different regions are the following (Fig. 846):

¹ Anatomists are far from agreed as to the best method of subdividing the abdominal cavity. Cunningham suggests that the lower line should encircle the body on a level with the highest point of the iliac crest, as seen from the front—a point corresponding with a prominent tubercle on the outer lip of the iliac crest about two inches behind the anterior superior spine. Addison (Journal of Anatomy and Physiology, vols. xxxiv. and xxxv.), in a careful analysis of the abdominal viscera in forty subjects, adopts the following lines: (1) a median, from the symphysis pubis to the ensiform cartilage; (2) two lateral lines drawn vertically through a point midway between the anterior superior iliac spine and the symphysis pubis; (3) an upper transverse line half-way between the symphysis pubis and the suprasternal notch; and (4) a lower transverse line midway between the last and the upper border of the symphysis pubis.—Pp. of 15th English edition.

Joessel draws a line through the cartilaginous ends of the tenth ribs; a line through the two anterior superior spines of the ilia. On each side he carries a perpendicular line from the iliopectineal eminence to the horizontal line connecting the tenth ribs. By this plan the highest plane is subcostal.
Right Hypochondriac.
The greater part of the right lobe of the liver, the hepatic flexure of the colon, and part of the right kidney.

Epigastric Region.
The greater part of the stomach, including both cardiac and pyloric orifices, the left lobe and part of the right lobe of the liver and the gall-bladder, the pancreas, the duodenum, the suprarenal capsules, and parts of the kidneys.

Left Hypochondriac.
The fundus of the stomach, the spleen, the extremity of the pancreas, the splenic flexure of the colon, and part of the left kidney.

Right Lumbar.
Ascending colon, part of the right kidney, and some convolutions of the small intestines.

Umbilical Region.
The transverse colon, part of the great omentum and mesentery, transverse part of the duodenum, and some convolutions of the jejunum and ileum, and part of both kidneys.

Left Lumbar.
Descending colon, part of the omentum, part of the left kidney, and some convolutions of the small intestines.

Right Inguinal or Iliac.
The caecum and vermiform appendix and a portion of the ascending colon.

Hypogastric Region.
Convolutions of the small intestines, the bladder in children, and in adults if distended, and the uterus during pregnancy.

Left Inguinal or Iliac.
Sigmoid flexure of the colon and a portion of the descending colon.

The regions of the abdomen as described in the new nomenclature are shown in Fig. 845.

If the anterior abdominal wall is reflected in the form of four triangular flaps by means of vertical and transverse incisions—the former from the ensiform cartilage to the symphysis pubis, the latter from flank to flank at the level of the umbilicus—the abdominal or peritoneal cavity is freely opened into and the contained viscera are in part exposed.\footnote{1}

Above and to the right side is the liver, situated chiefly under the shelter of the right ribs and their cartilages, but extending across the middle line, and reaching for some distance below the level of the ensiform cartilage. Below and to the left of the liver is the stomach, from the lower border of which an apron-like fold of peritoneum, the great omentum, descends for a varying distance, and obscures, to a greater or lesser extent, the other viscera (Fig. 874). Below it, however, some of the coils of the small intestine can generally be seen, while in the right and left iliac regions respectively the caecum and the sigmoid flexure of the colon are exposed. The bladder occupies the anterior part of the pelvis, and, if distended, will project above the symphysis pubis; the rectum lies in the concavity of the sacrum, but is usually obscured by the coils of the small intestine.

If the stomach is followed from left to right it will be found to be continuous with the first part of the small intestine, or duodenum, the point of continuity being marked by a thickened ring which indicates the position of the pyloric valve.

\footnote{1 It must be borne in mind that, although the term abdominal cavity is used, there is, under normal conditions, only a potential cavity or lymph-space, since the viscera are everywhere in contact with the parietes.—Ed. of 15th English edition.}
The duodenum passes toward the under surface of the liver, and then, curving downward, is lost to sight. If, however, the great omentum be thrown upward over the chest, the terminal part of the duodenum will be observed passing across the spine toward the left side, where it becomes continuous with the coils of the small intestine. These measure some twenty feet in length, and if followed downward will be seen to end in the right iliac fossa by opening into the caecum, the commencement of the large intestine. From the caecum the large intestine takes an arched course, passing at first upward on the right side, then across the middle line and downward on the left side, and forming respectively the ascending, transverse, and descending parts of the colon. In the left iliac region it makes still another bend, the sigmoid flexure, and then follows the curve of the sacrum as far as the rectum.

The spleen lies behind the stomach in the left hypochondriac region, and may be in part exposed by pulling the stomach over toward the right side. The glistening appearance of the deep surface of the abdominal wall and of the exposed viscera is due to the fact that the former is lined and the latter more or less completely covered by a serous membrane, the peritoneum.

Development of the Alimentary Canal, Viscera and Peritoneum.—When the paraxial mesoblast of the embryo has developed a series of transverse segmentations it becomes converted into a row of dark, square segments known as the protovertebrae or the mesoblastic somites, which are separated by clear, transverse intervals. They appear first in the region that is to become the neck, and from there extend back along the entire length of the trunk. These bodies are not solely the representatives of the future permanent vertebrae, but differentiate partly into muscles and true skin.

On each side of the protovertebrae the lateral mesoblast splits into two layers. The upper layer is applied to the epiblast, and forms with it the somatopleure or body-wall. The lower layer becomes adherent to the hypoblast, and forms the splanchnopleure or wall of the alimentary canal. The space between these two
layers is the **caelum** or the **pleuropertitoneal cavity**. This body-cavity is of large size in the early stages of the development of the embryo.

Anteriorly—or, if the body is in the erect posture, superiorly—there is developed a comparatively large space called the **pericardiothoracic cavity**; and a transverse fold develops, which marks off this cavity from the future abdominal cavity. This fold, with many veins of large size, develops into the primary Diaphragm, although its dorsal part remains incomplete. The dorsal part is completed at a later period, constituting the Diaphragm as we see it in the adult. As Dr. Frederick J. Brockway expresses it: "The Diaphragm is thus made up of a ventral, younger part, and a dorsal, older part. When this posterior part fails to develop, there is opportunity for a congenital diaphragmatic hernia to be present."

The pericardiothoracic cavity becomes divided into three cavities, and the two lateral ones are for a time continuous with the abdominal cavity. This continuation is, however, but temporary, and they are afterward separated. In this manner, four large serous sacs are formed. The two **lateral thoracic sacs** are known as the **pleural sacs**, and are lined with the pleura; the **median thoracic sac** is the **pericardial sac**, and is lined with the pericardium; and the **abdominal sac** forms the abdominal cavity, and is lined with the peritoneum.

The primitive alimentary canal, which was formed early by the closure within the embryo of a portion of the blastodermic vesicle, consists of three parts: first, the **fore-gut**, within the cephalic flexure, dorsal to the heart; second, the **mid-gut**, opening freely into the yolk-sac; and third, the **hind-gut**, within the caudal flexure. In the fore-gut are developed the back portion of the mouth, the tongue, the pharynx, the oesophagus, the stomach, the larger part of the duodenum, and the

---

**Fig. 846.**—The regions of the abdomen and their contents. Edge of costal cartilages in dotted outline.
organs that have grown out from these structures. The hind-gut forms a portion of the colon and the rectum, with the exception of the latter's anal end; and the mid-gut gives rise to the remainder of the digestive tube.

**Development of the Alimentary Canal.**—The fore-gut and hind-gut end blindly, there being at first neither mouth nor anus (Figs. 847 and 848). The upper part of the fore-gut becomes dilated to form the pharynx, in relation to which the branchial arches are developed (Fig. 850); the succeeding part remains tubular, and with the descent of the stomach is elongated to form the esophagus. Soon a fusiform dilatation, the future stomach, makes its appearance, and beyond this the mid-gut opens freely into the yolk-sac (Figs. 850 and 851).

This opening is at first wide, but, as the body-walls close in around the umbilicus, it is gradually narrowed into a tubular stalk, the **yolk-stalk** or **vitello-intestinal duct.**

At this stage, therefore the alimentary canal forms a nearly straight tube in front of the notochord and primitive aorta (Fig. 848). From the stomach to the rectum it is attached to the notochord by a band of mesoblast, from which the common

---

![Diagram](image-url)
mesentery of the gut is subsequently developed. The stomach undergoes a further dilatation, and its two curvatures can be recognized (Figs. 852 and 855), the greater directed toward the vertebral column and the lesser toward the anterior wall of the abdomen, while of its two surfaces one looks to the right and the other to the left. The mid-gut also undergoes great elongation, and forms a V-shaped loop which projects downward and forward; from the bend or angle of the loop the vitello-intestinal duct passes to the umbilicus (Fig. 855). For a time a part of the loop extends beyond the abdominal cavity into the umbilical cord, but by the end of the third month this is withdrawn. With the lengthening of the tube, the mesoblast, which attaches it to the future vertebral column and which carries the blood-vessels for the supply of the gut, is thinned and drawn out to form the **primitive or common mesentery**. The portion of this mesentery which is attached to the greater curvature of the stomach is named the **mesogastrium**, and the parts which suspend the colon and rectum are respectively termed the **mesocolon** and **mesorectum** (Fig. 855). About the sixth week a lateral diverticulum makes its appearance a short distance beyond the vitello-intestinal duct, and indicates the future
caecum or boundary between the small and the large intestine. This caecal diverticulum has at first a uniform calibre, but its blind extremity remains rudimentary and forms the vermiform appendix (Figs. 855 and 856). Changes also take place in the position and direction of the stomach. It falls over on its right surface, which henceforth is directed backward, while its original left surface looks
forward; further, its greater curvature is drawn downward and to the left, away from the vertebral column, while its lesser curvature is directed, upward, and the commencement of the duodenum is pushed over to the right side of the middle line. The mesogastrium, being attached to the greater curvature, must necessarily follow its movements, and hence it becomes greatly elongated and drawn outward from the vertebral column, and, like the stomach, what was originally its right surface is now directed backward and its left forward. In this way a pouch, the bursa omentalis, is formed behind the stomach; this pouch is the future lesser sac of the peritoneum, and it increases in size as the alimentary tube undergoes further development; the entrance to the pouch constitutes the future foramen of Winslow (Figs. 852, 856, and 859). The remainder of the mid-gut becomes greatly increased in length, so that the tube is coiled on itself, and this increase in length demands a corresponding increase in the width of the intestinal attachment of the mesentery, so that it becomes plaited or folded.

At this stage the small and the large intestines are attached to the vertebral column by a common mesentery, the coils of the small intestine falling to the right of the middle line, while the large intestine lies on the left side.1

---

1 Sometimes this condition persists throughout life, and it is then found that the duodenum does not cross from the right to the left side of the vertebral column, but lies entirely on the right side of the mesial plane, where it is continued into the jejunum; the arteries to the small intestine (rami intestini tenuis) also arise from the right instead of the left side of the superior mesenteric artery.
The abdomen grows downward to form the great omentum, and this downward extension lies in front of the transverse colon and the coils of the small intestine. The anterior layer of the transverse mesocolon is at first quite distinct from the posterior wall of the bursa omentalis, but ultimately the two blend, and hence the great omentum appears as if attached to the transverse colon (Figs. 859, 860, and 861). The mesentery of the duodenum, in which the rudiment of the pancreas is enclosed, disappears, and so this part of the gut becomes fixed to the posterior abdominal wall, and the pancreas lies entirely behind the peritoneal membrane. The mesenteries of the ascending and descen-
ing parts of the colon disappear in the majority of cases, while that of the small intestine assumes the oblique attachment characteristic of its adult condition.

The small omentum is formed by a thinning of the mesoblast or anterior primitive mesentery, which attaches the lesser curvature of the stomach to the anterior abdominal wall. By the subsequent growth of the liver this leaf of mesoblast is divided into two parts—viz., the small omentum between the stomach and liver, and the falciform ligament between the liver and the abdominal wall and Diaphragm (Fig. 858).

The anus is developed as a slight invagination of the epiblast a short distance in front of the posterior end of the hind-gut. This invagination is termed the proctodaeum, the mesoblast between it and the hypoblastic lining of the hind-gut is thinned, and ultimately the septum breaks down and disappears, and the hind-gut opens on the surface; into this part of the hind-gut the urinary and generative organs open for a time, and so constitutes a common cloaca. The small portion of the hind-gut behind the orifice of the anus is named the caudal or post-anal gut; it communicates with the neural tube by means of a canal, the neurenteric canal, already referred to. Ultimately the post-anal gut becomes obliterated, and it, together with the neurenteric canal, finally disappears.
The peritoneal cavity is the space left between the visceral and parietal layers of the mesoblast, and the serous membrane is developed from these layers.

The tongue originates from the floor of the pharynx. The anterior or papillary portion first appears as a rounded elevation, the tuberculum impar, between the ventral ends of the mandibular and hyoid arches (Fig. 862). Between the third and fourth arches a second larger elevation arises, in the centre of which is a median groove or furrow. This second elevation is termed the furcula, and from it the epiglottis is developed, while the median furrow becomes the entrance to the larynx (Fig. 863). The tuberculum impar and the furcula are at first in apposition, but are soon separated by a ridge produced by the forward growth of the second and third arches. This ridge gives rise to the posterior part of the tongue and extends forward in the form of a V, so as to embrace between its two limbs the tuberculum impar. At the apex of the V there is a pit-like invagination to form the middle thyroid rudiment, and this depression persists as the foramen caecum of the adult. The union of the two parts of the tongue is indicated even in the adult by a V-shaped depression, the apex of which is at the foramen caecum, while the two limbs run outward and forward parallel to but a little behind the circumvallate papillæ, which are therefore developed from the tuberculum impar (Figs. 862, 863, and 864). The tonsils are developed from the second branchial cleft, and make their appearance between the fourth and fifth months.

The liver arises in the form of two diverticula or hollow outgrowths from the ventral surface of that portion of the fore-gut which afterward becomes the duodenum (Figs. 850 and 851). The outgrowths, which represent the right and the left lobes, respectively, of the adult liver, give off solid buds of cells, which grow into columns or cylinders; these unite with one another in every direction to form a close network, in the meshes of which are contained the capillary blood-vessels. Some of these columns become hollowed out and form the bile-ducts, while the remainder constitute the secreting structure. The minute ducts thus produced unite to form the right and left hepatic ducts; while the common bile-duct is developed as a protrusion from the duodenal wall, and as it grows the liver becomes shifted away from the duodenum. The gall-bladder and cystic duct are formed by

Fig. 859.—Schematic figure of the bursa omentalis, &c. Human embryo of eight weeks. (Kollmann.)
a hollow evagination from the wall of the common bile-duct. About the third month the liver almost fills the abdominal cavity. From this period the relative
devolution of the liver is less active, more especially that of the left lobe, which now becomes smaller than the right; but up to the end of foetal life the liver remains relatively larger than in the adult.

The pancreas is also an early formation, being far advanced in the second month. It originates as a hollow projection from the hypoblast of the dorsal wall of the duodenum (Figs. 851 and 852), opposite the hepatic diverticula, which, as we have already seen, spring from its ventral wall. This hollow process grows between the two layers of the dorsal mesentery and sends out offshoots, which
branch abundantly and form a complicated tubular gland. As torsion of the stomach takes place, the pancreas assumes a transverse position and becomes fixed across the dorsal wall of the abdomen, the posterior layer of its mesentery undergoing absorption. Its duct ultimately opens into the duodenum together with the common bile-duct.

The spleen, on the other hand, is of mesoblastic origin, for there is never any connection between the intestinal cavity and the substance of this organ. It originates in the mesenteric fold which connects the stomach to the vertebral column (mesogastrium) (Fig. 855).

The peritoneum (TUNICA SEROSA).

During life and in the uncut corpse the peritoneal cavity (cavum peritonaei) is air-tight. It is not a real cavity, as muscular tension and atmospheric pressure permit no vacant space to form. When the surgeon or anatomist opens the abdomen, the peritoneal cavity is at that moment produced.

The peritoneum (from περί, about, and τεντόνιο, I stretch) is the largest serous membrane in the body, and consists, in the male, of a closed sac, a part of which is applied against the abdominal parietes, while the remainder is reflected over the contained viscera. In the female the peritoneum is not a closed sac, since the free extremities of the Fallopian tubes open directly into the peritoneal cavity. The portion of the peritoneum applied against the abdominal parietes constitutes the parietal peritoneum; the portion reflected over the viscera, the visceral peritoneum. The free surface of the membrane is smooth, covered by a layer of flattened endothelium, and lubricated by a small cavity of serous fluid. Hence the viscera can glide freely against the wall of the cavity or upon one another with the least possible amount of friction. Its attached surface is rough, being con-
nected to the viscera and inner surface of the parieties by means of areolar tissue termed the subserous areolar tissue (tela subserosa). The parietal portion is loosely connected with the fascia lining the abdomen and pelvis, but more closely to the under surface of the Diaphragm and also in the middle line of the abdomen.

The peritoneum differs from the other serous membranes of the body in presenting a much more complex arrangement—an arrangement which can only be clearly understood by following the changes which take place in the alimentary canal during its development; and therefore the student is advised to preface his study of the peritoneum by reviewing the remarks on Embryology.

**Structure of the Peritoneum.**—It is a thin, glistening serous membrane and consists of a connective-tissue layer and one layer of flat endothelial cells upon the free surface of the membrane. The connective-tissue layer consists of bundles of connective tissue which contain many connective-tissue cells and elastic fibres. It contains a multitude of lymph-spaces, lymph-vessels, and lymph-capillaries. Beneath the peritoneum is a layer of lax and spongy connective tissue which serves to bind the serous membrane to parts beneath. This layer is called the subserous connective tissue. In some regions it is plentiful; in others, as over the liver and intestine, it is very scantily developed. The endothelial cells are flat and polygonal. Some hold that they are joined together by cement-substance. Robinson asserts that there is no cement-substance, but rather an organized connection between the protoplasmic processes of adjacent cells.

On the surface of the endothelium between the cells numerous apertures or interruptions are to be seen. These openings which many think are due to retracted epithelium communicate with lymph-spaces beneath the epithelial layer. The idea is held by some that the openings are permanent stomata and join lymphatic capillaries. Some openings which are noted, the stigmata or pseudo-stomata, are mere interruptions in the endothelial layer, and are occupied by processes of the branched connective-tissue corpuscle of the subjacent tissue.

The amount of fluid contained in the closed sac is, in most cases, only sufficient to moisten the surface, but not to furnish any appreciable quantity of free liquid. When a small quantity can be collected, it is found to resemble lymph, and, like that fluid, coagulates spontaneously; but when present in large quantities, as in dropsy, it is a more watery fluid, but still contains a considerable amount of proteid which is coagulated on boiling.

The peritoneum contains a great quantity of lymphatic structures. In the subserous tissue the numerous lymph-spaces obtain fluid from the peritoneal cavity. The subendothelial interstitial lymph-spaces intercommunicate and can take up an immense quantity of fluid from the peritoneal cavity. Normally the spaces contain both nutrient material and waste products. Lymphatics are particularly plentiful in—1, the tendinous portion of the Diaphragm; 2, the ligamenta lata; 3, the omentum; 4, the ventral surface of the small intestine; 5, the liver and spleen.

The lymph from this region reaches the mediastinal or diaphragmatic glands. The serous surface of the Diaphragm is the region chiefly efficient in absorption from the peritoneum, and there is a current in the peritoneal cavity directed toward the Diaphragm. Absorption from the peritoneal cavity is very active. Wegner has shown that an amount of fluid equal to from 3 to 8 per cent. of the body weight may be absorbed in one hour. Absorption is most active from the region of the Diaphragm and least active from the region of the pelvis. There are a multitude of nerves in the peritoneum, and it seems probable that each endothelial cell receives a nerve ending. The minute arteries of the peritoneum are surrounded by nerve-plexuses. According to Robinson, the nerves of the peritoneum are:

---

1 The Peritoneum. By Byron Robinson.
2 Ibid.
3 Ibid.
1. Myelinic. 2. Amyelinic. 3. Fibres of Remak. 4. The Vater-Pacinian corpuscles and other varieties of nerve endings. 5. Nerve-cells. The visceral peritoneum contains many more nerves than the parietal peritoneum.

The **parietal peritoneum** (*peritonaeum parietale*) lines the wall of the abdominal cavity. The **visceral peritoneum** (*peritonaeum viscerale*) covers the viscera. Back of the parietal peritoneum is a space, the **retro-peritoneal space** (*spatium retro-peritoneale*), which contains the great vessels and nerves, the suprarenal capsules, the kidney, and ureters (Figs. 866, 867, 868, 869, and 870).

We describe the peritoneum as consisting of two saes, a **greater sac** and a **lesser sac** (Fig. 866). The larger part of the abdominal cavity is lined by the greater sac, as most of the viscera are covered by it. The lesser sac is placed largely behind the stomach. These two saes are not two distinct cavities which communicate. They constitute one cavity, a portion of which has been formed into a diverticulum or recess by a process of constriction, the result of changes produced in the position of adjacent viscera by development. Prof. Birmingham says: "If the great sac be compared to a bag, the lesser sac might be represented as a pocket lying behind, and opening into it by a narrow orifice, the **foramen of Winslow**, on its posterior wall."

The greater sac lines the walls of the abdominal cavity and covers the viscera which are invested by peritoneum, except the posterior portion of the stomach, the suprarenal capsule of the left side, the superior surface of the pancreas, the Spigelian lobe and the caudate lobes of the liver, and portions of the spleen, left kidney, and transverse colon, which are covered by peritoneum of the lesser sac.²

To trace the continuity of the membrane from one viscus to another, and from the viscera to the parietes, it is necessary to follow its reflections in the vertical and horizontal directions, and in doing so it matters little where a start is made.

If the stomach is drawn downward, a fold of peritoneum will be seen stretching from its lesser curvature to the transverse fissure of the liver (Figs. 866 and 872). This is the **gastro-hepatic** or **lesser omentum**, and consists of two layers; these, on being traced downward, split to envelop the stomach, covering respectively its anterior and posterior surfaces. At the greater curvature of the stomach they again come into contact and are continued downward in front of the transverse colon, forming the anterior two layers of the **great** or **gastro-colic omentum** (Figs. 866 and 874). Reaching the free edge of this fold they are reflected upward as its two posterior layers, and thus the great omentum consists of four layers of peritoneum. Followed upward the two posterior layers separate so as to enclose the transverse colon, above which they once more come into contact and pass backward to the abdominal wall as the **transverse mesocolon** (*mesocolon transversum*) (Fig. 866). Reaching the abdominal wall about the level of the transverse part of the duodenum, the two layers of the transverse mesocolon become separated from each other and take different directions; the upper or anterior layer, known as the **ascending layer of the transverse mesocolon**, ascends in front of the pancreas, and its further course will be followed presently (Fig. 866). The lower or posterior layer is carried downward, as the anterior layer of the mesentery, by the superior mesenteric vessels to the small intestine, around which it may be followed and subsequently traced upward as the posterior layer of the mesentery to the abdominal wall. From the posterior abdominal wall it sweeps downward over the aorta into the pelvis, where it invests the first part of the rectum and attaches it to the front of the sacrum by a fold termed the **mesorectum** (Fig. 866). Leaving first the sides and then the front of the second part of the rectum it is reflected on to the back of the bladder, and, after covering the posterior and upper aspects of this viscus, is carried by the **urachus** and **obliterated hypogastric arteries** as folds,

¹ Prof. Cunningham's Text-book of Human Anatomy.
² Ibid.
on to the posterior surface of the anterior abdominal wall (Fig. 865). The fold upon the urachus is the plica urachi (plica umbilicalis media); the fold on each obliterated hypogastric artery is the plica hypogastrica (plica umbilicalis lateralis). Between the rectum and bladder it forms a pouch, the recto-vesical pouch (excavatio rectouderina), bounded on the sides by two crescentic or semilunar folds (plicae rectovesicales), which pass from the posterior surface of the bladder to the sides of the rectum; the bottom of this pouch is about on a level with the middle of the vesiculae seminales—i. e., three inches or so from the orifice of the anus. When the bladder is distended the peritoneum is carried up with the expanded viscus, so that a considerable part of the anterior surface of the latter lies directly against the abdominal wall without the intervention of the peritoneal membrane. When the bladder is empty the peritoneum forms a transverse fold over its upper surface (plica vesicalis transversa).

In the female the peritoneum is reflected from the rectum on the upper part of the posterior vaginal wall, forming the recto-vaginal pouch or pouch of Douglas (excavatio rectouterina) (Fig. 866). In the pouch of Douglas are two folds of peritoneum (plica rectouterinae), which begin at the posterior surface of the cervix, extend back to the sides of the rectum, and bound above the deepest portion of the pouch. The pouch is then carried over the posterior aspect and fundus of the uterus on to its anterior surface, which it covers as far as the junction of the body and cervix uteri, forming here a second but shallower depression, the utero-vesical pouch (excavatio vesicouterina). It is also reflected from the sides of the uterus to the lateral wall of the pelvis on each side as an expanded fold, the broad ligament of the uterus (ligamentum latum uteri), in the free margin of each broad ligament can be felt a thickened cord-like structure, the Fallopian tube (tuba uterina [Fallopii]).

When the peritoneum lining the anterior abdominal wall is examined from behind, it is noticed that certain structures which lie in front of it form five peritoneal ridges (Fig. 865). The structure in the middle line is the urachus, which is the remains of the fectal allantois. In the adult it is a fibrous cord which passes from the umbilicus to the summit of the bladder. This cord is slender above, but broader below. External to the urachus are the fibrous cords which resulted from obliteration of the hypogastric arteries (arteriae umbilicales). These cords become more slender as they ascend toward the sides of the urachus and pass to the umbilicus. More external still are the folds formed by the deep epigastric arteries. The fold over each epigastric artery is the plica epigastrica; the fold over each obliterated hypogastric artery is the plica hypogastrica; the fold over the obliterated urachus is the plica urachi.

The five peritoneal ridges formed by the above-named structures create three peritoneal fossae on each side, called the inguinal fossae or pouches (fovea inguinales). The external inguinal fossa (fovea inguinalis lateralis) is external to the deep epigastric artery and corresponds to the internal abdominal ring. There is a funnel-shaped depression in its floor marking the point at which the inguinal process passed down. This depression, if marked, predisposes to oblique inguinal hernia. The middle inguinal fossa (fovea inguinalis medialis) is placed between the deep epigastric arteries and the obliterated hypogastric vessels. The internal inguinal fossa or the supravescical fossa (fovea supravescicalis) is between the obliterated hypogastric artery and the urachus. Just beneath the inner termination of Poupart's ligament there is another fossa, the femoral or crural fossa (fovea femoralis), which corresponds to the situation of the femoral ring. The obliterated hypogastric artery is to the inner side of this fossa.

On following the parietal peritoneum upward on the back of the anterior abdominal wall it is seen to be reflected around a fibrous band, the ligamentum teres or obliterated umbilical vein (Figs. 868, 869, and 870), which reaches from the
umbilicus to the under surface of the liver. Here the membrane forms a somewhat triangular fold, the falciform or suspensory ligament of the liver (ligamentum falciforme hepatis), which attaches the upper and anterior surfaces of that organ to the Diaphragm and abdominal wall. With the exception of the line of attachment of this ligament the peritoneum covers the under surface of the anterior part of the Diaphragm and is reflected from it on to the upper surface of the liver as the anterior or superior layer of the coronary ligament (ligamentum coronarium hepatis anterior). Covering the upper and anterior surfaces of the liver it is reflected around its sharp margin on to its under surface as far as the transverse fissure, where it is continuous with the anterior layer of the small omentum from which a start was made (Fig. 866). The posterior layer of this omentum is carried backward from the transverse fissure over the under surface and Spigelian lobe of the liver, and is then reflected, as the posterior or inferior layer of the coronary ligament (ligamentum coronarium hepatis posterior), on to the Diaphragm and is prolonged downward over the pancreas to become continuous with the ascending layer of the transverse mesocolon (Fig. 866). Between the two layers of the coronary ligament there is a triangular surface of the liver which is devoid of peritoneum; it is named the bare area of the liver, and is attached to the Diaphragm by connective tissue. If, however, the two layers of the coronary ligaments are traced toward the right and left margins of the liver, they approach each other, and, ultimately fusing, they form the right and left lateral ligaments of the liver and attach its right and left lobes respectively to the Diaphragm.

If the small omentum is followed toward the right side it is seen to form a distinct free edge around which its anterior and posterior layers are continuous
with each other and between which are situated the portal vein, hepatic artery, and bile-duct. If the finger is introduced behind this free edge, it passes through a somewhat constricted ring, the foramen of Winslow (foramen epiploicum [Winslow]) (Figs. 866, 868, and 871). This is the communication between what are termed the greater and lesser sacs of the peritoneum and has the following boundaries: in front, the free edge of the gastro-hepatic omentum. This free edge is called the ligamentum hepatoduodenale. The gastro-hepatic omentum has the portal vein, hepatic artery, and bile-duct between its two layers (Fig. 872); behind the foramen of Winslow is the postcava; above, are the Spigelian and caudate lobes of the liver; below, the duodenum and the hepatic artery, as the latter passes forward and upward from the coeliac axis.

The lesser peritoneal cavity or the lesser sac of the peritoneum (bursa omentalís) (Figs. 866, 868, and 871), therefore, lies behind the small omentum and has the following dimensions: above, it is limited by the portion of the liver which lies behind the transverse fissure; below, it extends downward into the great omentum, reaching, in the foetus, as far as its free edge (Fig. 860); in the adult, however, its vertical extent is limited by adhesions between the layers of the omentum. In front, it is bounded by the small omentum, stomach, and anterior two layers of the great omentum; behind, by the two posterior layers of the great omentum, the transverse colon, and ascending layer of the transverse mesocolon which passes upward in front of the pancreas as far as the posterior surface of the liver. Laterally the lesser sac reaches from the foramen of Winslow on the right side as far as the spleen on the left (recessus lienalís) (Fig. 873), where it is limited by the lienorenal ligament. The extent of the lesser sac and its relations to surrounding parts can be definitely made out by tearing through the small omentum and inserting the hand through the opening thus made. A passage (vestibulum bursae omentalís) leads out from the foramen of Winslow over the head of the pancreas to the left as far as the median vascular gastro-pancreatic fold (plica gastropancreatíca) (Fig. 871). This fold carries the gastric artery and the coronary vein. From the vestibule there is a narrow and upward prolongation behind the lesser omentum and caudate lobe of the liver and in front of the lumbar portion of the Diaphragm. This prolongation is the superior omental recess (recessus omentalís superior). The chief part of the lesser peritoneal cavity extends downward from the gastro-pancreatic fold and is called the inferior omental recess (recessus omentalís inferior). The constriction which separates the two recesses is due to the passage around the lesser sac and to the front of the gastric and hepatic arteries. “The former winds around its left side, the latter around its right, and each raises up a fold of peritoneum which projects strongly into the sac and partially divides it into two” (Cunningham). A small projection of the lesser sac passes to the right side behind the beginning of the duodenum. The splenic artery in its course to the spleen lies back of the posterior layer of the lesser sac.

It should be stated that during a considerable part of foetal life the transverse colon is suspended from the posterior abdominal wall by a mesentery of its own—the two posterior layers of the great omentum passing, at this stage, in front of and above the colon (Fig. 860). This condition sometimes persists throughout adult life, but, as a rule, adhesion occurs between the mesentery of the transverse colon and the posterior layer of the great omentum, with the result that the colon appears to receive its peritoneal covering by the splitting of the two posterior layers of the latter fold.

In addition to tracing the peritoneum vertically, it is necessary to trace it horizontally (Figs. 867, 868, 869, and 870). If this is done below the transverse colon, the circle is extremely simple, as it includes only the greater sac of the peritoneum (Fig. 867). Above the level of the transverse colon the arrangement is more complicated, on account of the existence of the two sacs.
Starting from the linea alba, below the level of the transverse colon, and tracing the continuity in a horizontal direction to the right, the peritoneum covers the internal surface of the abdominal wall almost as far as the anterior border of the Quadratus lumborum muscle; it encloses the caecum, and is reflected over the sides and anterior surface of the ascending colon, fixing it to the abdominal wall, from which it can be traced over the kidney to the front of the bodies of the vertebrae. It then passes along the mesenteric vessels to invest the small intestine, and back again to the spine, forming the mesentery, between the layers of which are contained the mesenteric blood-vessels, nerves, lacteals, and glands. Lastly, it passes over the left kidney to the sides and anterior surface of the descending colon, and, reaching the abdominal wall, is continued along it to the middle line of the abdomen.

Above the transverse colon (Fig. 868) the peritoneum can be traced, forming the greater and lesser cavities, and their communication through the foramen of Winslow can be demonstrated. Commencing in the middle line of the abdomen, the membrane may be traced lining its anterior wall, and sending a process backward to encircle the obliterated umbilical vein (the round ligament of the liver), forming the falciform or longitudinal ligament of the liver. Continuing its course to the right, it is reflected over the front of the upper part of the right kidney, across the postcava and aorta, and over the left kidney to the hilum of the spleen, forming the anterior layer of the lienorenal ligament, the posterior layer being formed by the termination of the cul-de-sac of the greater cavity between the kidney and spleen. From the hilum of the spleen it is reflected to the stomach, forming the posterior layer of the gastro-splenic omentum (ligamentum...
gastrolieneale). It covers the posterior surface of the stomach, and from its lesser curvature it passes around the portal vein, hepatic artery, and bile-duct, and back again to the stomach, as the lesser omentum, and thus it forms the anterior boundary of the foramen of Winslow. It now covers the front of the stomach, and upon reaching the cardiac extremity it passes to the hilum of the spleen, forming the anterior layer of the gastro-splenic omentum. From the hilum of the
spleen it can be traced over the surface of this organ, to which it gives a serous covering; it is then reflected from the posterior border of the hilum on to the left kidney, forming the posterior layer of the lienorenal ligament.

Numerous folds, formed by the peritoneum, extend between the various organs or connect them to the parietes. These serve to hold the organs in position, and at the same time enclose the vessels and nerves proceeding to each part. Some of these
folds are called ligaments, such as the ligaments of the liver and the false ligaments of the bladder. Others, which connect certain parts of the intestine with the abdominal wall, constitute the mesenteries; and lastly, those which proceed from the stomach to certain viscera in its neighborhood are called omenta.

The Ligaments of the Peritoneum.—The ligaments, formed by folds of the peritoneum, include those of the liver, spleen, bladder, and uterus. They will be found described with their respective organs.

The Omenta.—The omenta are: the lesser omentum, the great omentum, and the gastro-splenic omentum.

The Lesser or Gastro-hepatic Omentum (omentum minus) (Figs. 866 and 871) is the duplicature which extends between the transverse fissure of the liver and the right side of the abdominal portion of the oesophagus, the lesser curvature of the stomach, and the upper portion of the superior surface of the duodenum. The portion going to the oesophagus and stomach is called the hepato-gastric ligament (ligamentum hepatogastricum). The division of the ligament which goes to the oesophagus is strong and dense; the division which goes to the lesser curvature of the stomach is thin and relaxed. The portion of the lesser omentum which goes to the duodenum is continuous with the first-named portion. It is called the hepato-duodenal ligament (ligamentum hepatoduodenale). The right margin of this ligament is free and concave. The hepato-colic ligament (ligamentum hepaticocolicum) is not invariably present. It is a fold of the hepato-duodenal ligament and runs from the posterior surface of the gall-bladder to the descending portion of the duodenum or possibly to the transverse colon. From the free margin of the termination of the hepato-duodenal ligament a fold often passes to the front of the right kidney. It is known as the duodeno-renal ligament (ligamentum duodenorenale). The lesser omentum is extremely thin, and consists of two layers of peritoneum; that is, the two layers covering respectively the anterior and
posterior surfaces of the stomach. The posterior layer is part of the wall of the lesser peritoneal cavity; the anterior layer, of the greater peritoneal cavity. When the two layers reach the lesser curvature of the stomach, they join together and ascend as the double fold to the transverse fissure of the liver; to the left of this fissure the double fold is attached to the fissure of the ductus venosus as far as the Diaphragm, where the two layers separate to embrace the end of the oesophagus. At the right border the lesser omentum is free, and the two layers of which it is composed are continuous. The anterior layer, which belongs to the greater sac, turns around the hepatic vessels to become continuous with the posterior layer belonging to the lesser one. They here form a free, rounded margin, which contains between its layers the hepatic artery, the common bile-duct, the portal vein, lymphatics, and the hepatic plexus of nerves (Fig. 872)—all these struc-
tures being enclosed in loose areolar tissue, called Glisson's capsule. Between the layers where they are attached to the stomach lie the gastric artery and the pyloric branch of the hepatic artery, anastomosing with it. From the left side of the greater curvature of the stomach a fold passes to the gastric surface of the spleen, covers the spleen, and passes from the renal surface of the spleen around the left kidney to the Diaphragm. The fold passing to the spleen is known as the gastro-splenic ligament or the gastro-splenic omentum (Fig. 873). The portion passing to the Diaphragm is known as the spleno-phrenic ligament (ligamentum phrenicolienale). The gastric veins or vasa brevia pass from the left side of the greater curvature of the stomach toward the spleen in the gastro-splenic omentum.

The Great or Gastro-colic Omentum (omentum majus) (Figs. 866 and 874) is the largest peritoneal fold. It consists of four layers of peritoneum, two of which descend from the stomach, one from its anterior, the other from its posterior surface, and, uniting at its lower border, descend in front of the small intestines, sometimes as low down as the pelvis; they then turn upon themselves, and ascend again as far as the transverse colon, where they separate and enclose that part of the intestine. These separate layers may be easily demonstrated in the young subject, but in the adult they are more or less inseparably blended. At the free margins the two outer layers and the two inner layers become continuous. The left border of the great omentum is continuous with the gastro-splenic omentum; its right border extends as far only as the duodenum. The great omentum is usually thin, presents a cribriform appearance, and always contains some adipose tissue, which in fat subjects accumulates in considerable quantity. Between its two anterior layers is the anastomosis between the right and left gastro-epiploic arteries. In opening the abdomen the great omentum is rarely found spread out evenly over the intestines. It often projects between intestinal coils, or is largely gathered in some one region, or is pushed in front of the stomach by distention of the colon.

The lower portion of the lesser sac of the peritoneum continues for a distance between the ascending and descending layers of the great omentum (Fig. 866). The portion of the lesser peritoneal cavity within the great omentum is more or less obliterated in the adult by adhesion between its opposing layers. At birth the omentum is very short and barely reaches the umbilicus. In adults its length varies greatly. In some individuals it is very short; in others it passes into the pelvis. Mr. Lockwood points out that in persons under forty-five years of age the omentum can rarely be pulled down below the level of the pubic spine; it generally can be in older persons.

The Gastro-splenic Omentum is the fold which connects the margins of the hilum of the spleen to the cul-de-sac of the stomach, being continuous by its lower border with the great omentum. It was described as the gastro-splenic ligament (Fig. 873).

The Mesenteries.—The mesenteries are: the mesentery proper, the transverse mesocolon, the sigmoid mesocolon, the mesorectum (p. 1269), and the mesentery of the vermiform appendix. In addition to these there are sometimes present an ascending and a descending mesocolon.

The Mesentery (mesenterium) (µεσον ἑπερον) (Figs. 866, 875, and 876), so called from being connected to the middle of the cylinder of the small intestine, is the broad fold of peritoneum which connects the convolutions of the jejunum and ileum with the posterior wall of the abdomen. It consists of a layer of connective tissue, each side of which is covered with peritoneum. In the connective tissue there are fatty masses. Its root (radix mesenterii), the part connected with the vertebral column, is narrow, about six inches in length, and directed obliquely

---

from the left side of the second lumbar vertebra to the right sacro-iliae symphysis (Fig. 876). Its intestinal border is vastly broader (measures about twenty feet); and here its two layers separate so as to enclose the intestine, and form its peritoneal coat. Its breadth, between its vertebral and intestinal border, is about eight inches. Its upper border is continuous with the under surface of the transverse mesocolon; its lower border, with the peritoneum covering the caecum and

ascending colon. The origin of the mesentery above is just beyond the termination of the duodenum, and it terminates below in the angle formed by the junction of the ileum and the colon. It serves to retain the small intestines in their position, and contains between its layers the mesenteric vessels and nerves, the lymphatic vessels and mesenteric glands. These glands number from 50 to 150. Occasionally congenital mesenteric openings exist. In stout individuals the mesentery contains much fat. If there is much fat the mesentery is not translucent; if there is little fat it is translucent. It may be actually transparent above and translucent or opaque below. The thinnest part of the mesentery is above. As we descend it becomes thicker, because of the presence of fat, fibrous ligament, and muscular tissue.1

In most cases the peritoneum covers only the front and sides of the ascending and descending parts of the colon. Sometimes, however, these are surrounded by the serous membrane and attached to the posterior abdominal wall by an ascending mesocolon (mesocolon ascendens) and a descending mesocolon (mesocolon descendens) respectively. At the place where the transverse colon turns downward to form the descending colon, a fold of peritoneum is continued to the under surface of the Diaphragm opposite the tenth and eleventh ribs. This is the phreno-colic ligament (ligamentum phrenicoocolicum); it passes below the spleen, and serves to support this organ, and therefore it has received the second name of sustentaculum lienis.

The Transverse Mesocolon (mesocolon transversum) (Fig. 876) is a broad fold, which connects the transverse colon to the posterior wall of the abdomen. It is formed by the two ascending or posterior layers of the great omentum, which, after separating to surround the transverse colon, join behind it, and are continued backward to the spine, where they diverge in front of the duodenum. This fold contains between its layers the vessels which supply the transverse colon.
The Sigmoid Mesocolon (mesocolon sigmoideum) (Fig. 876) is the fold of peritoneum which retains the sigmoid flexure in connection with the left iliac fossa. This portion of intestine remains always freely movable.

The Mesorectum is really only the lower portion of the sigmoid mesocolon. It is the name formerly given to the narrow fold which, according to the old defini-

![Diagram](https://via.placeholder.com/150)

**FIG. 876.—Diagram devised by Dr. Delépine to show the lines along which the peritoneum leaves the wall of the abdomen to invest the viscera.**
fold of peritoneum covering the caecum. As a rule, the entire appendix is covered with peritoneum; sometimes a portion of the base is uncovered, and this portion of the diverticulum is then extraperitoneal. The tip is never extraperitoneal. The mesoappendix may be attached to the entire length of the appendix, but, as a rule, the tip is free. In fact, one-third, one-half, or two-thirds may be free and occasionally the mesoappendix is a mere vestige. Between the two peritoneal layers of the mesoappendix there is connective tissue, and often fat. In the connective tissue are the appendicular blood-vessels, lymph-vessels, and nerves.

The Appendices Epiploicae are small pouches of the peritoneum filled with fat and situated along the colon and upper part of the rectum. They are chiefly appended to the transverse colon.

**Retro-peritoneal Fossae.**—In certain parts of the abdominal cavity there are recesses of peritoneum forming culs-de-sac or pouches, which are of surgical interest in connection with the possibility of the occurrence of retro-peritoneal hernia. One of these, which was previously described, is the lesser sac of the peritoneum (Figs. 866 and 868), which may be regarded as a recess of peritoneum through the foramen of Winslow, in which a hernia may take place, but there are several others, of smaller size, which require mention.

These recesses of fossae may be divided into three groups, viz.: (1) the duodenal fossae; (2) pericæal fossae; and (3) the intersigmoid fossa.

1. Duodenal Folds and Fossae. —Moynihan has described no less than nine fossæ as occurring in the neighborhood of the duodenum. Three of these are fairly constant. Five of the fossæ are here considered. (a) The inferior duodenal fossa or fossa of Treitz (Fig. 877) is the most constant of all the peritoneal fossæ in this region, being present in from 70 to 75 per cent. of cases. It is situated opposite the third lumbar vertebra on the left side of the ascending portion of the duodenum. The opening into the fossa is directed upward, and is bounded by a thin, sharp fold of peritoneum with a concave free upper margin. This fold of peritoneum is called the inferior duodenal fold (*plica duodenomesocolica*). The tip of the index finger introduced into the fossa under the fold passes some little distance up behind the ascending or fourth portion of the duodenum. One margin of the fold is attached to the ascending portion of the duodenum; another margin is attached to the parietal peritoneum. (b) The superior duodenal fossa (Fig. 877) is the next most constant pouch or recess, being present in from 40 to 50 per cent. of cases. It often coexists with the inferior one, and its orifice looks downward, in the opposite direction to the preceding fossa. It lies to the left of the ascend-
ing portion of the duodenum. It is bounded in front by the superior duodenal fold (plica duodenojejunalis), which is triangular and has a free semilunar base; to the right it is blended with the peritoneum covering the ascending duodenum, and to the left with the peritoneum covering the perirenal tissues. The fossa is bounded in front by the superior duodenal fold; behind by the second lumbar vertebra; to the right by the duodenum. Its depth is 2 cm., and it terminates in the angle formed by the left renal vein crossing the aorta. This fossa is of importance, as it is in relation with the inferior mesenteric vein; that is to say, the vein almost always corresponds to the line of union of the superior duodenal fold with the posterior parietal peritoneum. (c) The duodeno-jejunal fossa or mesocolic fossa (recessus duodenojejunalis) is formed where the duodeno-jejunal angle enters the root of the transverse mesocolon. There are two forms: (1) a single fossa and (2) a double fossa. It can be seen by pulling the jejunum downward and to the right, after the transverse colon has been pulled upward. It will appear as an almost circular opening, looking downward and to the right, and bounded by two free borders or folds of peritoneum, the duodeno-mesocolic ligaments. The opening admits the little finger into the fossa to the depth of from 2 to 3 cm. The fossa is bounded above by the pancreas, to the right by the aorta, and to the left by the kidney; beneath is the left renal vein. The fossa exists in from 15 to 20 per cent. of cases, and has never yet been found in conjunction with any other form of duodenal fossa. (d) Paraduodenal fossa or the fossa of Landzert (recessus duodenoejunalis) is most distinct in the infant, and is to the left of the ascending portion of the duodenum. The fold of peritoneum to its outer side and above is produced by the inferior mesenteric vein. Its lower limit is a fold called the mesenterico-mesocolic fold. (e) The retroduodenal fossa (Fig. 878) was described in 1893 by Jonnesco. It is a peritoneal cul-de-sac, sometimes found behind the horizontal and ascending portions of the duodenum.

2. Pericæal Folds and Fossae.—There are at least three pouches or recesses to be found in the neighborhood of the caecum, which are termed pericæal fossæ. (1)
The ilio-colic fossa or superior ilio-caecal (recessus ileocaecalis superior) (Fig. 879) is formed by a fold of peritoneum, the ilio-colic fold, arching over a branch of the ilio-colic artery, which supplies the ilio-colic junction, and appears to be the direct continuation of the artery. The fossa is a narrow chink situated between the ilio-colic fold in front, and the mesentery of the small intestine, the ileum, and a small portion of the caecum behind. (2) The ilio-caecal, inferior ilio-caecal or ilio-appendicular fossa (recessus ileocaecalis inferior) (Fig. 880) is situated behind the angle of junction of the ileum and caecum. It is formed by a fold of peritoneum, the ilio-caecal fold (plica ileocaecalis), which Treves called the “bloodless fold.” Tuffier denies its non-vascularity, and Lockwood and Rolleston state that it contains fat, muscular fibres, and arteries and veins derived from the appendicular vessels and the anterior and posterior ilio-caecal vessels.¹ The upper border of the fold is attached to the ileum, opposite its mesenteric attachment, and the lower border, passing over the ilio-caecal junction, joins the mesentery of the appendix, and sometimes the appendix itself; hence this fold is sometimes called the ilio-appendicular fold. Between the ilio-caecal fold and the mesentery of the vermiform appendix is the ilio-caecal fossa. It is bounded above by the posterior surface of the ileum and the mesentery; in front and below by the ilio-caecal fold, and behind by the upper part of the mesentery of the appendix. (3) The retro-caecal or retro-colic

¹The Caecal Folds and Fossae. By Richard J. A. Barry.
fossae (recessus retrocaecalis) (Fig. 881) are situated behind the caecum and ascending colon. There may be no fossa present. There may be one fossa; there are usually two (external and internal retrocolic fossae); occasionally there are more than two. The fossae are brought into view by raising the caecum. According to Berry, one or other of the fossa is present in 30 per cent. of cases. Treves thinks the retrocolic fossae are extremely rare. There may be one fossa (20 per cent. of cases) or two fossae (10 per cent. of cases). If there is but one fossa it is the internal that exists three times as often as the external. The retro-colic space, if present, varies much in size and extent. In some cases it is sufficiently large to admit the index finger and extends upward behind the ascending colon in the direction of the kidney; in others it is merely a shallow depression. The external retro-colic fossa is bounded and formed by two folds: one, the external parieto-colic fold or the superior caecal fold, which is the outer layer of the ascending mesocolon, and is attached by one edge to the abdominal wall from the lower border of the kidney to the iliac fossa and by the other to the postero-

Fig. 881.—The retro-caecal fossa. The ileum and caecum are drawn backward and upward. (Souligoux.)

external aspect of the colon; and the other, the internal parieto-colic fold or inferior caecal fold, which is the inner layer of the ascending mesocolon. The internal retrocolic fossa is bounded externally by the internal parieto-colic fold, and is bounded internally by the mesenterico-parietal fold, which is the insertion of the mesentery into the iliac fossa.

3. The Intersigmoid Fossa (recessus intersigmoidus).—The intersigmoid fossa is constant in the foetus and common during infancy, but disappears in a large percentage of cases as age advances. Upon drawing the sigmoid flexure upward, the left surface of the sigmoid mesocolon is exposed, and on it will be seen a funnel-shaped recess of the peritoneum, lying on the external iliac vessels, in the interspace between the Psoas and Iliacus muscles. This is the orifice leading to the fossa intersigmoididea, which lies behind the sigmoid mesocolon, and in front of the parietal peritoneum. This fossa is produced by the incomplete fusion in the foetus of the descending mesocolon with the parietal peritoneum. The fossa varies

---

1 The Caecal Folds and Fossae. By Richard J. A. Barry.
in size; in some instances it is a mere dimple, whereas in others it will admit the whole of the index finger.

Any of these fossae may be the site of a retro-peritoneal hernia. The periceliac fossae are of especial interest, because hernia of the vermiform appendix frequently takes place into one of them, and may there become strangulated. The presence of these pouches also explains the course which pus has been known to take in cases of perforation of the appendix, where it travels upward behind the ascending colon as far as the Diaphragm.1

Surgical Anatomy.—Study of the peritoneum by Robinson and others shows that absorption takes place most rapidly from the region of the Diaphragm, less rapidly but still very actively from the region of the small intestine, slowly from the pelvic region. Clinically we know that pelvic peritonitis is not nearly so dangerous as peritonitis in the small intestine or Diaphragm areas, and that peritonitis in the region of the Diaphragm is the most fatal form of the infection. After abdominal operations in infected cases, it is well to elevate the head of the bed (Fowler’s position), so as to obtain the aid of gravity in draining septic fluids away from the dangerous region and toward the safer region.2 In areas which absorption is rapid, protective exudation is not apt to form. In areas in which absorption is slow, inflammatory exudation is apt to circumscribe the area and prevent diffusion. After an operation in a non-infected case, if salt solution has been left in the abdominal cavity because of shock or hemorrhage, raising the foot of the bed will aid rapid absorption of the fluid by favoring the natural current toward the Diaphragm and hurrying the fluid to a region in which absorption is rapid. Dr. John B. Murphy’s plan of treating general peritonitis has proved remarkably successful. He does not remove the exudation of lymph which is seen upon the peritoneum. This exudation is conservative, blocks up lymph spaces, and lessens the absorption of dangerous toxins. He inserts a drainage tube into the peritoneal cavity above the pubes, puts the patient erect or semi-erect in bed (Fowler’s position), and administers salt solution continuously by low pressure protolysis. According to Murphy the lymph circulation is reversed and the peritoneum becomes a secreting surface. Certain it is that the salt solution absorbed from the rectum reaches the peritoneal cavity in large amounts and flows out of the drainage tube.

The great omentum stores up fat, and, being movable, it is able to pass to different parts of the peritoneal cavity. Dr. Robinson, in his work on the Peritoneum, describes its functions as follows: “The omentum is the great protector against peritoneal infectious invasions. It builds barriers of exudates to check infection. It is like a man-of-war, ready at a moment’s notice to move to invaded parts. It circumscribes abscesses; it repairs visceral wounds, and prevents adhesions of mobile viscera to the anterior abdominal wall. It resists infectious invasions by typical peritoneal exudates, and not by succumbing to absorbed sepsis. It is a director of peritoneal fluids, a peritoneal drain.”

In abdominal wounds the omentum often protrudes: This structure frequently constitutes or is part of a hernia, and is almost invariably present in unbilical hernia. As a result of inflammation, it may become adherent to adjacent structures. Adhesions may be of service by matting together the intestines and circumscribing infections. They may be harmful by constraining the bowels and producing obstruction. A portion of the omentum may become adherent to some other part and form a band, and under this band the gut may be caught and strangulated. Omentum may adhere to and plug a perforation in a hollow viscus, and the surgeon may utilize it for the same purpose, or to cover a raw surface or overlie a suture line. The omentum may be in the surgeon’s way while operating. If it is, the patient is placed in the Trendelenburg position (pelvis elevated).

Any tear or opening found by the surgeon in the great omentum must be closed with sutures, because of the danger that intestine might enter and be caught in such an opening. A tumor cut off from its proper blood-supply, for instance, an ovarian cyst with a twisted pedicle, may continue to receive nourishment from adherent omentum, and gangrene may thus be prevented. The lax character and shifting tendency of the subserous tissue explains the occurrence of ptosis of the abdominal viscera and kidneys.

The vast number of nerves in the peritoneum accounts for the profound shock which follows a wound, attends an intraperitoneal calamity, or which develops from infection. An infective process of any portion of the peritoneum produces pain and reflex symptoms (vomiting, abdominal rigidity, intestinal paresis, etc.).

The parietal peritoneum is very sensitive to pain, but not to touch; hence, after injecting a local anesthetic and opening the abdomen, a fairly satisfactory exploration can be made with the finger.

The intestine, the mesentery, the stomach, the anterior margin of the liver, and the gall-bladder are insensitive, and may be cut or even burned without pain.3

1 On the anatomy of these fossae, see the Arris and Gale Lectures by Moynihan, 1899.
2 George R. Fowler, in Medical Record, April 14, 1900.
3 Dr. K. E. L. Lennander, in Mitteilungen aus dem Grenzgebieten der Medizin und Chirurgie, Band x., Heft 1, 2.
Figs. 882, 883, 884, 885, 886, 887.—Diagrams showing the arrangement and variations of the loops of the mesenteric vessels for various segments of the small intestine of average length. Nearest the duodenum the mesenteric loops are primary, the vasa recta are long and regular in distribution and the translucent spaces (lunettes) are extensive. Toward the ileo-colic junction, secondary and tertiary loops are observed, the vessels are smaller and become obscured by numerous fat-tabs. (After Monks.)
Viscera which obtain their innervation purely from visceral nerves are insensitive; those which receive branches from somatic nerves are sensitive (Lenander).

The oblique origin of the mesentery causes this structure to form a sort of shelf. A hemorrhage or extravasation into the abdomen, to the right of the mesentery, tends to flow into the right iliac fossa; one occurring on the left side flows into the pelvis. Monks points out that in flushing the abdominal cavity the tube should not be aimlessly introduced, but should utilize the mesentery on each side of an intestinal loop, to "conduct the tip of the irrigating tube to the bottom of the two fossae." Monks also shows how the mesentery can be utilized to determine the direction of an intestinal loop:

"Now, let us suppose that the surgeon has between his fingers a loop of bowel, and wishes to determine its direction. He knows that one side of the loop is the left side of the intestine, and that the corresponding side of the mesentery, if closely followed down to the mesenteric root, will conduct him into the left fossa; he also knows that the other side of the bowel is its right side, and that the mesentery on that side will conduct him into the right fossa. Now, if his finger goes into the great fossa on the left side of the abdomen, after having closely followed the mesentery down to its root and arranged his loop to be parallel with that root, he then knows that the left and right sides of the intestine face to the left and right sides of the abdomen respectively, and that the end of the loop which points downward is the end nearest the ileo-cecal valve. He can determine the direction of the gut in a similar way in case his finger enters the right fossa. All this would seem very simple were it not for the twists in mesentery and intestine, which tend to mislead one. A little practice will usually enable one to recognize a twist in the mesentery. This should be untwisted by rotation of the gut, after which the direction is determined by another palpation of the mesenteric root."

The studies made of the arrangement and variations of the loops of the mesenteric vessels by Dr. Thomas Dwight have been utilized and expanded by Dr. George H. Monks in laying down rules for the determination of the exact portion of small intestine which may be in the surgeon's hand. His views are as follows:

"General Vascularity of the Mesentery near the Bowel.—Opposite the upper part of the bowel the mesenteric vessels are distinctly larger than opposite any other part of it. These vessels grow smaller and smaller as we pass downward until the lower third of the gut is reached, where they remain about the same size as far as the ileo-cecal valve. The arrangement of the mesenteric vessels has some features which intimately concern the subject in hand, and which I shall describe with some detail. Diagrammatically speaking, the main branches of the superior mesenteric artery unite with each other by means of loops, which are called for convenience 'primary loops;' in some parts of the tube, 'secondary loops,' and even, occasionally, 'tertiary loops' are superimposed upon these. From these loops little straight vessels—the vasa recta already referred to—run to the bowel, upon which they ramify, alternating, as a rule, as to the side of the intestine which they supply. The mesenteric veins are arranged in a manner somewhat similar to the arteries.

"The Loops of the Mesenteric Vessels (Figs. 882, 883, 884, 885, and 886).—Opposite the upper part of the bowel there are only primary loops. Occasionally a secondary loop appears, but it is small and insignificant as compared with the primary loops, which are large and quite regular. As we proceed down the bowel secondary loops become more numerous, larger, and approach nearer to the bowel than the primary loops in the upper part. As a rule, secondary loops become a prominent feature at about the fourth foot. As we continue farther downward, the secondary loops (and, possibly, tertiary loops) become still more numerous and the primary loops smaller, the loops all the time getting nearer and nearer to the gut. Opposite the lower part of the gut the loops generally lose their characteristic appearance, and are represented by a complicated network.

"The Vasa Recta.—Opposite the upper part of the intestine the vasa recta are from three to five centimetres long, when the loop of small intestine to which they run is lifted up so as to put them gently on the stretch. They are straight, large, and regular, and rarely give off branches in the mesentery. In the lower third they are very short, being generally less than one centimetre in length. Here they are less straight, smaller, less regular, and have frequent branches in the mesentery."

The translucency of the mesentery varies greatly; in some parts it may be almost transparent, in others almost or quite opaque. Its thinnest part is above. It is thickened below by fat, fibrous tissue, and muscular tissue. In very fat subjects it may be impossible to see the vessels (Monks). According to Monks, if a loop is raised and looked at against the light close to the gut "little transparent spaces" are seen between the vasa recta, and even in the thickest mesentery; some of these "hunettes" exist along the upper portion of the intestine. As we descend in our examination, they grow smaller and become fatty, and disappear about the eighth foot of the intestines.

THE STOMACH (VENTRICULUS) (Figs. 874, 888, 889, 891, 892).

The stomach is the principal organ of digestion. It is the most dilated part of the alimentary canal, and is situated between the termination of the oesophagus (cardia) and the commencement of the small intestine. Its form varies because of varied conditions, but, as a rule, it is somewhat pyriform. It is placed, in part, immediately behind the anterior wall of the abdomen and beneath the Diaphragm. Viewing the stomach from in front it appears that the right margin of the oesophagus is continued downward as the upper two-thirds of the lesser curvature of the stomach, the remaining third of this border bending sharply backward and to the right, to complete the smaller curvature (Fig. 888). The greater curvature begins at the left border of the termination of the oesophagus in a somewhat acute angle; it then passes upward and to the left to the under surface of the Diaphragm, with which it lies in contact for some distance, and then sweeps downward with a convexity to the left, and, continued across the middle line of the body, finally turns upward and backward, to terminate at the commencement of the small intestine. It will thus be seen that the stomach may be divided into a fundus (fundus ventriculi) and a middle portion or body (corpus ventriculi). The portion of the body adjacent to the cardia being known as the cardiac portion (pars cardiaca), the long axis of which is directed downward with a slight inclination forward and to the right; and the portion adjacent to the pylorus being known as the pyloric portion (pars pylorica), the long axis of which is horizontal or rather upward with an inclination backward. Of the two openings, the cardiac orifice, by which it communicates with the oesophagus, is situated slightly to the left of the middle line of the body to the right of the fundus, or dilated upper extremity of the stomach, and is directed downward; the other, the pyloric orifice, by which it communicates with the small intestine, is on a lower plane, close to the right of the mid-line, and looks directly backward.

Relations of the Stomach.—The stomach lies in a space or chamber called the stomach chamber (Fig. 874). When distended the viscus completely fills the space. When the stomach is empty it lies upon the floor of the chamber, and the portion it has vacated is occupied by the transverse colon, which ascends in front of the stomach and finally gets above it. The anterior wall of the stomach chamber is formed by the anterior abdominal wall. The roof is formed by the under surface of the Diaphragm and the under surface of the left lobe of the liver. The floor is formed by the left suprarenal capsule and the summit of the left kidney, the gastric face of the spleen, the upper surface of the pancreas, the transverse mesocolon, and the colon.2

Surfaces.—The stomach has two surfaces, called anterior and posterior surfaces, and two borders, termed the greater and lesser curvatures.

In regard to the so-called anterior and posterior surfaces of the stomach, it must be borne in mind that these names are not strictly correct, as the anterior surface has a certain amount of inclination upward and the posterior downward.

1 Annals of Surgery, October, 1903.
2 Prof. Birmingham in Prof. Cunningham's Text-book of Anatomy.
The Anterior, Upper or Parietal Surface (paries anterior).—The anterior surface is directed forward and to the right side. It has a somewhat flattened appearance when the stomach is empty, but when it is full the surface becomes convex. It is in relation with the Diaphragm; the thoracic wall formed by the anterior parts of the seventh, eighth, and ninth ribs of the left side; the left lobe of the liver; and the anterior abdominal wall. Between the part covered by the liver and that covered by the left ribs there is a triangular segment of the anterior wall of the stomach, which is in contact with the abdominal wall and is the only part of the stomach which is visible when the abdominal wall is removed and the viscera allowed to remain in situ. Its area is about 40 sq. cm., and it is of great importance to the surgeon, as the stomach can readily be reached in this situation. Occasionally the transverse colon may be found lying in front of the lower part of the anterior surface of the stomach. The whole of this surface of the stomach is covered by peritoneum.

The Posterior, Lower or Visceral Surface (paries posterior).—The posterior surface of the stomach is directed backward and to the left. It is in relation with the Diaphragm, the gastric surface of the spleen, the left suprarenal capsule, the upper part of the left kidney, the anterior surface of the pancreas, the splenic flexure of the colon, and the ascending layer of the transverse mesocolon. These structures form a shallow concavity or bed, on which this surface of the stomach rests. The transverse mesocolon intervenes between the stomach and the duodeno-jejunal junction and commencement of the ileum. Its greater curvature is in relation with the transverse colon and has attached to it the anterior two layers of the great omentum. Almost the whole of this surface is covered with peritoneum, but behind the cardiac orifice there is a small portion of the stomach which is uncovered by peritoneum and is in contact with the Diaphragm and frequently with the upper portion of the left suprarenal capsule.

The Lesser Curvature (curvatura ventriculi minor).—The lesser curvature of the stomach extends between the cardiac and pyloric orifices along the right border of the organ. It descends in front of the left crus of the Diaphragm, along the left side of the eleventh and twelfth thoracic vertebrae, and then turning to the right it crosses the first lumbar vertebra and ascends to the pylorus. It gives attachment to the two layers of the gastro-hepatic omentum, between which blood-vessels and lymphatics pass to reach the organ.

The Greater Curvature (curvatura ventriculi major).—The greater curvature of the stomach is directed to the left, and is four or five times as long as the lesser curvature. Starting from the cardiac orifice, it forms an arch to the left with its convexity upward, the highest point of which is on a level with the costal cartilage of the sixth rib of the left side. It then passes nearly straight downward, with a slight convexity to the left, as low as the costal cartilage of the ninth rib, and then turns to the right to end at the pylorus. As it crosses the median line the lowest edge of the greater curvature is about two fingers’ breadth above the umbilicus. The lower part of the greater curvature gives attachment to the two anterior layers of the great omentum, between which layers vessels and lymphatics pass to the organ.

The Cardia (Fig. 889).—The cardia is the point at which the oesophagus enters the stomach wall. The opening is called the cardiac orifice or the oesophageal opening. At the cardia the circular muscular fibres constitute a sphincter.

The Cardiac Orifice (Fig. 889).—The cardiac orifice is the opening by which the oesophagus communicates with the stomach. It is therefore sometimes termed the oesophageal opening. It is the most fixed part of the stomach, and is situated about two inches below the highest part of the fundus on a level with the body of the tenth or eleventh thoracic vertebra to the left and a little in front of the aorta. This would correspond on the anterior surface of the body to the articulation of
the seventh left costal cartilage to the sternum. It is placed far off from the surface and is at least four inches back of the seventh left chondro-sternal articulation.

The Pylorus (Fig. 889).—The pylorus is the point at which the stomach passes into the duodenum. The opening of communication is called the pyloric orifice. At the pylorus the muscular fibres constitute a sphincter.

The Pyloric Orifice (Fig. 889).—The pyloric orifice communicates with the duodenum, the aperture being guarded by a valve (Fig. 890). Its position varies with the movements of the stomach. When the stomach is empty the pylorus is situated just to the right of the medium line of the body, on a level with the upper border of the first lumbar vertebra. On the anterior surface of the body its position would be indicated by a point one inch below the tip of the ensiform cartilage and a little to the right. As the stomach becomes distended the pylorus moves to the right, and in a fully distended stomach may be situated two or three inches to the right of the median line. The direction of the pylorus is upward and to

Fig. 889.—The mucous membrane of the stomach and duodenum with the bile-ducts.

the right, which position prevents "the weight of the gastric contents bearing directly on the sphincter apparatus." The pylorus is on a somewhat higher level than the lowest point of the stomach. Near the pylorus the stomach frequently exhibits a slight dilatation, which is named the antrum of the pylorus (antrum pyloricum). The pylorus is indicated by a constriction, the direction of which is circular. The pylorus lies upon the neck of the pancreas behind. Above it and in front of it is the liver.

The size of the stomach varies considerably in different subjects. When moderately distended its greatest length, from the top of the fundus to the lowest part of the greater curvature, is from ten to twelve inches and its diameter at the

1 W. J. Mayo, Medical Record, June 11, 1904.
widest part from four to five inches. The distance between the two orifices is three to six inches, and the measurement from the anterior to the posterior wall three and a half inches. Its weight, according to Clendinning, is about four ounces and a half, and its capacity in the adult male is five to eight pints. The stomach of a newborn child holds about one ounce.

Alterations in Position.—There is no organ in the body the position and connections of which present such frequent alterations as the stomach. When empty, it lies at the back part of the abdomen, some distance from the surface, and is in the left hypochondriac region and the left portion of the epigastric region. Its fundus is directed upward and backward toward the Diaphragm. The long axis of the viscus is nearly horizontal. Its pyloric end is directed upward and backward, is situated close to or very slightly to the right of the middle line, covered in front by the left lobe of the liver, and being on a level with the first lumbar vertebra. When empty, the stomach assumes a more or less cylindrical form, especially noticeable at its pyloric end. The entire viscus is small and contracted, and the pyloric region resembles the intestine. When the stomach is distended, its surfaces, which are flattened when the organ is empty, become convex and the shape becomes pyriform. The viscus becomes very oblique and approaches the vertical, its long axis being downward, forward, and to the right. The greater curvature is elevated and carried forward, so that the anterior surface is turned more or less upward and the posterior surface downward, and the stomach is brought well against the anterior wall of the abdomen. Its fundus expands and rises considerably above the level of the cardiac orifice; in doing this the Diaphragm is forced upward, contracting the cavity of the chest; hence the dyspnea complained of, from inspiration being impeded. The apex of the heart is also tilted upward; hence the oppression in this region and the palpitation experienced in extreme distention of the stomach. The left lobe of the liver is pushed to the right side. When the stomach becomes distended the change in the position of the pylorus is very considerable; it is shifted to the right, some two or three inches from the median line, and lies under cover of the liver, near the neck of the gall-bladder. In consequence of the distention of the stomach the lesser cul-de-sac bulges over the pylorus, concealing it from view, and causing it to undergo a rotation, so that its orifice is directed backward. When the stomach is greatly distended its lower border may enter the umbilical and the left lumbar regions. During inspiration the stomach is displaced downward by the descent of the Diaphragm, and it is elevated by the pressure of the abdominal muscles during expiration. Pressure from without, as from tight lacing, pushes the stomach down toward the pelvis. In fact, in the female, because of tight lacing, the stomach may be to the left side of the vertebral column and nearly vertical in direction, the lower portion being sharply angled upward toward the pylorus, which lies underneath the liver. Besides the angulation, the lower end, the stomach may have a median constriction, and there may even be an hour-glass stomach. The descent of the stomach from tight lacing may cause the pancreas to become nearly vertical. In disease the position and connection of the stomach may be greatly changed, from the accumulation of fluid in the chest or abdomen, or from alteration in size of any of the surrounding viscera.

Variations according to Age.—In an early period of development the stomach is vertical, and in the newborn child it is more vertical than later on in life, as owing to the large size of the liver it is more pushed over to the left side of the abdomen, and the whole of the anterior surface is covered by the left lobe of this organ.

On looking into the pyloric end of the stomach, the mucous membrane is found projecting inward in the form of a circular fold, the pyloric valve (Fig. 890), leaving a narrow circular aperture, about half an inch in diameter, by which the stomach communicates with the duodenum.

The Pyloric Valve (valvula pylori) (Fig. 890).—The pyloric valve is formed by a reduplication of the mucous membrane of the stomach, containing numerous circular fibres, which are aggregated into a thick circular ring, the pyloric sphincter (m. sphincter pylori); the longitudinal fibres and serous membrane being continued over the fold without assisting in its formation (Fig. 890). The pylorus is normally kept closed by the action of this aggregation of circular fibres which constitutes the Sphincter muscle. During the early stage of digestion it remains closed, but after a time opens now and then. The opening becomes more frequent and the period of patency is prolonged as digestion advances.
The diameter of the pylorus is uncertain. It is usually said to be half an inch. But it is closed when the pylorus is at rest, and it can certainly dilate even in a child to at least an inch and let bodies of this size pass through.

The Peritoneum.—The *great omentum* comes off from the greater curvature of the stomach and passes to the transverse colon. The *lesser omentum* comes off from the lesser curvature and passes to the liver. The *gastro-splenic ligament* or *omentum* passes from the under surface of the stomach just below the greater curvature to the spleen. A fold of peritoneum passes up from the stomach along the left side of the oesophagus to the Diaphragm. This is the *gastro-phrenic ligament*.

**Supports of the Stomach.**—The stomach lies on the bed of the stomach chamber, which was described on p. 1277. The great omentum gives no support to the stomach, neither does the gastro-splenic ligament, because of the movability of the spleen. The *lesser omentum* does give support to the stomach and so do

![Diagram of the stomach](image)

**Fig. 891.**—The superficial muscular layer of the stomach, viewed from above and in front. (Spalteholz.)

the *gastro-phrenic ligament* and the *hepato-duodenal ligament*. The two chief points of support are the attachment of the oesophagus to the Diaphragm and the fixation of the duodenum to the front of the vertebral column.

**Structure.**—The wall of the stomach consists of four coats: *serous, muscular, areolar,* and *mucous,* together with vessels and nerves.

The Peritoneal or Serous Coat (*tunica serosa*).—The peritoneal or serous coat covers the entire surface of the organ, excepting along the greater and lesser curvatures, at the points of attachment of the greater and lesser omenta; at each curvature the two layers of peritoneum leave a small triangular space, to which the peritoneum is not attached, although it is attached in front of it and
back of it. Along these spaces the nutrient vessels and nerves pass. On the posterior surface of the stomach, close to the cardiac orifice and below and to the left of it, there is a smaller triangular area uncovered by peritoneum, where the organ is in contact with the under surface of the Diaphragm, and it may be with the left suprarenal body and the summit of the left kidney. When the stomach is moderately distended this uncovered area measures about one and a half inches from above downward, and about two inches from before backward. At the left angle of this uncovered area the insertion of the great omentum begins. At the right angle the gastric artery reaches the stomach.

The Muscular Coat (tunica muscularis) (Figs. 891 and 892).—The muscular coat is situated immediately beneath the serous covering, to which it is closely connected. It consists of three sets of fibres—longitudinal, circular, and oblique.

The Longitudinal Fibres (stratum longitudinale) are most superficial; they are continuous with the longitudinal fibres of the oesophagus, radiating in a stellate manner from the cardiac orifice. They are most distinct along the curvatures, especially the lesser, but are very thinly distributed over the surfaces. At the pyloric end they are more thickly distributed, and continuous with the longitudinal fibres of the small intestine. The bundles of longitudinal muscle-fibre on the upper and lower surfaces of the pylorus are particularly firm and distinct, and are called the pyloric ligaments (ligamenta pylori).

The Circular Fibres (stratum circulare) form a uniform layer over the whole extent of the stomach, except the fundus, beneath the longitudinal fibres. At the pylorus they are most abundant, and are aggregated into a circular ring or sphincter, which projects into the cavity, and forms, with the fold of mucous membrane covering its surface, the pyloric valve (Fig. 890). They are continuous with the circular fibres of the oesophagus.
The Oblique Fibres (fibrae obliquae) arise at the left side of the cardia from the circular fibres of the oesophagus. The fibres pass down in the anterior and posterior walls. Those of the anterior wall are parallel to the lesser curvature and almost reach the pylorus. Those of the posterior wall are more nearly transverse to the long axis of the stomach (Spalteholz). These fibres gradually assume the direction of the circular fibres and terminate in them. The layer of oblique fibres is beneath the circular layer. Certain oblique muscular fibres encircle the fundus of the stomach in a series of rings.

The Areolar or Submucous Coat (tela submucosa).—The areolar or submucous coat consists of loose, filamentous, areolar tissue, connecting the mucous and muscular layers. It supports the blood-vessels previous to their distribution to the mucous membrane; hence it is sometimes called the vascular coat.

The Mucous Membrane (tunica mucosa) (Figs. 893, 894, and 895).—The mucous membrane is thick; its surface smooth, soft, and velvety. In the fresh state it is of a pinkish tinge at the pyloric end, and of a red or reddish-brown color over the rest of the surface. In infancy it is of a brighter hue, the vascular redness being more marked. It is thin at the cardiac extremity, but thicker toward the pylorus. During the contracted state of the organ it is thrown into numerous plaits or rugae (plicae mucosae) (Figs. 893 and 895, A), which for the most part have a longitudinal direction, and are most marked toward the lesser end of the stomach and along the greater curvature, and which contain also submucous tissue. These folds are entirely obliterated when the organ becomes distended. A constant fold exists at the pylorus (Fig. 890). It is called the pyloric valve, and is produced by the presence beneath it of the Sphincter muscle.

Besides the large folds or rugae and the pyloric valve, there are numerous small elevations of mucous membrane known as gastric areas (areae gastricae), which are partly separated from each other by furrows and which vary greatly in shape (Fig. 893). According to Spalteholz, each one of these elevations has an area of several square millimetres.
Structure of the Mucous Membrane.—When examined with a lens the inner surface of the mucous membrane presents a peculiar honeycomb appearance, from being covered with small shallow depressions or alveoli (foveolae gastricae) (Figs. 894 and 895, B) of a polygonal or hexagonal form, which vary...
from $\frac{1}{10}$ to $\frac{3}{10}$ of an inch in diameter, and are separated by slightly elevated ridges (plicae villosae). The ridges are most distinct at the pylorus. These foveolae are within the areae gastricae. The ridges on section resemble villi. In the bottom of the alveola are seen the orifices of minute tubes, the gastric glands (Fig. 895 B), which are placed perpendicularly side by side throughout the entire substance of the mucous membrane. The surface of the mucous membrane of the stomach is covered by a single layer of columnar epithelium; it lines the alveoli, and also for a certain distance the mouths of the gastric glands. This epithelium commences very abruptly at the cardiac orifice, where the cells suddenly change in character from the stratified epithelium of the oesophagus. The cells are elongated, and consist of two parts, the inner or attached portions being granular, and the outer or free parts being clear and occupied by a mucosaluminous substance.

The Gastric Glands.—The gastric glands are of three kinds: the true gastric glands, the pyloric glands, and the cardiac glands.

The True Gastric Glands (Fig. 897) are called also the oxyntic glands, the fundus glands, and the peptic glands (glandulae gastricae propriae). They are distributed throughout the entire fundus and body, and may be found even at the pylorus. They are tubular in character, and are formed of a delicate basement-membrane, lined with epithelium. The basement-membrane consists of flattened transparent endothelial cells, with processes which extend between and support the epithelium. Into the crypt of a true gastric gland three or more caecal tubes, branched or unbranched, empty. The duct, however, in these glands is shorter than in the other variety, sometimes not amounting to more than one-sixth of the whole length of the gland; it is lined throughout by columnar epithelium. At the point where the terminal tubes open into the duct, and which is termed the neck, the epithelium alters, and consists of short columnar or polyhedral, granular cells, which almost fill the tube, so that the lumen becomes suddenly constricted, and is continued down as a very fine channel. They are known as the chief or the peptic or the central cells of the glands, and furnish pepsin. Between these cells and the basement-membrane are found other darker granular-looking cells, studded throughout the tubes at intervals, and giving it a beaded or varicose appearance. These are known as the parietal or oxyntic cells. Some of the parietal cells empty directly into the lumen of the gland by secretory capillaries; others empty by a duct which divides into secretory capillaries. The parietal cells secrete the acid of the gastric juice. Between the glands the mucous membrane consists of a connective-tissue framework with lymphoid tissue. In places this latter tissue, especially in early life, is collected into little masses, which to a certain extent resemble the solitary glands of the intestine, and are by some termed the lenticular glands of the stomach. They are not, however, so distinctly circumscribed as the solitary glands.

The Pyloric Glands (glandulae pyloricae) (Fig. 896) are the branched tubular glands, and secrete mucus.

They are placed most plentifully about the pylorus, but between the fundus and pylorus, in the region known as the transitional or intermediate zone, both true gastric glands and pyloric glands are found. Each pyloric gland consists of two or three short, closed tubes opening into a common duct, the external orifice of which is situated at the bottom of an alveolus. The caecal tubes are wavy, and are of about equal length with the duct. The tubes and duct are lined throughout with epithelium, the duct being lined by columnar cells continuous with the epithelium lining the surface of the mucous membrane of the stomach, the tubes with shorter and more cubical cells, which are finely granular. The pyloric glands branch more frequently, are more curved in direction, and open into deeper foveolae than the true gastric glands (Szymonowicz). They contain only chief or peptic cells and do not possess parietal cells.
The **Cardiac Glands** are found about the oesophageal orifice. They resemble the pyloric glands.

Beneath the mucous membrane, and between it and the submucous coat, is a thin stratum of involuntary muscular fibre (*muscularis mucosae*), which in some parts consists only of a single longitudinal layer; in others, of two layers, an inner circular, and an outer longitudinal.

**Vessels and Nerves.**—The arteries supplying the stomach are—the *gastric* or *coronary*, the *pyloric* and the *right gastro-epiploic branch of the gastro-duodenal*, the *left gastro-epiploic* and *vasa brevia* from the splenic. The gastric artery passes to the lesser curvature just below the cardia. It gives off the *oesophageal branch*, and passes from left to right along the lesser curvature of the stomach beneath the peritoneum between the two layers of the lesser omentum and upon the wall of the stomach. It may in this course be a single vessel, or may divide into two branches, which run along each side of the lesser curvature (Fig. 899). If there is a single artery it gives off six or seven descending branches to the anterior wall and about the same number to the posterior wall of the stomach. It also gives branches to the lesser omentum. If two *vascular arches* form, one gives branches to the anterior wall of the stomach, the other to the posterior wall, and both to the lesser omentum. The termination of the gastric anastomoses with the pyloric branch or two rami of the pyloric branch of the hepatic artery. From each arch six or seven *descending branches* come off to the anterior and posterior walls of the stomach. The *gastro-duodenal artery* is given off by the hepatic. From the gastro-duodenal comes the right gastro-epiploic. The left gastro-epiploic comes from the splenic. The **right gastro-epiploic artery** passes from right to left in the gastro-colic omentum below the greater curvature of the
stomach. The left gastro-epiploic artery passes forward in the gastro-splenic ligament to below the greater curvature of the stomach, and passes from left to right along that curvature in the gastro-colic omentum, and joins the right gastro-epiploic artery. The gastro-epiploic arteries are not upon but are distinctly below the stomach wall. From them numerous gastric branches are sent to the anterior and posterior walls of the stomach, and they anastomose with branches of the gastric and pyloric. Vasa brevia, four or five in number, arise from the splenic, pass forward in the gastro-splenic ligament, and supply the fundus. The arteries of the stomach lie first beneath the peritoneum, but soon enter the muscular coat, supply it, pierce it, ramify in the submucous coat, and are finally distributed to the mucous membrane. The arrangement of the vessels in the mucous membrane is somewhat peculiar (Fig. 898). The arteries break up at the base of the gastric tubules into a plexus of fine capillaries which run upward between the tubules, anastomosing with each other, and ending in a plexus of larger capillaries, which surround the mouths of the tubes and also form hexagonal meshes around the alveoli.

The capillary networks about the glands give origin to the veins. The various small veins unite and form a plexus in the submucous tissue (Fig. 898). From this plexus come branches which pass through the muscular coat and terminate in the right gastro-epiploic branch of the superior mesenteric, the left gastro-epiploic branch of the splenic, the veins to the splenic which correspond to the vasa brevia arteries, and the gastric or coronary branch of the portal.

The lymphatics (Figs. 505 and 506) arise in the mucous membrane and terminate in a network in the submucous tissue. From this network trunks arise which perforate the muscular coat in the regions of the curvatures and terminate in the sero-muscular collecting trunks.¹

According to Cunéo, there are three groups of these collectors. Those from the lesser curvature pass to the point where the gastric artery reaches the stomach and enter the glands along the gastric artery. Those from the greater curvature pass from left to right and enter the sub-pyloric glands. Those from the fundus pass from right to left and end in the splenic glands. Cunéo further pointed out that the region drained by the collectors of the lesser curvature is divided from the others by the line shown in Fig. 506. This division exists on both surfaces of the stomach. The limit between the collectors which drain into the splenic glands and those which drain into the sub-pyloric glands is also shown in Fig. 506. Along the lesser curvature the lymph-glands are few in number and are limited to the pyloric region, and the lymph-vessels are placed directly upon the stomach wall. The lymph-glands and vessels are not upon but are distinctly below the greater curvature.

The subserous and submucous lymphatic networks of the stomach communicate with the corresponding networks of the oesophagus, but in all probability do not communicate with the networks of the duodenum.

The nerves of the stomach come from the right and left vagus and from the solar plexus of the sympathetic. The left vagus passes to the front of the stomach, and the right nerve passes to the back, and they unite with the fibres of the sympathetic. The fibres thus formed are mostly amylenic. They form Auerbach's plexus in the muscular coat between the circular and longitudinal fibres and Meissner's plexus in the submucous coat, the latter plexus being formed by fibres from the former. Fibres from Meissner's plexus ramify in the submucous coat and terminate in the muscularis mucosae and the mucous membrane, branches passing to the gastric glands and to just beneath the epithelium.

¹ The Lymphatics. By Poirier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf.
THE ORGANS OF DIGESTION

Movements and Innervation of the Stomach.

Movements.—It has apparently been demonstrated that the stomach "consists of two parts physiologically distinct." The cardiac portion of the stomach is a food reservoir in which salivary digestion continues; the pyloric portion is the seat of active digestion. Cannon affirms that there are no peristaltic waves in the cardiac portion, but that as the food passes from the pyloric portion into the intestines, tonic contraction of the muscles of the fundus squeezes the contents of the pyloric portion. Moritz, Levan, and Cannon assert that muscular activity is chiefly manifested in the pyloric portion. In this portion during digestion there is a succession of peristaltic waves, which waves in the human being pass at the rate of three per minute (Moritz). Cannon points out that the efficiency of peristalsis in mixing the food depends upon the contraction of the pyloric sphincter. So long as the sphincter holds, each constriction-ring coursing from the middle to the end of the stomach presses the food into a blind pouch; the food, unable to escape through the pyloric opening, has as its only outlet the opening in the advancing ring. This is an admirable device for bringing the food under the influence of the glandular secretions of the pyloric region. For, as a constriction occurs, the secreting surface enclosed by the narrowed muscular ring is pressed close around the food within the ring. As the constriction advances it continually presses inward fresh glandular tissue, and further-more, as the constriction advances, a thin stream of food is continuously forced back through the ring and thus past the mouths of the glands. The old view that the pyloric sphincter only opens after several hours' continuance of the process of digestion and that then the stomach empties at once is incorrect. It is emptied in small amounts which escape at frequent intervals because of the intermittent opening of the pylorus. When the pylorus is open a wave of peristalsis forces some of the material from the stomach into the duodenum (Cannon).

Cannon is of the opinion that the pyloric sphincter is caused to relax by the presence of free hydrochloric acid in the pyloric portion of the stomach. When the pylorus is open acid chyme passes into the duodenum and acid in the duodenum causes the pylorus to close. The acid in the duodenum causes a flow of alkaline pancreatic juice and the acid is neutralized. "As the neutralizing proceeds the stimulus closing the pylorus is weakened until the acid in the stomach again opens the sphincter."1

Innervation.—The stomach, as previously shown, has nerve plexuses in its walls and is connected to the brain, spinal cord, and sympathetic system. It is probable that gastric peristalsis is due to a local reflex from Auerbach's plexus (Magnus), the local reflex being inaugurated by local stimulation, which stimulation, in the words of Bayliss and Starling, "produces excitation above and inhibition below the excited spot."2 Reversed peristalsis cannot occur if "the reflex mechanism is intact" (Cannon). Cannon in the previously quoted article states that cutting the vagus or splanchnic nerves does not destroy the reflex mechanism of the pylorus, but, nevertheless, it is markedly affected by the central nervous system.

Surface Form (see p. 1280).—The cardiac orifice corresponds to the articulation of the seventh left costal cartilage with the sternum. The pyloric orifice of the empty stomach is in a vertical line drawn from the right border of the sternum, two and a half or three inches below the level of the sterno-xiphoid articulation. According to Braune, when the stomach is distended, the pylorus moves considerably to the right, as much sometimes as three inches. The fundus of the stomach reaches, on the left side, as high as the level of the sixth costal cartilage of the left side, being a little below and behind the apex of the heart. The portion of the distended stomach which is in contact with the abdominal walls, and is therefore accessible for opening in the operations of gastrotomy and gastrostomy, is represented by a triangular space, the base of which is formed by a line drawn from the tip of the tenth costal cartilage on the left side to the tip of the ninth costal cartilage on the right, and the sides by two lines drawn from the extremity of the eighth costal cartilage on the left side to the ends of the base line.

Surgical Anatomy.—Operations on the stomach are frequently performed, ulcers are excised, malignant growths are removed with the associated lymphatic involvement, the entire stomach may be removed for cancer, etc. By "gastrotomy" is meant an incision into the stomach for the removal of a foreign body, or the arrest of hemorrhage or for exploration, the opening being immediately afterward closed—in contradistinction to "gastrostomy," the making of a more or less permanent fistulous opening. Gastrotomy is probably best performed by an incision in the linea alba, especially if the foreign body is large. The cut may reach from the ensiform cartilage to the umbilicus. The incision may be made over the body itself, where this can be felt, or by one of the incisions for gastrostomy, to be mentioned shortly. The peritoneal cavity is opened, and the point at which the stomach is to be incised decided upon. This portion is then brought out of the abdominal wound and sponges carefully packed around. The stomach is now opened by a transverse incision and the foreign body extracted. The wound in the stomach is then closed by Lembert sutures—t. c., by sutures passed through the peritoneal,

1 Walter B. Cannon, Medical News, May 20, 1905. 2 Ibid. 3 Ibid.
muscular and submucous coats in such a way that the peritoneal surfaces on each side of the wound are brought into apposition. \textit{Gastrectomy} was formerly done in two stages by the \textit{direct} method. The first stage consisted in opening the abdomen, drawing up the stomach into the external wound, and fixing it there; and the second stage, performed from two to four days afterward, consisted in opening the stomach. The operation is now done by a \textit{valvular} method. The following plan is known as the Saabanejew-Frank operation. An incision is commenced opposite the eighth intercostal space, two inches to the left of the median line, and carried downward for three inches. By this incision the fibres of the Rectus muscle are exposed and these are separated from each other in the same line. The posterior layer of the sheath, the transversalis fascia and the peritoneum, are then divided, and the peritoneal cavity is opened. Instead of the above incision, the curved incision of Fenger can be made at the margin of the left costal cartilages. The anterior wall of the stomach is now seized and drawn out of the wound and a silk suture passed through its submucous, muscular, and serous coats at the point selected for opening the viscus. This is held by an assistant so that a long conical diverticulum of the stomach protrudes from the external wound, and the parietal peritoneum and the posterior layer of the sheath of the rectus are sutured to the base of the cone. A second incision is made through the skin, over the margin of the costal cartilage, \textit{above and a little to the outer side of the first incision}. If Fenger’s incision were used, the second incision should be above the margin of the cartilages. With a pair of dressing forceps a track is made under the skin through the subcutaneous tissue from the one opening to the other and the diverticulum of the stomach is drawn along this track by means of the suture inserted into it; so that its apex appears at the second opening. A small perforation is now made into the stomach through this protruding apex and its margin carefully and accurately sutured to the margin of the external wound. The remainder of this incision and the whole of the first incision are then closed in the ordinary way and the wound dressed.

In cases of \textit{gastric ulcer}, perforation sometimes takes place, and this was formerly regarded as an almost fatal complication. In the present day, by opening the abdomen and closing the perforation, which is generally situated on the anterior surface of the stomach, a considerable percentage of cases are cured, provided the operation is undertaken within twelve to fifteen hours after the perforation has taken place. The opening is best closed by bringing the peritoneal surfaces on either side into apposition by means of Lembert sutures.

\textit{Pylorectomy} or excision of the pylorus is performed, particularly for early cancer, but is also done for cicatricial stricture and for ulcer. The mortality after operation for cancer was, until recently, very great, but of late years it has been notably reduced, though it is still much higher than that which follows operation for any non-malignant condition.

In operating for cancer, bear in mind Cuneo’s study of the lymphatics (page 806). These observations indicate that the fundus and two-thirds of the greater curvature are free from lymphatic involvement in pyloric cancer.\textsuperscript{1} In every operable case of cancer of the pylorus the lesser curvature must be removed up to the gastric artery (Mikulicz’s point), and the greater curvature must be removed to the left of the involved glands (Hartmann’s rule).

\textit{Gastro-enterostomy} is an operation which establishes a fistulous communication between the stomach and jejunum. The operation is often called \textit{gastro-jejunostomy}. The opening may be made upon either the anterior or the posterior wall of the stomach, between the cardia and the seat of pyloric disease. The operation is employed for stricture of the pylorus (benign or malignant), and occasionally for ulcer of the stomach.

\textit{Loreta’s operation} is digital division of the pylorus for cicatricial stricture, the stomach being incised transversely near the pylorus to admit the finger, and the wound in the stomach being sutured after division has been effected. The operation has been abandoned, because contraction recurs.

\textit{Pyloroplasty}, or the Heineke-Mikulicz operation, displaced Loreta’s operation. In this procedure an incision is made through the stricture in the direction of the long axis of the stomach and bowel. By making traction on each side of the incision, the longitudinal wound assumes a vertical direction, and sutures are inserted so as to close the wound in a vertical line. The method of pyloroplasty devised by Finney, of Baltimore, makes a large permanent opening at the most dependent part of the stomach, and is the most satisfactory method of which we are possessed.\textsuperscript{2}

\textit{Total gastrectomy} is the removal of the entire stomach. It is only used for cancer. It was first performed by Conner, of Cincinnati. The first successful operation was done by Schlatter, of Zurich, in 1898. A number of successes have been reported. It is a justifiable operation only in a case in which almost the entire stomach is cancerous, in which the vices is movable, in which there are no secondary deposits, and no irremovable diseased glands.

\textit{Gastro-gastrectomy} is an operation employed in hour-glass stomach. In this operation an anastomosis is made between the pyloric and cardiac ends of the stomach.

\textsuperscript{2} Johns Hopkins Hospital Bulletin, July, 1902.
**Gastroplication** is the operation of suturing the stomach wall into folds or reefs, in order to lessen its size. It is employed in some cases of gastric dilatation.

**Gastroptosis** is a condition in which the stomach is displaced downward. In some of these cases the greater curvature almost reaches the level of the symphysis pubis, and the lesser curvature is midway between the umbilicus and ensiform cartilage. The condition is usually associated with **enteroptosis** and **movable kidney** (nephroptosis). In this condition the gastro-hepatic omentum and the gastro-phrenic ligament are pulled upon and lengthened. The best operation for gastroptosis was devised by Beyea. He applies sutures so as to make folds in and thus shorten the stretched ligament and omentum. Thus the stomach is elevated to its proper position, and its mobility is not lessened, as it is in other operations which suture it to the abdominal wall.

**THE SMALL INTESTINE (INTESTINUM TENUE).**

The small intestine is a convoluted tube, extending from the pylorus to the ileo-caecal valve, where it terminates in the large intestine. It fills up the greater part of the abdominal cavity and of the pelvic cavity. It is about twenty feet in length, and gradually diminishes in size from its commencement to its termination. The diameter of the duodenum is almost two inches; the diameter of the lower portion of the small intestine is little more than one inch. It is contained in the central and lower part of the abdominal cavity, and is surrounded above and at the sides by the large intestine; a portion of it extends below the brim of the pelvis and lies in front of the rectum; it is in relation, in front, with the great omentum and abdominal parietes; and connected to the spine by a fold of peritoneum, the **mesentery** (p. 1266). The small intestine is divisible into three portions — the **duodenum**, the **jejunum**, and **ileum**.

The **Duodenum** (Figs. 900, 905, 906, 907, 908).

The duodenum has received its name from being about equal in length to the breadth of twelve fingers (ten inches). It is the shortest, the widest, and the most fixed part of the small intestine, being closely and firmly attached to the posterior abdominal wall. It does not possess a mesentery. Somewhat more than the upper half of the duodenum is placed in the epigastric region; the remainder is in the umbilical region. The duodenum, with the exception of the ascending portion, is to the right of the median line. Its course presents a remarkable curve, which in the adult, as regards the greater part of its extent, is horseshoe-shaped, though sometimes, in consequence of the transverse portion being very short or altogether wanting, it partakes more of the character of the letter V. The opening of the horseshoe being directed upward and to the left. In children up to the age of about seven the duodenum is annular. The two extremities of the duodenum are nearly on the same level, the exit being slightly lower than the entrance. The two ends are about two inches apart; and between them it describes a regular curve embracing the head of the pancreas, the neck of which lies between the two extremities of the ring.

In the adult the course of the duodenum is as follows: commencing at the pylorus the direction of the first portion depends upon the amount of distention of the stomach and therefore upon the position of the pylorus. When the stomach is empty and the pylorus is situated at the right of the upper border of the first lumbar vertebra, it is nearly horizontal and transverse; but where the stomach is distended, in consequence of the alteration of the position of the pylorus to the right the proximal end of the duodenum also becomes altered in position, while the

---

1 Treves states that in one hundred cases the average length of the small intestine in the adult male was 22 feet 6 inches, and in the adult female 23 feet 4 inches; but that it varies very much, the extremes in the male being 31 feet 10 inches in one case and 15 feet 6 inches in another, a difference of over 15 feet. He states that he has convinced himself that the length of the bowel is independent, in the adult, of age, height, and weight.—Ed. of 15th English edition.
THE DUODENUM

distal end remains fixed and the direction of this portion of the bowel is now antero-posterior. Whether directed transversely or antero-posteriorly, it reaches

the fourth lumbar vertebra. It now takes a second bend, and passes across the front of the vertebral column from right to left and finally ascends on the left side of the vertebral column and aorta to the level of the upper border of the second lumbar vertebra and there terminates in the jejunum. As it unites with the jejunum it often turns abruptly forward, forming the duodeno-jejunal angle. Prof.

Birmingham points out that the incomplete ring formed by the duodenum does not lie throughout in the same plane. "Its greater part is placed in a transverse vertical plane; the middle portion bends strongly backward, around the right side of the vena cava, and lies almost in a sagittal plane." From the above description it will be seen that the duodenum may be divided for purposes of description into four portions—superior, descending, transverse and ascending.

The First or Superior Portion (pars superior) (Figs. 900, 905, and 907) is very variable in length, but is usually estimated as being about two inches. Beginning at the pylorus, it ends at the level of the neck of the gall-bladder.

---

1 Prof. Cunningham's Text-book of Anatomy.
When the stomach is empty this portion of the duodenum is horizontal and transverse; when the stomach is distended it extends from before backward. It is the most movable of the four portions. It is almost completely covered by peritoneum derived from the two layers of the lesser omentum. A small part of its posterior surface is not completely covered by peritoneum (Fig. 901). The first inch of the superior portion of the duodenum is completely covered by peritoneum; the lesser omentum is attached above and the greater omentum below (Fig. 901). The other portion has only its anterior wall covered by peritoneum. The posterior and lateral surfaces are uncovered by peritoneum and are near the neck of the gall-bladder and the posteava. The first portion of the duodenum is in such close relation with the gall-bladder that it is usually found to be stained by bile after death, especially on its anterior surface. It is in relation above and in front with the quadrate lobe of the liver, lying in a slight concavity, the impression duodenalis. It is also in relation above in part with the gall-bladder; behind with the gastro-duodenal artery, the common bile-duct, and the portal vein; and below with the head of the pancreas. The superior portion of the duodenum crosses the transverse fissure of the liver, and by means of the superior flexure of the duodenum (flexura duodeni superior) passes into the second or descending portion beneath the caudate lobe.

The Second or Descending Portion (pars descendens) (Figs. 900, 905, and 907) is between three and four inches in length, and extends from the neck of the gall-bladder on a level with the first lumbar vertebra along the right side of the vertebral column as low as the body of the fourth lumbar vertebra. It is crossed in its middle third by the transverse colon, the posterior surface of which is uncovered by peritoneum and is connected to the duodenum by a small quantity of connective tissue. The portions of the descending part of the duodenum above and below this interspace are named the supracolic and infracolic portions, and are covered in front by peritoneum (Fig. 902). The right side of the supracolic portion is covered by peritoneum derived from the anterior surface of the right kidney, the left side of the same portion being covered by the peritoneum forming the lesser sac. The infracolic part is covered by the right leaf of the mesentery. Posteriorly the descending portion of the duodenum is uncovered by peritoneum. The descending portion of the duodenum is in relation, in front, with the transverse colon, and above this with the right lobe of the liver, where it lies in the impression duodenalis for the second part of the duodenum; behind with the front of the right kidney, to which it is connected by loose areolar tissue, the renal vessels and the postcava; at its inner side is the head of the pancreas, and the ductus communis choledochus; to its outer side is the hepatic flexure of the colon. The common bile-duct passes downward behind the first portion of the duodenum, descends to the inner side of the second portion, is joined by the pancreatic duct, and the two ducts perforate the inner side of this portion of the intestine obliquely, and empty into the duodenum by a common opening or by two openings at the summit of a papilla, some three or four inches below the pylorus. The relations of the second portion of the duodenum to the right kidney present considerable variations. The descending portion passes into the transverse portion by means of the flexura duodeni inferior.

The Third, Pre-aortic, Horizontal or Transverse Portion (pars horizontalis inferior) (Figs. 900, 905, and 907) varies much in length; when the duodenum assumes the ordinary horseshoe form, it measures from two to three inches; but when it presents the rarer V-shaped form, it is practically wanting or very much reduced in length. The transverse portion is described as the horizontal part of the ascending or last portion by those authors who divide the duodenum into three parts instead of four. It commences at the right side of the fourth lumbar vertebra and passes from right to left, with a slight inclination upward, in front of the great
vessels and crura of the Diaphragm, and ends in the fourth portion in front of or just to the left of the abdominal aorta. It is crossed by the superior mesenteric vessels and mesentery. The *posterior surface* rests upon the aorta, the post-cava, and the crura of the Diaphragm. By its upper surface this portion of the duodenum is in relation with the head of the pancreas. The front of the third portion of the duodenum is covered by peritoneum except where the mesenteric vessels and root of the mesentery cross it (Fig. 903). The left side of the termination of the ascending portion is also covered by peritoneum, and in this region the *duodenal fossae* are found (p. 1270).

The **Fourth or Ascending Portion of the Duodenum** (*pars ascendens*) (Figs. 900, 905, and 907) is about two inches long. It ascends on the left side of the vertebral column and aorta, as far as the level of the upper border of the second lumbar vertebra, where it turns abruptly to the right and forward to become the jejunum, forming the *duodeno-jejunal angle* or *flexure* (*flexura duodenojejunalis*) (Fig. 905). It is covered entirely in front and partly at the sides by peritoneum, derived from the left portion of the mesentery (Fig. 904). The superior mesenteric artery and vein are in front of it. It touches the left kidney, slightly overlapping its inner margin, and rests upon the left crus of the Diaphragm.

The first part of the duodenum, as stated above, is somewhat movable, but the rest is practically fixed and is bound down to neighboring viscera and the posterior abdominal wall by the peritoneum. In addition to this, the fourth part of the duodenum and the duodeno-jejunal flexure is further bound down and fixed by a structure called the **Suspensory muscle of the duodenum** or the ** suspensory ligament of Treitz** (*m. suspensorius duodeni*) (Fig. 905). This structure commences in the connective tissue around the coeliac axis and left crus of the Diaphragm, and passes downward to be inserted into the superior border of the duodeno-jejunal curve and a part of the ascending duodenum, and from this it is continued into the mesentery. It possesses, according to Treitz, some few plain muscular fibres mixed with the
fibrous tissue, of which it is principally made up. It is of little importance as a muscle, but acts as a suspensory ligament.

Fig. 906.—The interior of the duodenum. (Spalteholz.)

Fig. 907.—The duodenum, its four parts marked a, b, c, d. The liver is lifted up; the greater part of the stomach is removed, broken lines indicating its former position. (Testut.)
**Interior of the Duodenum** (Fig. 906).—In the beginning of the duodenum valvulae conniventes are absent. They begin to appear in the lower half of the first portion, being at first trivial elevations irregularly placed. They become higher, regular, and more numerous lower down, and near the termination of the duodenum are strongly marked and closely placed transverse or spiral folds (Fig. 906 and p. 1260). In the descending portion (Fig. 906) to the side and rear is a longitudinal fold (plica longitudinalis duodeni), which is formed by the projection of the bile-duct and pancreatic duct beneath the mucous membrane.

The **caruncula major of Santorini** or the **bile papilla** is a projection or pit in the lower part of the longitudinal fold. At the summit of this papilla are seen two openings, if the bile-duct and pancreatic duct have not united, or one common opening for both of them, if they have united. One inch above and half an inch or more in front of the bile papilla is a much smaller papilla, the **caruncula minor of Santorini** (papilla duodeni [Santorini]), on the summit of which the accessory pancreatic duct of Santorini opens.

**Structure of the Duodenum.**—The peritoneal coat (tunica serosa) has been described. The **muscular coat** (tunica muscularis) is practically identical with the muscular coat of the balance of the intestine. The bile-duct and pancreatic duct pass through it. The **submucous coat** (tela submucosa) contains lymph-nodes and **glands of Brunner** (glandulae duodenales). These glands are particularly plentiful in the first half of the duodenum (p. 1303). The mucous membrane is thicker in the duodenum than in the rest of the small intestine, is covered with villi, and from the lower half of the first portion down is formed into circular folds or valvulae conniventes. In the descending part it exhibits the previously described longitudinal fold.

**Vessels and Nerves.**—The **arteries** (Fig. 908) supplying the duodenum are the pyloric and pancreatico-duodenal branches of the hepatic, and the **inferior pancreatico-duodenal branch of the superior mesenteric**. The **veins** (Fig. 908) correspond to the arteries. The **superior duodenal vein** passes into the superior mesenteric, and the **inferior duodenal vein** passes into the portal. The **lymphatics** pass along with the pancreatico-duodenal arteries, glands being present here and there, and terminate in the glands about the coeliac axis. The **duodenal fossae** are described on p. 1270. The **nerves** are derived from the solar plexus.
The Jejunum and Ileum (Figs. 875, 877, 878, 880, 905).

The remainder of the small intestine from the termination of the duodenum comprises the jejunum and ileum; the former name being given to the upper two-fifths and the latter to the remaining three-fifths. Spalteholz and others call all of the small intestine below the duodenum the intesinum tenue mesenteriale. There is no morphological line of distinction between the jejunum and ileum, and the division is arbitrary; but at the same time it must be noted that the character of the intestine gradually undergoes a change from the commencement of the jejunum to the termination of the ileum, so that a portion of the bowel taken from these two situations would present characteristic and marked differences. These are briefly as follows:

**Differences between the Jejunum and Ileum.**—If the jejunum high up is contrasted with the ileum low down, it is noted that the former is thicker, of greater diameter, contains more blood-vessels, and hence is more distinctly red, has well-marked valvulae conniventes, but a few small-sized Peyer’s patches, and the villi are short and broad. In the ileum large Peyer’s patches are present in numbers, and the villi are thin (Prof. Birmingham).

**The Jejunum (intestinum jejunum).**—The jejunum, which derives its name from the Latin word jejunus (empty), because it was formerly supposed to be empty after death, is wider, its diameter being about one inch and a half, and is thicker, more vascular, and of a deeper color than the ileum, so that a given length weighs more. Its valvulae conniventes are large and thickly set and its villi are larger than in the ileum. The glands of Peyer are almost absent in the upper part of the jejunum, and in the lower part are less frequently found than in the ileum, and are smaller and tend to assume a circular form. Brunner’s glands are only found in the upper part of the jejunum. By grasping the jejunum between the finger and thumb the valvulae conniventes can be felt through the walls of the gut; these being absent in the lower part of the ileum, it is possible in this way to distinguish the upper from the lower part of the small intestine.

**The Ileum (intestinum ileum).**—The ileum (so called from the Greek word εἰλεῖος, to twist, on account of its numerous coils and convolutions) is placed below and to the right of the jejunum. It is narrower, its diameter being one inch and a quarter, and its coats are thinner and less vascular than those of the jejunum. It possesses but few valvulae conniventes, and they are small and disappear entirely toward its lower end, but Peyer’s patches are larger and more numerous. The jejunum for the most part occupies the umbilical and left iliac regions, while the ileum occupies chiefly the umbilical, hypogastric, right iliac, and pelvic regions, and terminates in the right iliac fossa by opening into the inner side of the commencement of the large intestine. The upper portion of the jejunum passes to the left of the duodeno-jejunal flexure, and is in relation with the under surface of the pancreas and the transverse mesocolon. The lower portion of the ileum is in the pelvis and rises from above the brim, passing upward, backward, and to the right to reach the ileo-cecal opening. Treves points out that another portion of the small intestine may be in the pelvis, viz., the portion with the longest mesentery. This is a portion somewhere between a point six feet from the duodenum and a point eleven feet from the duodenum. The jejunum and ileum are attached to the posterior abdominal wall by an extensive fold of peritoneum, the mesentery (p. 1266), which allows the freest motion, so that each coil can accommodate itself to changes in form and position. The mesentery is fan-shaped; its posterior border, about six inches in length, is attached to the abdominal wall from the left side of the second lumbar vertebra to the right iliac fossa (Fig. 875). Its length is about eight inches from its commencement to its termination at the intestine, and it is rather longer about its centre than at either end of the bowel. According to Lockwood,
it tends to increase in length as age advances. Between the two layers of which it is composed are contained blood-vessels, nerves, lacteals, and lymphatic glands, together with a variable amount of fat.

**Meckel's Diverticulum (diverticulum ilei).**—Occasionally there may be found connected with the lower part of the ileum, on an average about three feet from its termination, a blind diverticulum or tube, varying in length, but averaging about two inches, and being of about the same diameter as the piece of intestine of which it is a part. Sometimes only a portion of the proximal end is open and the balance of the structure is obliterated and shrunk to a fibrous cord. In other cases the diverticulum is actually of greater diameter than the intestine. It usually is at a right angle to the intestine, but may take almost any direction. In most cases it has a mesentery. It is attached to and communicates with the lumen of the bowel by one extremity, and by the other is unattached or may be connected with the abdominal wall or with some other portion of the intestine by a fibrous band. This is Meckel's diverticulum, and represents the remains of the vitelline or omphalo-mesenteric duct, the duct of communication between the umbilical vesicle and the alimentary canal in early foetal life.

**Structure of the Small Intestine, including the Duodenum.**—The wall of the small intestine is composed of four coats—serous, muscular, areolar or submucous, and mucous.

**The Serous Coat (tunica serosa).**—The relation of the peritoneum to the duodenum has been described. The remaining portion of the small intestine is surrounded by the peritoneum, excepting along its attached or mesenteric border; here a space is left for the vessels and nerves to pass to the gut.

**The Muscular Coat (tunica muscularis).**—The muscular coat consists of two layers of fibres, an external or longitudinal layer and an internal or circular layer.

The **Longitudinal Fibres** (stratum longitudinale) are thinly scattered over the surface of the intestine, and are more distinct along its free border.

The **Circular Fibres** (stratum circulare) form a thick, uniform layer; they surround the cylinder of the intestine in the greater part of its circumference, and are composed of plain muscle-cells of considerable length. The muscular coat is thicker at the upper than at the lower part of the small intestine.

**The Areolar or Submucous Coat (tela submucosa).**—The areolar or submucous coat connects together the mucous and muscular layers. It consists of loose, filamentous areolar tissue, which forms a bed for the subdivision of the nutrient vessels, previous to their distribution to the mucous surface.

The submucous coat contains **lymph-nodules** (noduli lymphatici). Each nodule is pyramidal or pear-shaped, and the apex lies in the mucous membrane and forms a rounded elevation. These rounded elevations mark the solitary glands and Peyer's patches (Figs. 909, 911, and 918), and in nowise resemble villi. In the duodenum the submucous tissue contains the **duodenal glands**. The submucous tissue is prolonged into the **valvulae conniventes**. It contains blood-vessels, Meissner's plexus of nerves, and lymph-vessels.

**The Mucous Membrane (tunica mucosa).**—The mucous membrane is thick and highly vascular at the upper part of the small intestine, but somewhat paler and thinner below. It consists of the following structures: next the areolar or submucous coat is a layer of unstriped muscular fibres, the **muscularis mucosae**; internal to this is a quantity of retiform tissue, enclosing in its meshes lymph-corpuscles, and in which the blood-vessels and nerves ramify. Lastly, a basement-membrane, supporting a single layer of epithelial cells, which throughout the intestines are columnar in character. They are granular in appearance, and each possesses a clear, oval nucleus. At their superficial or unattached end they present a distinct layer of highly refracting material, marked by vertical striae, which were formerly
believed to be minute channels by which the chyle was taken up into the interior of the cell, and by them transferred to the lacteal vessels of the mucous membrane.

The mucous membrane presents for examination the following structures contained within it or belonging to it:

Valvulae conniventes. Duodenal glands.
Villi. Lymphatic nodules
Simple follicles. Solitary glands.

The Valvulae Conniventnes or the Valves of Kerkring (plicae circulares [Kerkringi]) (Fig. 910) are large folds or valvular flaps projecting into the lumen of the bowel. They are composed of reduplications or folds of the mucous membrane, the two layers of the fold being bound together by submucous tissue; they contain no muscular fibres, and, unlike the folds in the stomach, they are permanent, and are not obliterated when the intestine is distended. The majority extend transversely across the cylinder of the intestine for about one-half or two-thirds of its circumference, but some form complete circles, and others have a spiral direction; the latter usually extend a little more than once around the bowel, but occasionally two or three times. The spiral arrangement is the characteristic one of the shark family of fishes. The larger folds are about one-third of an inch in depth at their broadest part; but the greater number are of smaller size. The larger and smaller folds alternate with each other. They are not found at the commencement of the duodenum, but begin to appear about one or two inches beyond the pylorus. In the lower part of the descending portion, below the point where the bile and pancreatic ducts enter, the intestine, they are very large and closely approximated. In the transverse portion of the duodenum and upper half of the jejunum they
are large and numerous; and from this point, down to the middle of the ileum, they diminish considerably in size. In the lower part of the ileum they almost entirely disappear; hence the comparative thinness of this portion of the intestine as compared with the duodenum and jejunum. The valvulae conniventes retard the passage of the food along the intestine, and afford a more extensive surface for absorption.

The villi (villi intestinales) (Figs. 909, 911, 912, 913, and 918) are minute, highly vascular processes, never larger than one millimetre, projecting from the mucous membrane of the small intestine throughout its whole extent, and giving to its surface a velvety appearance. They spring from the valvulae conniventes and also from the spaces between them. In shape, according to Rauber, they are short and leaf-shaped in the duodenum, tongue-shaped in the jejunum, and filiform in the ileum. They are largest and most numerous in the duodenum and jejunum, and become fewer and smaller in the ileum. Krause estimates their number in the upper part of the small intestine at from fifty to ninety in a square line; and in the lower part from forty to seventy, the total number for the whole length of the intestine being about four millions.

Structure of the Villi (Figs. 912 and 913).—The structure of the villi has been studied by many eminent anatomists. We shall here follow the description of Watney, whose researches have a most important bearing on the physiology of that which is the peculiar function of this part of the intestine, the absorption of fat.

The essential parts of a villus are—the lacteal vessel, the blood-vessels, the epithelium, the basement-membrane and muscular tissue of the mucosa, these structures being supported and held together by retiform lymphoid tissue.

1 Phil. Trans., vol. clxv. part ii.
These structures are arranged in the following manner: situated in the centre of the villus is the lacteal, terminating near the summit in a blind extremity;
running along this vessel are unstriped muscular fibres; surrounding it is a plexus of capillary vessels, the whole being enclosed by a basement-membrane, and covered by columnar epithelium. Those structures which are contained within the basement-membrane—namely, the lacteal, the muscular tissue, and the blood-vessels—are surrounded and enclosed by a delicate reticulum which forms the matrix of the villus, and in the meshes of which are found large, flattened cells with oval nuclei, and, in smaller numbers, lymph-corpuscles. These latter are to be distinguished from the larger cells of the villus by their behavior with reagents, by their size, and by the shape of the nucleus, which is spherical. Transitional forms, however, of all kinds are met with between the lymph-corpuscles and the proper cells of the villus. Nerve-fibres are contained within the villi; they form ramifications throughout the reticulum.

The lacteals are in some cases double, and in some animals multiple. Situated in the axis of the villi, they commence by dilated caecal extremities near to, but not quite at, the summit of the villus. The walls are composed of a single layer of endothelial cells, the interstitial substance between the cells being continuous with the reticulum of the matrix.

The muscular fibres are derived from the muscularis mucosae, and are arranged in bundles around the lacteal vessel, extending from the base to the summit of the villus, and giving off laterally individual muscle-cells, which are enclosed by the reticulum, and by it are attached to the basement-membrane.

The blood-vessels form a plexus between the lacteal and the basement-membrane, and are enclosed in the reticular tissue; in the interstices of the capillary plexus, which they form, are contained the cells of the villus.

These structures are surrounded by the basement-membrane, which is made up of a stratum of endothelial cells, and upon which is placed a layer of columnar epithelium. The reticulum of the matrix is continuous through the basement-membrane (that is, through the interstitial substance between the individual endothelial cells) with the interstitial cement substance of the columnar epithelial cells on the surface of the villus. Thus we are enabled to trace a direct continuity between the interior of the lacteal and the surface of the villus by means of the reticular tissue, and it is along this path that the chyle passes in the process of absorption by the villi; that is to say, it passes first of all into the columnar epithelial cells, and, escaping from them, is carried into the reticulum of the villus, and thence into the central lacteal.
The Simple Follicles, Intestinal Glands, Crypts or Glands of Lieberkühn (glandulae intestinales [Lieberkühni]) (Figs. 914, 915, and 918) are found in considerable numbers over every part of the mucous membrane of the small intestine. They consist of minute tubular depressions of the mucous membrane, arranged perpendicularly to the surface, upon which they open by small circular apertures. They may be seen with the aid of a lens, their orifices appearing as minute dots scattered between the villi (Fig. 909). Their walls are thin, consisting of a basement-membrane lined by columnar epithelium, and covered on their exterior by capillary vessels.

The Duodenal or Brunner's Glands (glandulae duodenales [Brunneri]) are limited to the duodenum and commencement of the jejunum. They are small, flattened, granular bodies embedded in the submucous areolar tissue, and open upon the surface of the mucous membrane by minute excretory ducts. They are most numerous and largest near the pylorus. They are small, compound, acino-tubular glands, and much resemble the small glands which are found in the mucous membrane of the mouth. They are believed by Watney to be direct continuations of the pyloric glands of the stomach. They consist of a number of tubular alveoli, lined by epithelium, and opening by a single duct on the inner surface of the intestine.

The Lymph Nodules (noduli lymphatici) are small pyriform structures. The bodies of the nodes are in the submucous coat; the apices are in the mucous membrane, which is thrown by them into rounded elevations. They are divided into solitary glands and Peyer's glands.

The solitary glands (noduli lymphatici solitarii) (Figs. 909 and 911) are found scattered throughout the mucous membrane of the small intestine and the large intestine. In the small intestine they are most numerous in the lower part of the ileum, upon and between the valvulae conniventes. They are small, round, whitish bodies, from one-twenty-fourth of an inch to one-quarter of an inch in diameter. Their free surface is covered with villi, and each gland is surrounded by the openings of the follicles of Lieberkühn. They are now recognized as lymph-
nodules. They consist of a dense interlacing retiform tissue closely packed with lymph-corpuscles and permeated with an abundant capillary network. The interspaces of the retiform tissue are continuous with larger lymph-spaces at the base of the gland, through which they communicate with the lacteal system. They are situated partly in the submucous tissue, partly in the mucous membrane, whence they form slight projections of its epithelial layer, after having penetrated the muscularis mucosae. The villi situated on them are generally absent from the very summit (or "cupola," as Frey calls it) of the gland.

**Peyer's glands, Peyer's patches**, the agminated glands or the tonsillae intestinales (noduli lymphatici aggregati [Peyerii]) (Figs. 916, 917, and 918) may be regarded as aggregations of solitary glands, forming circular or oval patches from twenty-five to forty in number, and varying in length from half an inch to four inches. They are largest and most numerous in the ileum. In the lower part of the jejunum they are small, of a circular form, and few in number. They are occasionally seen in the duodenum. They are placed lengthwise in the intestine, and are situated

![Diagram of Peyer's patch](image)

in the portion of the tube most distant from the attachment of the mesentery. Each patch is formed of a group of the above-described solitary glands covered with mucous membrane, and in almost every respect are similar in structure to them. They do not, however, as a rule, possess villi on their free surface. Each patch is surrounded by a circle of the crypts of Lieberkühn. They are best marked in the young subject, becoming indistinct in middle age, and sometimes altogether disappearing in advanced life. They are largely supplied with blood-vessels, which form an abundant plexus around each follicle and give off fine branches which permeate the lymphoid tissue in the interior of the follicle. The lacteal plexuses which are found throughout the small intestine are especially abundant around these patches; here they form rich plexuses with sinuses around the glands (Fig. 918). In typhoid fever there is ulceration of Peyer's patches.

**Vessels and Nerves.**—The arteries (vasa intestini tenues) are branches of the superior mesenteric (Fig. 423) and ascend within the mesentery, forming single, double, or even tertiary loops (Figs. 882, 883, 884, 885, 886, 887, and 919). The terminal branches reach the intestine, and each branch divides into two, one going to each side of the intestine and passing transversely around it. At first they are
directly beneath the peritoneum, but after a time they pass to the submucosa and form a plexus, from which branches go to the mucous membrane. Some of these enter the villi; others form plexuses about the glands of Lieberkühn (Birmingham).

Dr. George H. Monks\(^1\) points out that opposite the upper portion of the bowel the mesenteric vessels form only primary loops; as we pass down secondary loops appear, become larger and more and more numerous, and actually prominent features about the fourth foot. As we descend the secondary loops become larger and more numerous and the primary become smaller. All the time the loops get nearer and nearer to the bowel. Tertiary loops may appear. Opposite the lower part of the ileum the loops cease to be characteristic and they form a network. (Monks's views are fully set forth on p. 1276.) In the upper part of the gut the vasa recta are from 3 to 5 cm. long, when the loop of small intestine to which they run is lifted up so as to put them gently on the stretch. They are straight, large, and regular, and rarely give off branches in the mesentery. In the lower third they are very short, being generally less than 1 cm. in length. Here they are less straight, smaller, less regular, and have frequent branches in the mesentery.

The veins correspond to the arteries, and the venous blood passes to the superior mesenteric vein, which, it will be remembered, unites with the splenic vein to form the portal vein. The mesenteric veins are devoid of valves.

The lacteals are lymphatics (Figs. 911, 912, 913, and 918) which arise in the villi. Lymphatics also begin in sinuses at the base of the solitary glands and as lymph-nodes in the submucous coat. Peyer's patches are aggregations of lymph-nodes. There is an extensive lymphatic plexus in the submucous coat, another in the muscular coat, another under the peritoneum. The submucous plexus is formed by lymphatics from the villi and mucous membrane. This plexus is joined by lymphatics from the bases of the solitary glands, and the lymph passes by vessels to larger vessels at the mesenteric border of the gut. The muscular lymphatics are placed between the two muscular layers. They

\(^1\) Annals of Surgery, May, 1903.
form a plexus and communicate freely with the lymphatics from the mucous membrane, and empty themselves in the same manner into the commencement

Fig. 921.—Meissner's plexus. (Ramón y Cajal.)

Fig. 922.—Meissner's plexus. (Klein and Noble Smith.)
of the lacteal vessels at the attached border of the gut. The vessels from all sources of lymphatic supply pass up between the two layers of the mesentery, being connected with the mesenteric glands (Fig. 507), and unite to form a trunk, the intestinal lymphatic trunk, which opens into the receptaculum chyli, or the vessels unite to form several trunks, which open separately into the receptaculum chyli.

The nerves of the small intestine (Figs. 920, 921, and 922) are derived from the coeliac plexus about the superior mesenteric artery, which is one of the divisions of the solar plexus. They pass along within the mesentery with the superior mesenteric artery and reach the intestine. They pass to the plexus of nerves and ganglia situated between the circular and longitudinal muscular fibres (Auerbach's plexus), from which the nerve branches are distributed to the muscular coats of the intestine. From this plexus a secondary plexus is derived (Meissner's plexus). It is formed by branches which have perforated the circular muscular fibres (Fig. 922). This plexus lies between the muscular and mucous coats of the intestine. It is also gangliated, and from it the ultimate fibres pass to the muscularis mucosae, to the villi, and to the mucous membrane. The nerves of the intestine are amyelinic, and some of the fibres are derived from the vagus.

THE LARGE INTESTINE (INTESTINUM CRASSUM) (Figs. 812, 874, 875, 923, 924).

The large intestine extends from the termination of the ileum to the anus. It is about five feet or more in length, being one-fifth of the whole extent of the intestinal canal. It is largest at its commencement at the caecum, and gradually diminishes as far as the rectum, where there is a dilatation of considerable size just above the anus. The diameter of the distended caecum is usually about three inches; the diameter of the descending colon is about one and one-half inches. The large intestine differs from the small intestine in its greater size, its more fixed position, its sacculated form (Figs. 923 and 924), and in possessing certain appendages to its external coat, the appendices epiploicae (Fig. 924). The appendices epiploicae are peritoneal pouches containing fat, unless the subject is greatly wasted; they protrude here and there from the peritoneal coat of the entire large bowel, except the rectum, and are particularly frequent along the anterior longi-
tudinal band. Further, the longitudinal muscular fibres of the large intestine do not form a continuous layer around the gut, but are arranged in three longitudinal bands or taeniae (taeniae coli) (Fig. 924). The large intestine, in its course, describes an arch, which surrounds the convolutions of the small intestine. It commences in the right inguinal region, in a dilated part, the caecum. It ascends through the right lumbar and right hypochondriac regions to the under surface of the liver; it here takes a bend to the left, the hepatic flexure, and passes transversely across the abdomen on the confines of the epigastric and umbilical regions, to the left hypochondriac region; it then bends again, the splenic flexure, and descends through the left lumbar region to the left iliac fossa, where it becomes convoluted, and forms the sigmoid flexure; finally it enters the pelvis, and descends along its posterior wall to the anus. The large intestine is divided into the caecum, colon, and rectum.

The Caecum (Intestinum Caecum) (Figs. 925, 926).

The caecum, the commencement of the large intestine, is the large blind pouch, or cul-de-sac, situated below the ileo-caecal valve. Its name is derived from caecus, blind. Its blind end or fundus is directed downward, and its open end upward, communicating directly with the colon, of which this blind pouch appears to be the beginning or head, and hence the old name caput caecum coli was applied to it. An incomplete groove marks the upper limit of the caecum. This groove is at the level of the opening of the ileum. When the caecum is contracted it bends on this groove as on a hinge and forms an angle with the ascending colon. In the contracted caecum sacculations are but slightly evident; in the distended caecum they are definite. Its size is variously estimated by different authors, but on an average it may be said to be two and a half inches in length and three in breadth. In 435 careful autopsies, Robinson found the caecum and appendix congenitally absent in one case. Sometimes a very large, sometimes an exceedingly small, caecum is encountered. A large caecum may be four inches in width, entirely surrounded by peritoneum and usually is excessively mobile. An adult caecum may be only one inch in width and one-half an inch in length, and it is usually devoid of mobility. It is situated in the right iliac fossa, above the outer half of Poupart's ligament, usually rests on the Ilio-psoas muscle, the iliac fascia intervening, and lies immediately behind the abdominal wall. The right side of the caecum is in contact with the outer wall of the abdomen, and the outer aspect of the anterior wall of the caecum is in contact with the anterior abdominal wall (Spalteholz). When the caecum is full the small intestine lies in front of the left side and lower portion of the anterior caecal wall. If the caecum is empty the small intestine lies in front of its anterior wall, and the lower end is on a higher level than when this portion of the gut is full. In a small per cent. of cases the

1 St. Louis Courier of Medicine, October-December, 1902.
caecum is covered by the omentum. Robinson describes four positions of the caecum: 1. On the Psoas muscle. 2. To the right of the Psoas muscle. 3. In the pelvis. 4. The potential position, in which it lies free in the abdominal cavity. It may be found in various positions in the abdomen, because of elongation of the fixation apparatus. The commonest position is on the Psoas muscle, and this position is even more common in men than in women. It is twice as often in the pelvis in women as in men—20 per cent. of cases in the former; 10 per cent. in the latter. As a rule, it is entirely enveloped on all sides by peritoneum, but in a certain number of cases (6 per cent., according to Berry) the peritoneal covering is not complete, so that a small portion of the upper end of the posterior surface is uncovered and connected to the iliac fascia by connective tissue. As a matter of fact, there is no real mesocaecum—meaning by the term a peritoneal fold which holds the caecum to the dorsal wall of the abdomen—except when there is failure in development. Originally the caecum receives its blood along a single peritoneal fold, the ileo-caecal fold, which is a simple mesentery. As development advances, this simple mesentery becomes a double fold and practically bloodless, and is replaced by two vascular folds, the mesoappendix to the left and the mesenterico-colic to the right. The mobility of the caecum varies. Very small caeca are fixed. In most cases the caecum lies quite free in the abdominal cavity and enjoys a considerable amount of movement. Sometimes it is excessively mobile, and in such cases is usually also of large size. Such mobility is due to a stretched fixation apparatus. A very large and mobile caecum may be made to come in contact with any abdominal viscus and may enter any hernial sac on either side. It is to be remembered that a mobile caecum carrying with it the appendix may pass to almost any region of the abdomen. Sometimes the caecum fails to descend or only descends a part of the way during development, the axial rotation of the intestinal tract having been arrested. In such a case it may terminate at the level of the gall-bladder, and the ascending colon is absent. In 310 adult males Robinson found 8 per cent. with undescended caecum and appendix. Nondescent is found in less than 4 per cent. of adult females. A partly descended caecum usually lies upon the right kidney.

The caecum varies in shape, but, according to Treves, in man it may be classified under one of four types (Fig. 926). In early foetal life it is short, conical, and broad at the base, with its apex turned upward and inward toward the ileo-caecal junction. It then resembles the caecum of some of the monkey tribe, e.g., Mangabey monkey. As the foetus grows the caecum increases in length more than in breadth, so that it forms a longer tube than in the primitive form and without the broad base, but with the same inclination inward of the apex toward the ileo-caecal junction. This form is seen in others of the monkey tribe, e.g., the spider monkey. As development goes on, the lower part of the tube ceases to grow and the upper part becomes greatly increased, so that at birth there is a narrow tube, the vermiform appendix, hanging from a conical projection, the caecum. This is the infantile form, and as it persists throughout life, in about 2 per cent. of cases, it is regarded by Treves as the first of his four types of human caeca. The caecum is conical and the appendix rises from its apex. The three longitudinal bands start from the appendix and are equidistant from each other. In the second type, the conical caecum has become quadrate by the growing out of a saccule on either side of the anterior longitudinal band. These saccules are of equal size, and the appendix arises from between them, instead of from the apex of a cone. This type is found in about 3 per cent. of cases. The third type is the normal type of man. Here the two saccules, which in the second type were uniform, have grown at unequal rates: the right with greater rapidity than the left. In consequence of this an apparently new apex has been formed by the growing downward of the right saccule, and the original apex, with the appendix attached, is pushed
over to the left toward the ileo-caecal junction. The three longitudinal bands still start from the base of the appendix, but they are now no longer equidistant from each other, because the right saccule has grown between the anterior and posterolateral bands, pushing them over to the left. This type occurs in about 90 per cent. of cases. The fourth type is merely an exaggerated condition of the third;

the right saccule is still larger, and at the same time the left saccule has been atrophied, so that the original apex of the caecum, with the appendix, is close to the ileo-caecal junction, and the anterior band courses inward to the same situation. This type is present in about 4 per cent. of cases.

Supports of the Caecum.—According to Robinson,¹ the caecum is maintained in position by the mesocolon and a peritoneal fold, the right phrenico-colic ligament, which arises from the hepato-duodenal and hepato-renal ligaments. It receives support from the connective tissue about vessels and nerves, and inconstantly from folds which fixes it in the iliac fossa and in the region of the precava.

The Interior of the Caecum.—In the interior of the caecum are seen depressions which correspond to the surface hastrae, and semilunar folds (plicae semilunares coli) (Fig. 925), which correspond to the transverse surface constrictions. There are three openings in the caecum: that into the colon; that into the ileum, which is guarded by the ileo-caecal valve (p. 1315); and that into the appendix, which may be guarded by the valve of Gerlach.

¹ St. Louis Courier of Medicine, October-December, 1902.
Pericaecal Folds and Fossae.—See p. 1272, and Figs. 879, 880, and 881.

The Vermiform Appendix (processus vermiformis) (Figs. 879, 880, 881, 926, 927, 928, 929, and 931).—The vermiform appendix is found only in man, the higher apes, and the wombat, although in certain rodents a somewhat similar arrangement exists. In carnivorous animals the caecum is very slightly developed; in herbivorous animals (with a simple stomach) it is, as a rule, extremely large. It has been suggested that the vermiform process in man is the degenerated remains of the herbivorous caecum, which has been replaced by the carnivorous form. 1 The vermiform appendix is a long, narrow, worm-shaped, musculo-membranous tube, which starts from what was originally the apex of the caecum. After development has advanced the vermiform appendix comes off, as a rule, from the inner side of the posterior wall of the caecum that is below and behind the termination of the ileum. This origin usually corresponds to McBurney's point, which is in the abdominal wall, midway between the umbilicus and the anterior superior iliac spine, and which is the usual seat of the greatest tenderness in appendicitis. The origin of the appendix varies with the type of caecum present. These variations are shown in Fig. 926. In the foetal or infantile type of appendix it arises from the apex of the caecum; in the second type of caecum it arises between the two caecal sacculi; in the third type it arises between a large outer and a small inner sacculus; and on the posterior wall of the caecum, the excessive growth of the anterior wall having caused the appendix to originate posteriorly; in the fourth type there is no internal sacculus, and the appendix arises from the posterior caecal wall behind the ileo-caecal junction (p. 1310). The movable portion of the appendix may be met with in different situations. It may pass upward and in front of the caecum and colon, upward and behind the caecum, and even behind the colon between the two layers of the mesocolon; upward and to the inner side, or upward and to the outer side of the caecum and colon. It may pass to the left under the ileum and mesentery, upward and to the left or downward and to the left into the true pelvis. It may pass directly downward under the caecum. It may pass to the right in front of or back of the caecum. It may occupy any one of the caecal fossae (p. 1272), but most often enters the ileo-caecal fossa. In unusual cases the appendix is found in the inguinal canal as a portion of or the sole contents of a hernia; adherent to the parietal peritoneum in front of or to the side of the caecum, or "behind the peritoneum, below the caecum, adherent to the under surface of the caecum and in contact with its muscular wall and covered by its peritoneal coat." 2 When the caecum is mobile the appendix may be found almost anywhere within the abdomen. When the caecum is undescended, the appendix of course shares in the failure to descend, and may be below the gall-bladder or in front of the right kidney, and may pass in several directions: upward behind the caecum; to the left behind the ileum and mesentery; or downward and inward into the true pelvis. It varies from one-half an inch to nine inches in length, its average being about three inches. Its diameter is from one-eighth inch to one-quarter inch. The operating surgeon may occasionally fail to find an appendix buried in one of the caecal fossae, and may conclude that the diverticulum is absent. As a matter of fact, unless the colon is also absent, it seems doubtful if the appendix is ever absent, except as a result of disease. This view is maintained by Lockwood and Rolleston, 3 by Kelynack, 4 and others. It is asserted by some that the appendix is absent 5 times out of 10,000 autopsies. It is retained in position by a fold of peritoneum derived from the left leaf of the mesentery, which forms a mesentery for it, and is called the meso-appendix (p. 1269, and Figs. 879, 880, and 881). In color the healthy appendix is

---

2 Deaver's Surgical Anatomy.
4 A Contribution to the Pathology of the Vermiform Appendix.
yellowish-pink, is soft and smooth to the touch, and the "subperitoneal vessels are barely visible." The canal of the appendix is small and extends throughout the whole length of the tube. The walls of the healthy diverticulum are thick, and the diameter of the lumen is usually trivial as compared with the diameter of the appendix itself. The lumen of the appendix communicates with the caecum by an orifice which is placed below and behind the ileo-caecal opening (Fig. 932). It is sometimes guarded above and to the left side by a semilunar fold of mucous membrane, the valve of Gerlach (valvula processus vermiformis). The valve is inconstant, and is never perfect. It is stated that the appendix tends to undergo obliteration as an involution change in a functionless organ. The lumen rarely contains foreign bodies after death, but often contains fecal concretions. Certain it is that in 25 per cent. of necropsies upon adults or elderly people the lumen is found to be partially or completely occluded.

Structure of the Appendix (Fig. 930).—The coats of the appendix correspond to the coats of the bowel: serous, muscular (the outer layer of longitudinal, the inner of circular fibres), submucous, and mucous. In the deepest portion of the mucous coat, against the submucous coat, are the unstriated fibres constituting the muscularis mucosae. The muscularis mucosae is often present in some regions and absent in others. It may not be present at all.

The Outer or Serous Coat usually completely covers the appendix and has a definite mesentery, the mesoappendix (p. 1269). Occasionally the base of the appendix is not surrounded by peritoneum, but is extraperitoneal, lying in the retroperitoneal tissue. The appendiculο-ovarian ligament of Clado is occasionally present in females. It is a prolongation of the mesoappendix which passes into the broad ligament, and is extremely thin, and its fine connective-tissue fibres send prolongations into the longitudinal muscle-fibres of the appendix. Lockwood points out that the subperitoneal tissue of the meso-appendix and "the blood-vessels, nerves, and lymphatics which it contains are very intimately connected with the submucosa. This union takes place at certain large gaps in the muscular coats. These gaps serve for the transmission of blood-vessels, nerves, and lymphatics from the mesoappendix to the mucous coat. They are situated at the junction of the mesoappendix with the appendix."2

The Longitudinal Muscular Layer is thin and irregularly distributed, and in certain regions may be excessively thin or actually absent, and between the fibres are the blood-vessels, nerves, and lymphatics passing from the subperitoneal tissue to the mucous coat.

1 Appendicitis, its Pathology and Surgery. By Charles Barrett Lockwood.
2 Ibid.
The **Circular Fibres** are much better developed than the longitudinal fibres, and, according to Lockwood, the layer is 1 mm. thick. Large gaps are found here and there for the passage of vessels, lymphatics, and nerves to and from the meso-appendix and the mucous membrane, and a few vessels pierce the fibres at other points (Lockwood).

The **Submucous Coat** varies greatly in thickness. It contains blood-vessels, nerves, and lymphatics, and some lymphoid follicles.

The **Mucous Membrane** (Fig. 928) is covered by columnar epithelial cells and contains numerous solitary lymph-follicles, some glands of Lieberkühn, surrounded by lymphoid tissue, blood-vessels, lymphatics, and nerves.

The muscularis mucosae may be absent, may be scanty, or may be distinct. The **lymphoid follicles** are visible to the naked eye (Fig. 928). Some of them are in the sub-mucosa, some of them chiefly in the mucosa, the bases of the latter, however, being in the submucosa. Lockwood estimates that an appendix three and a half inches in length contains from 150 to 200 follicles.

**Blood-vessels of the Caecum and Appendix** (Figs. 927, 929, 945, and 946).—The **ileo-colic artery** in the ileo-colic angle gives off the **anterior** and **posterior ileo-caecal arteries**. The anterior ileo-caecal runs down over the front of the ileum and supplies the ileum, and sends off a terminal branch, the **anterior caecal artery**, which supplies the anterior surface of the caecum and of a portion of the ascending colon, and to the upper and lower margins of the ileo-caecal valve. It sends no branch to the appendix. The arteries of the appendix come from the **posterior ileo-caecal artery**. This vessel, after arising from the ileo-colic artery, passes back of the termination of the ileum and gives branches to the lower end of the ileum back of a portion of the ascending colon and to the lower margin of the ileo-caecal valve, where they anastomose with the valvular branches from the anterior ileo-caecal (Lockwood). From the posterior ileo-caecal comes the posterior caecal branch, which passes over the posterior and inner portion of the caecum near the base of the appendix and sends one or two branches to the appendix. The chief blood-supply of the appendix is the **appendicular artery**, which comes off the beginning of the posterior ileo-caecal or, occasionally, from the termination of the ileo-colic. If there is a distinct mesoappendix the largest branch of the artery passes along its free edge. If the mesoappendix is absent or rudimentary the artery usually lies upon the appendix from base to tip beneath the peritoneum.

Lockwood points out that the appendicular artery as it enters the mesoappendix divides into three branches. The largest branch runs along the free edge, and from this the tip of the appendix obtains its blood-supply; "the other two reach the appendix at intervals of half an inch." When the branches reach the appendix they divide and pass around it in the subperitoneal coat and send branches through the muscular gaps to enter and pass through the submucous coat.

In females there is occasionally some additional blood-supply through a branch of the **ovarian artery** in the appendiculoso-ovarian ligament.

The **veins** of the appendix are numerous, thin walled, and large. Veins from the submucous plexus pass through the muscular gaps and enter the subperi-
toneal plexus. Veins from the subperitoneal plexus pass into veins in the meso-
appendix which correspond to but do not really accompany the arteries (Lock-
wood). Most of the veins of the mesoappendix pass to the posterior ileo-caecal
vein, though some pass directly to the caecal vein. These veins are radicles of
the portal system.

![Diagram of arteries and veins of the caecum and vermiform appendix]

**Lymphatic System of the Caecum and Appendix** (Fig. 930).—Surrounding the base
of each lymph-follicle in the submucous tissue of the appendix is a lymph-space,
which Lockwood calls the *follicular* or *basilar lymph-sinus*. This sinus communic-
ates with the lymphatics of the submucous coat, "which again communicate
freely through the hiatus muscularis with those of the peritoneum and of the
mesoappendix." The collecting trunks from the caecum and appendix follow the

![Diagram of transverse section of the vermiform appendix]

blood-vessels (Fig. 931). The anterior collecting trunks of the caecum pass
through several small glands in the anterior ileo-caecal fold, and terminate in
glands along the ileo-colic artery (Fig. 931). The posterior collecting trunks pass
through some small glands and terminate in glands along the ileo-colic
artery. The appendicular collecting trunks enter the mesoappendix. There are
usually four of them, sometimes five. Some of them traverse a gland constantly
present at the ileo-caecal angle (Clado). Another gland is constant. It is situated
beneath the ileo-colic fossa (Lockwood and Rolleston). The editor subscribes to

1 Appendicitis, its Pathology and Surgery. By Charles Barrett Lockwood.
Lockwood's statement that in appendicitis there is often a chain of inflamed glands along the inner side of the ascending colon behind the ascending mesocolon. Hence this is one road taken by the lymphatics of the appendix. The others pass to the mesenteric glands.

The Ileo-caecal Valve or the Valve of Bauhin (*valvula coli*) (Figs. 932, 933, 934, and 935).—The lower end of the ileum terminates by opening into the inner and back part of the large intestine, at the point of junction of the caecum with the colon. The opening is guarded by a valve, consisting of two semilunar segments, an upper or colic segment (*labium superius*) and a lower or caecal segment (*labium inferius*), which project into the lumen of the large intestine. The upper one, nearly horizontal in direction, is attached by its convex border to
the point of junction of the ileum with the colon; the lower segment which is more concave and longer, is attached to the point of junction of the ileum with the caecum. At each end of the aperture the two segments of the valve coalesce, and are continued as a narrow membranous ridge around the canal for a short distance. Each ridge is known as the retinaculum or frenulum of the valve (frenulum valvulae coli). The left or anterior end of the aperture is rounded; the right or posterior is narrow and pointed. In the formation of the valve the termination of the small intestine invaginates for a short distance into the lumen of the large intestine (Fig. 933), the invaginated portion of the wall of the small intestine uniting with a corresponding portion of the wall of the large intestine.

Each segment of the valve is formed by a reduplication of the mucous membrane and of the circular muscular fibres of the intestine, the longitudinal fibres and peritoneum being continued uninterruptedly across from one portion of the intestine to the other. When the longitudinal fibres and peritoneum are divided or removed, the ileum may be drawn outward, and all traces of the valve will be lost, the ileum appearing to open into the large intestine by a funnel-shaped orifice of large size.

The surface of each segment of the valve directed toward the ileum possesses villi, and presents the characteristic structure of the mucous membrane of the small intestine; while that turned toward the large intestine is destitute of villi, and marked with the orifices of the numerous tubular glands peculiar to the mucous membrane of the large intestine. These differences in structure continue as far as the free margins of the valve. When the caecum is distended it is supposed that the margins of the opening are approximated so as to prevent reflux into the ileum. It is known, however, that a very large enema which distends the caecum and colon may in part enter the ileum, being driven there by waves of reversed peristalsis. The valve resists, but a certain amount of pressure overcomes it. Some believe that the so-called ileo-caecal valve is not a valve, but a distinct sphincter. This has been demonstrated to be true in cats and dogs, but lacks demonstration in man (p. 1331).
The Colon.

The colon is divided into four parts—the ascending, transverse and descending colon, and the sigmoid flexure.

The Ascending Colon (colon ascendens).—The ascending colon is smaller than the caecum, with which it is continuous. It passes upward, from its commencement at the frenula of the caecum, opposite the ileo-caecal valve, to the under surface of the right lobe of the liver, on the right of the gall-bladder, where it is lodged in a shallow depression on the liver, the impressio colica; here it bends abruptly inward to the left, forming the hepatic flexure (flexura coli dextra). It is retained in contact with the posterior wall of the abdomen by the peritoneum, which covers its anterior surface and sides, its posterior surface being connected by loose areolar tissue with the Quadratus lumborum and Transversalis muscles, and with the front of the lower and outer part of the right kidney (Fig. 936). Sometimes the peritoneum almost completely invests it, and forms a distinct but short mesocolon1 (p. 1269). It is in relation, in front, with the convolutions of the ileum and the abdominal parietes.

The Transverse Colon (colon transversum) (Fig. 871).—The transverse colon, the longest part of the large intestine, passes transversely from right to left across the abdomen, opposite the confines of the epigastric and umbilical zones, into the left hypochondriac region, where it curves downward beneath the lower end of the spleen, forming the splenic flexure (flexura coli sinistra). In its course the transverse colon describes an arch, the concavity of which is directed backward toward the vertebral column and a little upward; hence the name transverse arch of the colon. This is the most movable part of the colon, being almost completely invested by peritoneum, and connected to the spine behind by a large and wide duplication of that membrane, the transverse mesocolon (Fig. 876). The transverse colon is in relation, by its upper surface with the liver and gall-bladder, the great curvature of the stomach, and the lower end of the spleen; by its under surface, with the small intestines; by its anterior surface, with the anterior layers of the great omentum and the abdominal parietes; its posterior surface on the right side is in relation with the second portion of the duodenum, and on the left side is in contact with some of the convolutions of the jejunum and ileum.

The Descending Colon (colon descendens).—The descending colon passes downward through the left hypochondriac and lumbar regions along the outer border of the left kidney. At the lower end of the kidney it turns inward toward the outer border of the Psoas muscle, along which it descends to the crest of the ilium, where it terminates in the sigmoid flexure. At its commencement it is connected with the Diaphragm by a fold of peritoneum, the phreno-colic ligament (see p. 1268). It is retained in position by the peritoneum, which covers its anterior surface and sides, its posterior surface being connected by areolar tissue with the outer border of the left kidney, and the Quadratus lumborum and Transversalis muscles (Fig. 876). It is smaller in calibre and more deeply placed than the ascending colon, and is more frequently covered with peritoneum on its posterior surface than the ascending colon (Treves).

The Sigmoid Flexure, Pelvic Colon or Sigmoid Colon (colon sigmoideum) (Figs. 937, 938, 939, and 940) is the narrowest part of the colon; it is situated in the left iliac fossa, commencing from the termination of the descending colon, at the margin of the crest of the ilium, and then forming a loop, which varies in length

---

1 Treves states that after a careful examination of one hundred subjects, he found that in fifty-two there was neither an ascending nor a descending mesocolon. In twenty-two there was a descending mesocolon, but no corresponding fold on the left side. In fourteen subjects there was a mesocolon to both the ascending and the descending segments of the bowel; while in the remaining twelve there was an ascending mesocolon, but no corresponding fold on the left side. It follows, therefore, that in performing lumbar colostomy a mesocolon may be expected on the left side in 36 per cent. of all cases, and on the right in 26 per cent. (The Anatomy of the Intestinal Canal and Peritoneum in Man, 1885, p. 55.)—En. of 15th English edition.
and position, and which terminates in the rectum at the level of the attachment of the mesentery upon the front of the third sacral vertebra. It passes downward about two inches parallel to the outer border of the Psoas muscle, then taking a transverse direction enters the cavity of the pelvis, crosses this cavity from left to right and a little upward to the lower margin of the right iliac fossa; "from this

Fig. 936.—Diagram of the relations of the large intestine and kidneys, from behind.
point it passes downward, backward, and inward along the anterior surface of the sacrum to its junction with the rectum." ^1 

It is surrounded with the peritoneum and is attached to the posterior abdominal wall by the *mesosigmoid*, a continuation of the mesocolon, but which greatly exceeds the latter in length, hence the sigmoid is the most mobile portion of the large intestine. Tuttle divides the sigmoid into four portions. The *first* or *vertical portion*; the *second* or *transverse portion*; the *third portion*, which is a loop and is concave upward if the sigmoid occupies the pelvis, and is concave downward if it occupies the abdomen; the *fourth portion*, which is curved irregularly in the hollow of the sacrum, and which joins the rectum as often from the right as from the left. When the sigmoid is lifted up and to the right and the mesosigmoid is put slightly upon the stretch, an opening is seen at the parietal border of the left

layer of the mesosigmoid. This opening leads into a *cul-de-sac*, the *intersigmoid fossa*. When the sigmoid is empty most of it falls into the recto-vesical or recto-

---

^1 Tuttle, Diseases of the Anus, Rectum, and Pelvic Colon.
vaginal space (Fig. 938). When distended it mounts up into the abdomen, reaching to or even above the umbilicus. The sigmoid flexure is in relation in front with the small intestine and abdominal parietes. The sigmoid mesocolon is attached to a line running downward and inward from the crest of the ilium, across the Psoas muscle (Fig. 876).

The Rectum (Intestinum Rectum) (Figs. 937, 938, 939, 940, 941, 942).

The rectum is the terminal part of the large intestine, and extends from the termination of the sigmoid flexure to the level of the semilunar valves of Mor-

![Diagram of the pelvis showing the rectum and related structures.](image)

**Fig. 939.—Sagittal section in the median line of the pelvis. (Poirier and Charpy.)**

gagni. The sigmoid flexure terminates at the level of the attachment of the mesentery in front of the third sacral vertebra. This definition is practical and useful. It was suggested by Sir Frederick Treves. "It gives to the organ definite limits; it separates the mobile from the immobile portion of the gut; it marks the line where the course of the blood-supply changes; it indicates the point where the three longitudinal muscular bands of the colon spread out and become more or less equally distributed around the gut; and, finally, it marks a point at which there is always a decided narrowing in calibre, indicating the juncture of the rectum with the pelvic colon." The old division added to this the so-called first part of the rectum, which we consider as part of the sigmoid colon. The rectum is divided into two portions, a superior and an inferior. The superior or sacrococcygeal portion of the rectum (flexura sacralis) curves downward with the concavity forward and upward in front of the sacrum and coccyx, and

---

1 A Treatise on Diseases of the Anus, Rectum, and Pelvic Colon. By James P. Tuttle.
is continued as far as the apex of the prostate gland, about an inch in front of the tip of the coccyx. The inferior or prostatic portion (flexura perinealis) begins at this point. The bowel is directed downward and backward, being convex in front, and terminates at the beginning of the anus at the level of the semilunar valves of Morgagni. The inferior or prostatic portion of the rectum is described by Symington as the anal canal.

Curves of the Rectum.—It will be seen, therefore, that the rectum presents two antero-posterior curves: the first, with its convexity backward, is due to the conformation of the sacro-coccygeal column, and represents the arc of a circle, the centre of which is opposite the third sacral vertebra. The lower one has its convexity forward, and is angular. Its centre corresponds to a line drawn between the anterior parts of the ischiāl tuberosities. Two lateral curves are also described: the one to the right, opposite the junction of the third and fourth sacral vertebrae; the other to the left, opposite the sacro-coccygeal articulation. They are of little importance.

The adult rectum as here described has a length of from four to six inches in men, and from three and five-eighths to five and one-eighth inches in women. According to Tuttle the length of the rectum depends to some degree on the size of the subject, and is somewhat greater in the old than in the young. The prostatic portion is the narrowest portion of the rectum. The widest part of the rectum is the ampulla recti just above the anal canal (Figs. 939 and 940). The prostatic portion has no peritoneal investment whatever and includes the lower two inches of the superior portion of the rectum. When the rectum is empty it is a mere slit, the anterior and posterior walls being in contact. When distended it is "irregularly cylindrical" (Tuttle). At and above the level of the third sacral vertebra the gut is entirely surrounded by peritoneum, and there is a mesosigmoid. This is the mesorectum of those who describe the lower pelvic colon as the first part of the rectum. At the level
of the third sacral vertebra the true rectum begins, and the true rectum has no meso-
rectum. The rectum is covered in front and laterally by peritoneum at its upper part; 
gradually the peritoneum leaves its sides, and about an inch above the prostate is re-
lected from the anterior surface of the bowel on to the posterior wall of the bladder in 
the male, and the upper fifth of the posterior wall of the vagina in the female, forming 
the recto-vesical or recto-vaginal pouch (ex-
cavatio rectovesicalis and excavatio rectoute-
rina), as the case may be (Fig. 866). The 
balance of the rectum has no peritoneal cov-
ering. The level at which the peritoneum 
leaves the anterior wall of the rectum to be 
reflected on to the viscus in front of it is of 
considerable importance from a surgical 
point of view, in connection with removal of the lower part of the rectum. It is 
higher in the male than in the female. In the former the height of the recto-
vesical pouch is about three inches; that is to say, the height to which an ordinary 
index finger can reach from the anus. In the female the height of the recto-
vaginal pouch is about two and a quarter inches from the anal orifice.

The upper or sacro-coccygeal portion of the rectum is in relation, in front, in 
the male, with the recto-vesical pouch, the triangular portion of the base of the 
bladder, the vesiculæ seminales, and vasa deferentia, and more anteriorly with 
the under surface of the prostate. In the female, with the posterior wall of 
the vagina below, and the recto-vaginal pouch above, in which are some convolutions 
of the small intestine (Fig. 940). To the sides below the peritoneal reflections, 
the rectum is surrounded by cellular tissue in which on each side lie the lateral 
sacral artery and the bifurcated hypogastric plexus. This portion of the rectum is 
separated from the sacrum and coccyx by an interval, the retro-rectal space, which 
is filled with cellular tissue. The superior portion of the distended rectum is in con-
tact posteriorly and on each side with the sacral plexus, ganglia of the sympathetic, 
and the fascial origin of the pyramidalis muscle (Tuttle). The lower or prostatic 
portion in men is in relation anteriorly with the prostate gland and the membranous 
urethra; in women with the posterior wall of the vagina. The lower end of the 
rectum takes a backward turn, and the uro-genital organs turn forward; the inter-
vening space is called the perineum. In the female, the fibro-fatty and muscular 
tissue which occupies this space is called the perineal body. The prostatic portion 
of the rectum is invested by the Internal sphincter, supported by the Levatores 
ani muscles, and surrounded at its termination by the External sphincter; in the 
empty condition it presents the appearance of a longitudinal slit. Posteriorly 
the lower part of the rectum is in contact with cellular tissue, which separates it 
from the coccygeal gland and the coccyx.

Supports of the Rectum.—The rectum as it has been described in these pages is a 
fixed tube. The upper portion of the rectum is supported by “the inferior mesen-
teric arteries and the fibrous sheaths which surround them” (Tuttle); by the per-
itoneal folds which attach it to the sacrum; and by the peritoneal folds which pass 
in front to the bladder (plicæ rectovesicales), or to the uterus (plicæ rectouterinae), 
and laterally to the pelvis. The middle of the rectum receives some support 
from the lateral sacral arteries and their fibrous sheaths. The lower portion of the 
rectum is supported by the Levator ani, External sphincter, and Recto-coccygeus 
muscles.
Blood-vessels and Lymphatics of Rectum.—See pp. 1328 and 1329.

Nerves of Rectum.—See p. 1329.

Structure of Rectum.—See p. 1324.

![Diagram of Rectal Valves](image1)

**Fig. 942.**—The anal canal and lower part of the rectum in the foetus. *A,* aged four to five months; *B,* six months; *C,* nine months. In each the anal canal is distinctly marked off from the rectum proper; the columns of Morgagni and the rectal valves are distinct. (Cunningham.)

The Common Anal Canal (*pars analis recti*) (Figs. 942 and 943).—The anal canal is the third portion of the rectum of the older descriptions. It begins where the true rectum ends. This canal is the portion of the intestinal tract which

![Diagram of Rectal Canal](image2)

is below the distribution of genuine mucous membrane, and is just posterior to the middle of a line drawn from one tuberosity to the other. It lies between the true skin and the upper borders of the semilunar valves of Morgagni. When at rest it is a mere slit placed antero-posteriorly. The external opening of the anal canal is the **anus**. The skin about the anus is pigmented, is thrown into radiating folds by the contraction of the External sphincter muscle, and contains hairs, sebaceous glands, and sudoriparous glands (*glandulae circumanales*). Ascending into the canal, it alters its character and becomes muco-cutaneous, and true mucous membrane appears at the rectum proper. Back of the anus is a median cutaneous fold passing posterior to the coccyx and called the **anal raphé**. In front of the anus is a median fold which, in the female, passes forward and merges with the labia major and in the male continues into the raphé of the serotum. This is called the **perineal raphé**. The length of the anal canal is three-quarters to one inch. "Its circumference varies from 3 cm. (one and three-sixteenths inches) in normal condition to 15 cm. (five and five-sixteenths inches) in disease, following injury or vicious practices. The average anus will admit a cylinder of 65 mm. in circumference without rupturing the mucous membrane."

Relations of the Anal Canal.—It is surrounded by the external and internal sphincter muscles, and above by the Levatores ani. To each side is the ischio-rectal fossa containing fat. Between the anal canal and the coccyx is a collection of muscular fibres and connective tissue, the ano-coccygeal body of Symington. In front, in the male, is the bulb of the urethra and the base of the triangular ligament; in the female, is the perineal body, which separates the anus from the vagina. There are three layers in the wall of the anal canal:

1. The muco-cutaneous layer, which contains glands, blood-vessels, and numerous nerve-endings. The lower portion is covered with pavement-epithelium, but gradually there is a transition, and at the beginning of the rectum proper the epithelium is entirely columnar. The valves of Morgagni, the anal valves or the semi-lunar valves (Figs. 943 and 944) are in the upper portion of the anal canal between the lower ends of the columns of Morgagni (Figs. 943 and 944). Above the valves the canal is lined by transitional mucous membrane, below them by modified skin.

The ano-rectal line is not straight, but is irregularly dentated by trivial elevations, each of which is papilliform at its summit. According to Tuttle, these elevations number from five to eight. About one-fifth of an inch below the ano-rectal line is the depression known as Hilton's white line (annulus haemorrhoidalis) (Fig. 944). This line is somewhat indistinct to sight, but can always be felt with the finger. It marks the junction of the External with the Internal sphincter. Above Hilton's line are some mucous crypts and also dilatations produced by the internal haemorrhoidal plexus of veins (Fig. 944).

2. The fibro-cellular layer is beneath the mucous membrane. Above Hilton's line it is composed of cellular tissue; below it is a thin fascia-like layer which joins the superficial fascia.

The anal canal is surrounded by longitudinal fibres from the rectum, fibres from the Levator ani, the lower portion of the Internal sphincter, and particularly by the External sphincter.

Blood-vessels, Lymphatics, and Nerves of Anus.—See pp. 1328 and 1329.

Structure of Large Intestine (including the Rectum and Anal Canal).—The large intestine has four coats—serous, muscular, areolar or submucous and mucous.

The Serous Coat (tunica serosa).—The serous coat is derived from the peritoneum, and invests the different portions of the large intestine to a variable extent. The caecum is completely covered by the serous membrane, except in a small percentage of cases (5 or 6 per cent.), where a small portion of the upper end of the posterior surface is uncovered. The ascending and descending colon are usually covered only in front and at the sides; a variable amount of the posterior surface is uncovered. The transverse colon is almost completely invested, the parts corresponding to the attachment of the great omentum and transverse mesocolon being alone excepted. The sigmoid flexure is completely surrounded, except along the line to which the sigmoid mesocolon is attached. The upper two-thirds of the rectum is covered in front and laterally by the peritoneum, but not posteriorly, between the two posterior folds of peritoneum, the so-called mesorectum; later it is covered only on its anterior surface; and the lower portion is entirely devoid of any serous covering. In the course of the colon the peritoneal coat is thrown into a number of small pouches filled with fat, called appendices epiploicae. They are chiefly appended to the transverse colon, and are particularly numerous along the anterior band.

The Muscular Coat (tunica muscularis).—The muscular coat consists of an external longitudinal and an internal circular layer of muscular fibres.

The Longitudinal Fibres, although found to a certain extent all around the intestine, do not form a uniform layer over the whole surface of the large intestine. In the caecum and colon they are especially collected into three flat longitudinal bands or taeniae (taeniae coli) (Figs. 923 and 924), each being about
half an inch in width. These bands commence at the base of the vermiform appendix, which structure is surrounded by a uniform layer of longitudinal muscular fibres. The bands pass from the base of the appendix to the rectum. At this point they broaden, fuse, and surround the rectum. On the ascending, descending, and sigmoid colon the mesocolic band (taenia mesocolica) is posterior and internal; the omental band (taenia omentalis) is posterior and external; the free band (taenia libera) is anterior. On the transverse colon the taenia libera is inferior; the taenia mesocolica is posterior; the taenia omentalis is anterior and superior. These bands are one-sixth shorter than the other coats of the intestine to which they are applied, and serve to produce the sacculi (Fig. 924), which are characteristic of the caecum and colon; accordingly, when they are dissected off, the tube can be lengthened, and its sacculated character becomes lost. The sacculations are called haustra coli. There are three rows of the sacculations separated from each other by the longitudinal bands. These pouches are also subdivided by transverse furrows which correspond to concave folds of mucous membrane, called semilunar folds (plecae semilunares coli). In the sigmoid flexure the longitudinal fibres become more scattered; but upon its lower part, and around the rectum, they spread out and form a layer which completely encircles this portion of the gut, but is thicker on the anterior and posterior surfaces, where two accentuations exist, than on the lateral surfaces. In the rectum the external fibres of the longitudinal layer descend and are inserted into the fascia covering the Levator ani muscle. The middle fibres are mingled with descending fibres of the Levator ani and terminate by attachment to the rectal wall. The internal fibres descend between the External and Internal sphincter muscles and are inserted into the superficial fascia around the anal margin. The lower part of the rectum is surrounded by the Levator ani muscle (p. 453). In addition to the muscular fibres of the bowels, two bands of plain muscular tissue are to be noted. They arise from the front of the second and third cecocygeal vertebræ, and pass downward and forward to blend with the longitudinal muscular fibres on the posterior wall of the rectum. Each is known as the rectococygeal muscle (m. rectococygeus).

The Circular Fibres form a thin layer over the caecum and colon, being especially accumulated in the intervals between the sacculi. In the rectum the circular fibres constitute a thick coat at some portions of the circumference and a thinner coat at others. The circular fibres are thickened at every flexure. The thickenings only partly surround the gut, and hence are not to be considered as additional sphincters. Tuttle calls them the semicircular muscles of the rectum. These semi-circular muscles are opposite the insertion of Houston’s valves. At the lower end of the rectum the circular fibres become very numerous and constitute the Internal sphincter muscle (m. sphincter ani internus) (Fig. 943). Tuttle describes it as follows: “This muscle, composed of an aggregation of circular fibres, begins about 4 cm. above the anal margin, and gradually increases in thickness until it reaches the ano-rectal line, after which it thins out again and disappears about the middle of the anal canal. Its width from above downward averages 1 to 3 cm. (three-fifths of an inch to one and one-fifth inches). Its thickness is so variable that no accurate measurement can be given. Its lower fibres are below and within the grasp of the External sphincter, from which it is separated by a narrow zone of connective tissue. A depressed zone, not always perceptible to the eye, but appreciable by digital touch, marks the line of division between these two muscles.”

The Internal sphincter is an involuntary muscle. The external sphincter muscle is not a portion of the wall of the bowel. It is described on pages 450 and 451.

The Areolar Coat or Submucous Coat (tela submucosa).—The areolar or submucous coat connects the muscular and mucous layers closely together. This coat

is thicker, looser, and more elastic in the rectum than elsewhere. In this coat are
the blood-vessels, nerves, and lymphatics.

The Mucous Membrane (tunica mucosa).—The mucous membrane, in the caecum
and colon, is pale, smooth, destitute of villi, and raised into numerous crescentic
folds which correspond to the intervals between the sacculi. In the rectum it is
thicker, of a darker color, more vascular, and connected loosely to the muscular
coat, as in the oesophagus.

The rectum contains certain horizontal folds. Most of them disappear when
the gut is distended, but some of them do not disappear, but remain as distinct
folds with free crescentic edges. These permanent folds were first described by
Houston, of Dublin, and are known as rectal valves or Houston's valves (plicae
transversales recti) (Figs. 941 and 942). Each fold surrounds more than one-
third of the gut, and is composed of mucous membrane, submucous tissue, and
a layer from the circular muscular layer of the gut. There may be three, four, or
five of these folds. Three of them are constant. One is on the right rectal wall,
about the point of peritoneal reflection; another is on the left side, about one
inch above the margin of the anal canal. A third is on the rectal wall, either
toward the right or left, at the point where the rectum joins the front of the
sigmoid. These shelf-like valves are not perfectly flat, for on the superior surface
of each is a depression.

The borders of a valve are thinner than its base and are very flexible. These
valves support the mass of feaces as it descends, and give to it a rotary motion
(Tuttle). In the lower end of the rectum the mucous membrane forms longi-
tudinal folds known as the columns of Morgagni or the rectal columns (columnae
rectales [Morgagni]) (Figs. 943 and 944). There are from five to ten of these
folds, each of which is about one-half an inch long, and they contain longitudinal
muscle-fibres. They are most prominent when the sphincter contracts. The base
of each column helps to form the upper margin of the anal canal. The outer angle
of each below passes into a similiar valve. The grooves between the columns are
shallow above and deeper below, and end in the semilunar valves. The semilunar
valves, valves of Morgagni or anal valves (Figs. 943 and 944) are folds
which stretch from the base of one column to another, and form the anal pockets
or crypts of Morgagni (sinus rectales). These pockets are about 5 mm. in depth.
They are most marked pos'teriorly (Ball), but none exists in either the anterior

been removed to show the dilatation of the veins and how they pass through the muscular wall to anastomose
with the external haemorrhoidal plexus. (Luschka.)**
or posterior commissure (Tuttle). Below the sinuses is the white line of Hilton (Fig. 944), which reaches to the region where hair and sebaceous glands appear.

As in the small intestine, the mucous membrane consists of a muscular layer, the muscularis mucosae (Fig. 948); of a quantity of retiform tissue in which the vessels ramify; of a basement-membrane and epithelium, which is of the columnar variety, and exactly resembles the epithelium found in the small intestine. In the rectum the epithelial cells are columnar; at the lower end of the tube, however, they begin to change into stratified polyhedrons and prisms. The mucous membrane of the large intestine presents for examination simple follicles and solitary glands.

The Simple Follicles, Intestinal Glands, Crypts or Glands of Lieberkühn (glandulae intestinales [Lieberkuhni]) (Fig. 948) are minute tubular prolongations of the mucous membrane arranged perpendicularly, side by side, over its entire surface; they are longer, more numerous, and are placed in much closer apposition than those of the small intestine; and they open by minute rounded orifices upon the surface, giving it a cribriform appearance.

The Solitary Glands (noduli lymphatici solitarii) (Fig. 948) in the large intestine are most abundant in the caecum and vermiform appendix, but are irregularly scattered also over the rest of the intestine. They are similar to those of the small intestine.

Vessels of the Large Intestine.—The arteries supplying the large intestine give off large branches, which ramify between the muscular coats supplying them, and, after dividing into small vessels in the submucous tissue, pass to the mucous membrane. The caecum, the appendix, and the ileo-caecal valve are supplied by the branches from the anastomotic loops between the right colic and ileo-colic branches of the superior mesenteric artery (Figs. 945 and 946). In males the sole blood-supply of the appendix is by the appendicular artery from the posterior ilio-caecal branch of the ileo-caecal artery (Fig. 946). In the female the appendix occasionally receives an additional vessel along the appendiculoo-ovarian ligament.
from the ovarian artery. The ascending colon is supplied by the right colic, and the transverse colon by the middle colic branch of the superior mesenteric. The descending colon is supplied by the left colic branch of the inferior mesenteric, and the sigmoid flexure by the sigmoid branches of the inferior mesenteric. The rectum (Fig. 947) is supplied mainly by the superior haemorrhoidal branch of the inferior mesenteric, but also at its lower end by the middle haemorrhoidal from the internal iliac, and the inferior haemorrhoidal from the pudic artery. The supe-

Fig. 946.—The arterial blood-supply of the anterior (ventral) surface of the caecum and appendix. A, ileocolic artery; B, caecal-appendicular artery; D, anterior caecal artery; F and G, appendicular artery. Note that the caecal and appendicular arteries anastomose by fine capillaries, both ventrally and dorsally; C, Iliac artery; 1, right colon; 2, external sacculus of caecum (to right of taeniae coli); 3, appendix; 4, Iliac, and 5, Psoas muscles. (Robinson.)
STRUCTURE OF THE LARGE INTESTINE AND RECTUM 1329

trunk, the superior haemorrhoidal vein, which empties into the inferior mesenteric branch of the portal vein. This arrangement is termed the haemorrhoidal plexus (Fig. 473); it communicates with the tributaries of the middle and inferior haemorrhoidal veins at its commencement, and thus a communication is established between the systemic and portal circulations. The inferior haemorrhoidal veins empty into the internal pudic veins, and the middle haemorrhoidal veins empty into the internal iliac veins.

The Lymphatics of the Large Intestine.—The lymphatics of the large intestine begin in the mucous membrane and form an extensive plexus in the submucosa. There are also lymphatics more deeply seated, beneath the simple follicles. Those from the ascending colon and transverse colon open into the glands within the mesocolon and behind the colon (mesocolic glands), from which glands trunks pass to the superior mesenteric glands. The lymphatics from the transverse colon join with lymph-vessels of the great omentum, and hence communicate with the lymphatics of the greater curvature of the stomach. The lymph from the descending colon, from the sigmoid and from the pelvic colon passes to the glands along the inferior mesenteric artery. The lymphatics of the rectum pass first to the rectal glands, which lie on the muscular coat of the rectum, next to the glands which lie back of the rectum along the superior haemorrhoidal artery, and finally to the sacral glands. Lymphatics from the skin of the anus pass with the lymphatics of the skin to the superficial inguinal glands. Lymphatics from the anus between the skin margin and Hilton's white line pass to the hypogastric glands.

The Nerves of the Anus and Rectum.—The nerves of the anus and rectum are derived from both the sympathetic and cerebro-spinal system. The chief supply of the rectum is from the mesenteric, sacral, and hypogastric plexuses of the sympathetic. It also obtains small branches from the third, fourth, and fifth sacral nerves. The lower part of the rectum is much more sensitive than the upper part. The muscles of the anus and rectum are supplied "from the intricate plexuses formed by the second, third, fourth, and fifth sacral nerves" (Tuttle).
External sphincter is supplied by nerves which contain motor, sensor, and sympathetic fibres. These nerves come from three sources. "Two filaments from the branches formed by the third, fourth, and fifth sacral nerves extend transversely across the ischio-rectal fossa and distribute themselves to the middle portion of the muscle and to the peri-anal cutaneous surface; a filament which comes off from the internal pudic just before its division into terminal branches supplies the anterior portion of the muscle, and is called the anterior sphincterian nerve; while a filament coming off from the fifth and sixth sacral nerves passes down into the hollow of the sacrum, between the Levator ani muscle and the rectococcygeus ligament, and finally reaches the posterior superficial surface of the External sphincter."1 The spinal centre for the nerves of the anus and rectum is opposite the first lumbar vertebra, and is in practically the same region as the centre for the genito-urinary organs.

**Fig. 948.—Minute structure of large intestine.**

**Movements and Innervation of the Intestines.**

**Movements.**—As the small intestine is devoid of any sphincter arrangement peristalsis cannot mix the food as it does in the pyloric portion of the stomach. The process by which the food is mixed with the secretions and is brought against the intestinal wall for absorption is called by Cannon "rhythmic segmentation." Rhythmic motions "mix the food and expose it to the mucosa without advancing it appreciatively along the canal."2 In this process constrictions occur in the circular fibres, with the result that a collection of stationary food is divided into a number of segments. In the middle of each segment constrictions appear and the earlier constrictions relax. Then the latter constrictions relax and the earlier reappear and so on until the food is thoroughly mixed with digestive secretions. Finally the food is driven on by peristalsis coming again to rest and being again subjected to "rhythmic segmentation." Cannon says that in the duodenum "rhythmic segmentation" lasts for several minutes, but in other parts of the intestine it may continue for half an hour or more, the food which is being subjected to it scarcely moving along the canal. It is probable that in man there are from seven to eight segmentations per minute in a given area. It is also probable that there is a sphincter action at the ileo-caecal opening.

Cannon divides the large intestine into two parts: a distal part, in which the material is hard and lumpy and is "advanced by rings of tonic contraction," and a proximal part, in which the material is soft. In this part "the common movements are waves of constriction running backward toward the caecum." The resistance of the valve or sphincter enables reversed peristalsis or antiperistalsis to mix the food. When more food enters from the small intestine, antiperistalsis ceases, tonic contraction of the caecum and proximal portion of the colon occurs, some of the food is merged into the transverse colon, and antiperistalsis again begins to act on what remains. The above facts have been observed in animals and are probably true in man.

**Innervation.**—The vagus fibres of the small intestine seem to excite contraction of the circular fibres after a brief preliminary period of inhibition.3 Some observers maintain that the

3 Bayliss and Starling, Journal of Physiology, 1899.
Surgical Anatomy of the Intestines

Splanchnic fibres are inhibitory, but others claim that they are also motor. The local reflex of the small intestine is in Auerbach's plexus. Cannon quotes Bayliss and Starling to the effect that the pelvic visceral nerves to the large intestine, "arising like the vagus from the central nerve system, are augmentary nerves, whereas the supply from the sympathetic system is purely inhibitory in its action."

It is further contended that the pelvic visceral nerves are distributed to the distal colon only. "The region of antiperistalsis does not, therefore, receive motor impulses from the pelvic nerves."

**Surface Form.**—The coils of the small intestine occupy the front of the abdomen below the transverse colon, and are covered more or less completely by the great omentum. For the most part the coils of the jejunum occupy the left side of the abdominal cavity—i.e., the left lumbar and inguinal regions and the left half of the umbilical region—whilst the coils of the ileum are situated to the right, in the right lumbar and inguinal regions, in the right half of the umbilical region, and also in the hypogastric region. The caecum is situated in the right inguinal region. Its position varies slightly, but the mid-point of a line drawn from the anterior superior spinous process of the ilium to the symphysis pubis will about mark the middle of its lower border. It is comparatively superficial. From it the ascending colon passes upward through the right lumbar and hypochondriac regions, and becomes more deeply situated as it ascends to the hepatic flexure, which is deeply placed under cover of the liver. The transverse colon crosses the belly transversely on the confines of the umbilical and epigastric regions, its lower border being on a level slightly above the umbilicus, its upper border just below the greater curvature of the stomach. The splenic flexure of the colon is situated behind the stomach in the left hypochondrium, and is on a higher level than the hepatic flexure. The descending colon is deeply seated, passing down through the left hypochondriac and lumbar regions to the sigmoid flexure, which is situated in the left inguinal region, and which can be felt in thin persons, with relaxed abdominal walls, rolling under the fingers when empty, and when distended forming a distinct bulge. The usual position of the base of the vermiform appendix is indicated by a point on the cutaneous surface two inches from the anterior superior spinous process of the ilium, on a line drawn from this process to the umbilicus. This is known as *McBurney's point.* Another mode of defining the position of the base of the appendix is to draw a line between the anterior superior spines of the ilia and marking the point where this line intersects the right seminal line.

Upon introducing the finger into the rectum, the membranous portion of the urethra can be felt, if an instrument has been introduced into the bladder, exactly in the middle line; behind this the prostate gland can be recognized by its shape and hardness and any enlargement detected; behind the prostate the fluctuating wall of the bladder when full can be felt, and if thought desirable it can be tapped in this situation; on either side and behind the prostate the vesical seminales can be readily felt, especially if enlarged by tuberculous disease. Behind, the coccyx is to be felt, and on the mucous membrane one or two of Houston's folds. The ischiorectal fossae can be explored on either side, with a view to ascertaining the presence of deep-seated collections of pus. Finally, it will be noted that the finger is firmly gripped by the sphincter for about an inch up the bowel. By gradual dilatation of the sphincter, the whole hand can be introduced into the rectum so as to reach the descending colon. This method of exploration is not at the present day employed for diagnostic purposes.

**Surgical Anatomy.**—The small intestine is much exposed to injury, but, in consequence of its elasticity and the ease with which one fold glides over another, it is not so frequently ruptured as would otherwise be the case. Any part of the small intestine may be ruptured, but probably the most common situation is the transverse duodenum, on account of its being more fixed than other portions of the bowel, and because it is situated in front of the bodies of the vertebrae, so that if this portion of the intestine is struck a sharp blow, as from the kick of a horse, it is unable to glide out of the way, but is compressed against the bone and lacerated. Wounds of the intestine sometimes occur. If the wound is a small puncture, under, it is said, three lines in length, there may be no extravasation of the contents of the bowel. The mucous membrane becomes everted and perhaps plugs the little opening. The bowels, therefore, may be punctured with a fine capillary trocar, in cases of excessive distention of the intestine with gas, without much danger of extravasation. A longitudinal wound gaping more than a transverse wound, owing to the greater thickness of the circular muscular coat. In closing a wound of the intestine, use Lambert's inversion sutures, which bring the peritoneal surfaces in contact. Halsted showed us that these sutures must include the tough submucous coat. The portions of intestine which lie in the pelvis are inflamed in pelvic peritonitis and become embedded in adhesions. The portions of intestine which may be present are the termination of the ileum, the portion of small intestine with the largest mesentery (Treves), the rectum, and the pelvic colon. The small intestine, and most frequently the ileum, may become strangulated by internal bands, or through apertures, normal or abnormal. The bands may be formed in several different ways: they may be old peritoneal adhesions from previous attacks of peritonitis; or adherent omentum from the same cause; or the band may be formed by Meckel's diverticulum, which has contracted adhesions at its distal extremity; or the band may be the result of the abnormal attachment of some normal structure, as the adhesion of two appendices epiploicae, or an adherent vermiform appendix or...
Fallopian tube. Intussusception or invagination of the small intestine may take place in any part of the jejunum and ileum, but the most frequent situation is at the ileo-caecal valve, the valve forming the apex of the entering tube. This form may attain great size, and it is not uncommon in these cases to find the valve projecting from the anus. Stricture, the impaction of foreign bodies, and twisting of the gut (volvulus) may lead to intestinal obstruction. Volvulus is most common in the sigmoid flexure. Meckel's diverticulum may itself become twisted and strangulated.

Resection of a portion of the intestine may be required in cases of gangrenous gut; in cases of intussusception; for the removal of new growth in the bowel; in dealing with artificial anus; and in the treatment of cases of rupture. The operation is termed enterectomy, and is performed as follows: the abdomen having been opened and the amount of bowel requiring removal having been determined upon, the gut must be clamped on either side of this portion in order to prevent the escape of any of the contents of the bowel during the operation. The portion of bowel is then separated above and below by means of scissors. If the portion removed is small, it may be simply removed from the mesentery at its attachment and the bleeding vessels tied; but if it is large, it will be necessary to remove also a triangular piece of the mesentery, and having secured the vessels, suture the cut edges of this structure together. The surgeon then proceeds to unite the cut ends of the bowel together. He may do it by the operation termed end-to-end anastomosis. There are many ways of doing this, which may be divided into two classes: one, where the anastomosis is made by means of some mechanical appliance, such as Murphy's button, or one of the forms of decalcified bone bobbins; and the other, where the operation is performed by simply suturing the ends of the bowel in such a manner that the peritoneum covering the free divided ends of the bowel is brought into contact, so that speedy union may ensue.

In some cases after resection each open end of the gut is closed, the side of the terminal portion is sutured to the side of the initial portion, a fistula is made in each, and the suturing is completed so as to cause the two fistulae to correspond. A permanent side-to-side opening is thus made. Lateral anastomosis without resection may be practised between two pieces of intestine, in order to side-track an intervening portion, which is the seat of malignant disease or of an artificial anus. Complete exclusion of a portion of intestine is performed for irreremovable tumors or persistent fistulae of the large intestine. The intestine is cut through above and below the diseased area and the ends of the healthy gut are united to each other, or the larger end is closed, an opening is made into the side of the larger end and the smaller end is implanted in it (lateral implantation). The two ends of the excluded portion are fastened to the skin and are left open.

In ascites resulting from cirrhosis of the liver benefit occasionally follows the performance of Talma's operation (epiplenectomy). The abdomen is opened and the omentum is sutured to the anterior abdominal wall or in the abdominal wound in the hope of establishing a more free communication between the portal and systemic circulations, thus lowering portal pressure.

External hernia is considered on page 1333.

By the term internal hernia, we mean hernia into the foramen of Winslow, into the retro-duodenal fossa, into the retro-caecal fossa, or into the intersigmoid fossa. Such a hernia produces the symptoms of acute strangulation of the intestine.

In typhoid fever there is ulceration of Peyer's patches. One of these ulcers may perforate. The only chance for life is immediate laparotomy and closure of the perforation. This saves one-fifth, or possibly one-third, of the cases. The incision is made to expose the lower ileum, as in the vast majority of cases the perforation is in this portion of the gut.

Ulcer of the duodenum is more common than used to be thought. The portion of the duodenum between the pylorus and the bile papilla is about four inches in length, and is called by the Mayo brothers the vestibule of the duodenum. Here the acid gastric juice enters and may produce an ulcer. The portion of the duodenum below the vestibule is not liable to ulcer, because it is protected by the alkaline bile and pancreatic juice.

A duodenal ulcer may perforate a large duodenal vessel and cause death from hemorrhage, or may perforate the intestine and produce septic peritonitis. A perforated ulcer is treated by laparotomy and closure of the perforation. Occasionally ulceration of the duodenal glands (Curling's ulcer) may occur in cases of burns, but is not a very common complication.

The veriform appendix is very liable to become inflamed, the condition being known as appendicitis. This condition may be set up by a catarrhal inflammation arising in the appendix, or derived from the colon. It may remain catarrhal and then subside. It may become purulent or may be purulent from the beginning. Anything which lessens vital resistance makes the appendix a ready prey to bacteria. Among causes which lessen resistance are febrile concretions, twists of the mesoappendix cutting off the blood-supply, bruises inflicted by the Psoas muscle (Byron Robinson), blocking of the outlet of the appendix by catarrhal exudate, concretions, proliferated lymphoid tissue, or adhesions. Appendicitis may arise by the appendix becoming twisted, owing to the shortness of its mesentery, in consequence of distention of the caecum. As the result of inflammation, its blood-supply, which is mainly through one large artery running in the mesoappendix, becomes interfered with. Again, in rarer cases, the inflammation is set up by the impaction of a solid mass of feces or a foreign body in the appendix. The inflammation
Surgical Anatomy of the Intestines

may result in ulceration and perforation, or in gangrene of the appendix the appendix may be blocked and full of pus, or abscess may form outside of it (appendicular abscess). These conditions require prompt operative interference, and in cases of recurrent attacks of appendicitis it is advisable to remove this diverticulum between the attacks. In external hernia the ilium is the portion of the bowel most frequently herniated. When a part of the large intestine is involved, it is usually the cæcum, and this may occur even on the left side. In some few cases the vermiform appendix has been the part implicated in cases of strangulated hernia, and has given rise to serious symptoms of obstruction. The diameter of the large intestine gradually diminishes from the cæcum, which has the greatest diameter of any part of the bowel, to the point of junction of the sigmoid flexure with the rectum, at or a little below which point stricture most commonly occurs and diminishes in frequency as one proceeds upward to the cæcum. When distended by some obstruction low down, the outline of the large intestine can be defined throughout nearly the whole of its course—all, in fact, except the hepatic and splenic flexures, which are more deeply placed; the distention is most obvious in the two flanks and on the front of the abdomen just above the umbilicus. The cæcum, however, is that portion of the bowel which is, of all, most distended. It sometimes assumes enormous dimensions, and has been known to give way from the distention, causing fatal peritonitis. The hepatic flexure and the right extremity of the transverse colon are in close relationship with the liver, and abscess of this viscus sometimes bursts into the gut in this situation. The gall-bladder may become adherent to the colon, and gall-stones may find their way through into the gut, where they may become impacted or may be discharged per anum. The mobility of the sigmoid flexure renders it more liable to become the seat of a volvulus or twist than any other part of the intestine. It generally occurs in patients who have been the subjects of habitual constipation, and in whom, therefore, the mesosigmoid is elongated. The gut at this part being loaded with faeces, from its weight falls over the gut below, and so gives rise to the twist.

The surgical anatomy of the rectum is of considerable importance. There may be congenital malformation due to arrest or imperfect development. Thus, there may be no invagination of the epiblast, and consequently a complete absence of the anus; or the hind-gut may be imperfectly developed, and there may be an absence of the rectum, though the anus is developed; or the invagination of the epiblast may not communicate with the termination of the hind-gut from want of solution of continuity in the septum which in early fetal life exists between the two. The mucous membrane is thick and but loosely connected to the muscular coat beneath and thus favors prolapse, especially in children. The vessels of the rectum are arranged as mentioned above, longitudinally, and are contained in the loose cellular tissue between the mucous and muscular coats, and receive no support from surrounding tissues; and this favors varicosity. Moreover, the veins, after running upward in a longitudinal direction for about five inches in the submucous tissue, pierce the muscular coats, and are liable to become constricted at this point by the contraction of the muscular wall of the gut. In addition to this there are no valves in the superior hemorrhoidal veins, and the vessels of the rectum are placed in a dependent position, and are liable to be pressed upon and obstructed by hardened faeces. The anatomical arrangement, therefore, of the hemorrhoidal vessels explains the great tendency to the occurrence of piles. The presence of the Sphincter ani is of surgical importance, since it is the constant contraction of this muscle which prevents an ischio-rectal abscess from healing and tends to cause a fistula. Also, the reflex contraction of this muscle is the cause of the severe pain complained of in fissure of the anus. The relations of the peritoneum to the rectum are of importance in connection with the operation of removal of the lower end of the rectum for malignant disease. The membrane gradually leaves the rectum as it descends into the pelvis; first leaving its posterior surface, then the sides, and then the anterior surface to become reflected in the male on to the posterior wall of the bladder, forming the recto-vesical pouch, and in the female on to the posterior wall of the vagina, forming Douglas's pouch. The recto-vesical pouch of peritoneum extends to within three inches from the anus, so that it is not desirable to remove more than two and a half inches of the entire circumference of the bowel, for fear of the risk of opening the peritoneum. When, however, the disease is confined to the posterior surface of the rectum, or extends farther in this direction, a greater amount of the posterior wall of the gut may be removed, as the peritoneum does not extend on this surface to a lower level than five inches from the margin of the anus. The recto-vaginal or Douglas's pouch in the female extends somewhat lower than the recto-vesical pouch of the male, and therefore it is advisable to remove a less length of the tube in this sex. Of recent years, however, much more extensive operations have been done for the removal of cancer of the rectum, and in these the peritoneal cavity has necessarily been opened. If, in these cases, the opening is plugged with iodoform gauze until the operation is completed and then the edges of the wound in the peritoneum is accurately brought together with sutures, no evil result appears to follow. For cases of cancer of the rectum which are too low to be reached by abdominal section, and too high to be removed by the ordinary operation from below, Kraske has devised an operation which goes by his name. The patient is placed on his right side and an incision is made from the second sacral spine to the anus. The soft parts are now separated from the back of the left side of the sacrum as far as its left margin, and the greater and lesser sacro-sciatic liga-
ments are divided. A portion of the lateral mass of the sacrum, commencing on the left border at the level of the third posterior sacral foramen, and running downward and inward through the fourth foramen to the cornu, is now cut away with a chisel. The left side of the wound being now forcibly drawn outward, the whole of the rectum is brought into view, and the diseased portion can be removed, leaving the anal portions of the gut, if healthy. The two divided ends of the gut can perhaps then be approximated and sutured together. Kraske's operation is in many cases preceded by the performance of iliac colostomy. In cancer high up in the rectum removal of the growth through the abdomen is sometimes practised, the divided lower end of the rectum being sutured to the divided upper end (Weir's operation).

The colon frequently requires opening in cases of intestinal obstruction, and by some surgeons this operation is performed in cases of cancer of the rectum, as soon as the disease is recognized, in the hope that the rate of growth may be retarded by removing the irritation produced by the passage of fecal matter over the diseased surface. The operation of colostomy may be performed either in the inguinal or lumbar region; but inguinal colostomy (Maydl's operation) has at the present day superseded the lumbar operation. The main reason for preferring this operation is that a spur-shaped process can be formed which prevents any fecal matter finding its way past the artificial anus and becoming lodged on the diseased structures below. The sigmoid flexure being surrounded by peritoneum, a coil can be drawn out of the wound, and when it is opened transversely a spur is formed, and this prevents any fecal matter finding its way from the gut above the opening into that below. The operation is performed by making an incision two or three inches in length from a point one inch internal to the anterior superior spinous process of the ilium, parallel to Poupart's ligament. The various layers of abdominal muscles are cut through, and the peritoneum opened and sewed to the external skin. The sigmoid flexure is now sought for, and pulled out of the wound and fixed by pushing a glass bar through a slit in the mesocolon. The two parts of the loop are sutured together. The intestine is now sutured to the parietal peritoneum. The wound is dressed, and either immediately or between the second to the fourth day, according to the requirements of the case, the protruded coil of intestine is opened. It is opened transversely with the Paquelin cautery.

THE LIVER (HEPAR) (Figs. 949, 950, 951, 952).

The liver is the largest gland in the body, and is situated in the upper and right part of the abdominal cavity, occupying almost the whole of the right hypochondrium, the greater part of the epigastrium, and extending into the left hypochondrium as far as the mammary line. In the male it weighs from fifty to sixty ounces; in the female, from forty to fifty. It is relatively much larger in the foetus than in the adult, constituting, in the former, about one-eighteenth, and in the latter, about one-thirty-sixth of the entire body-weight. Its greatest transverse-
measurement is from eight to nine inches. Vertically, near its lateral or right surface, it measures about six or seven inches, while its greatest antero-posterior diameter is on a level with the upper end of the right kidney and is from four to five inches. Opposite the vertebral column its measurement from before backward is reduced to about three inches. Its consistence is that of a soft solid; it is,
however, friable and easily lacerated; its color is a dark reddish-brown, and its specific gravity is 1.05.

To obtain a correct idea of its shape, it must be hardened in situ, and it will then be seen to present the appearance of a wedge, the base of which is directed to the right and the thin edge toward the left. Symington describes its shape as that “of a right-angled triangular prism with the right angles rounded off.” It possesses five surfaces, viz., a superior, inferior, anterior, posterior, and a right lateral surface.

The superior and anterior surfaces are separated from each other by a thick rounded border, and are attached to the Diaphragm and anterior abdominal wall by a triangular or falciform fold of peritoneum, the suspensory or falciform ligament, which divides the liver into two unequal parts, termed the right and left lobes (Figs. 949, 953, and 954). Except along the line of attachment of this ligament to the liver, the superior and anterior surfaces are covered by peritoneum.

The Superior Area or Surface (facies superior) (Fig. 949).—The superior area or surface comprises a part of both lobes. Spalteholz considers as parts of the superior surface the right surface and the anterior surface. The superior surface is convex, and fits under the vault of the Diaphragm; its central part, however, presents a shallow depression, the cardiac depression (impressio cardiaca), which corresponds with the position of the heart on the upper surface of the Diaphragm. It is separated from the anterior, posterior, and lateral surfaces by thick, rounded borders. Its left extremity is continued into the under surface by a prominent sharp margin.

The Anterior Area or Surface.—The anterior area or surface is large and triangular in shape, comprising also a part of both lobes. It is directed forward, and the greater part of it is in contact with the Diaphragm, which separates it from the right lower ribs and their cartilages. In the middle line it lies behind the ensiform cartilage, to the left of which it is protected by the seventh and eighth left costal cartilages. In the angle between the diverging rib cartilages of opposite sides the anterior surface is in contact with the abdominal wall. It is continuous with the inferior surface by a sharp margin, and with the superior and lateral surfaces by thick rounded borders.

The Lateral Right Area or Surface (Figs. 949 and 951).—The lateral or right area or surface is convex from before backward and slightly so from above downward. It is directed toward the right side, forming the base of the wedge, and lies against the lateral portion of the Diaphragm, which separates it from the lower part of the left pleura and lung, outside which are the right costal arches from the seventh to the eleventh inclusive.

The Under or Visceral Area or Surface (facies inferior) (Figs. 951 and 952).—The under or visceral area or surface is uneven, concave, directed downward and backward and to the left, and is in relation with the stomach and duodenum, the hepatic flexure of the colon, and the right kidney. The surface is divided by a longitudinal fissure into a right and a left lobe, and is almost completely invested by peritoneum; the only parts where this covering is absent are where the gall-bladder is attached to the liver and at the transverse fissure, where the two layers of the lesser omentum are separated from each other by the blood-vessels and duct of the vices. The under surface of the left lobe presents to the right and near the centre a rounded eminence, the omental tuberosity (tuber omentale) (Fig. 951), which is in contact with the lesser omentum. It is surrounded by a broad depression, the gastric surface or impression (impressio gastrica), with which the stomach is in contact. Between the gall-bladder and the left lobe is the quadrate lobe. The quadrate lobe is bounded to the left by the umbilical fissure or the fissure of the umbilical vein (fossa venae umbilicus), which is the anterior portion of the longitudinal fissure and lodges the round ligament. The under surface of the right lobe is divided into two unequal portions by a fossa, which lodges the
gall-bladder and is called the fossa vesicalis (fossa-vesicae felleae); the portion to the left, the smaller of the two, is somewhat oblong in shape, its antero-posterior diameter being greater than its transverse. It is known as the quadrate lobe, and is in relation with the pyloric end of the stomach (impressio pylorica) and the first portion of the duodenum. The portion of the under surface of the right lobe to the right of the fossa vesicalis presents two shallow concave impressions, one situated behind the other, the two being separated by a ridge. The anterior of these two impressions, the colic impression (impressio colica), is produced by the hepatic flexure of the colon; the posterior, the renal impression (impressio renalis), is occupied by the upper end of the right kidney (Fig. 951). To the inner side of the latter impression is a third and slightly marked impression, lying between it and the neck of the gall-bladder. This is caused by the second portion of the duodenum, and is known as the duodenal impression (impressio duodenalis). Just in front of the postcava is a narrow strip of liver tissue, the caudate lobe, which connects the right inferior angle of the Spigelian lobe to the under surface of the right lobe. Immediately below it is the fornmen of Winslow.

The Posterior Area or Surface (facies posterior) (Figs. 950 and 952).—The posterior area or surface is rounded and broad behind the right lobe, but narrow on the left. Over a large part of its extent it is not covered by peritoneum; this uncovered area (Fig. 951) is about three inches broad, and is in direct contact with the Diaphragm, being united to it by areolar tissue. In this tissue are numerous small veins which join the portal circulation to the systemic circulation. The uncovered area is marked off from the upper surface by the line of reflection of the upper or anterior layer of the coronary ligament. It is in the same way marked off from the under surface of the liver by the line of reflection of the lower layer of the coronary ligament (Fig. 953). In its centre the posterior surface is deeply notched for the vertebral column and crura of the Diaphragm, and to the right of this is indented for the postcava, which is often partly embedded in its substance. Close to the right of this indentation and immediately above the renal impression is a small triangular depressed area, the suprarenal impression (impressio suprarenalis) (Fig. 951), the greater part of which is devoid of peritoneum; it lodges the right suprarenal capsule, which is inserted between the liver and Diaphragm. To the left of the fossa for the postcava is the Spigelian lobe, which lies between the fissure for the postcava and the fissure for the ductus venosus. Below and in front it projects and forms part of the posterior boundary of the transverse fissure. Here, to the right, it is connected with the under surface of the right lobe of the liver by the caudate lobe, and to the left it presents a tubercle, the tuberculum papillare (Fig. 951). It is opposite the tenth and eleventh thoracic vertebrae, and rests upon the aorta and crura of the Diaphragm, being covered by the peritoneum of the lesser sac. The lobe is nearly vertical in position, and is directed backward; it is longer from above downward than from side to side, and is somewhat concave in the transverse direction. On the posterior surface to the left of the Spigelian lobe is a groove, the oesophageal groove (impressio oesophagea), indicating the position of the abdominal portion of the oesophagus (Fig. 951).

Prof. Cunningham divides the liver into two surfaces, a visceral and a parietal, and subdivides the parietal surface into a posterior area and superior area, an anterior area and a right area. The parietal surface is separated from the visceral surface by the inferior border or margin.

The inferior border or margin (margo inferioris), posteriorly, is rather ill defined. It is the lower margin of the posterior surface; it follows the line of rib and is in contact with the right kidney. At the right side the lower margin is thick and distinct, and, as a rule, projects slightly below the thorax. The front of the inferior margin is called the anterior margin (margo anterior). It is a sharp edge which, on inspiration, corresponds to an oblique line on the abdominal wall.
THE ORGANS OF DIGESTION

drawn from “a point half an inch below the margin of the ribs (tip of tenth costal cartilage), on the right side, to a point an inch below the nipple on the left, and extending down in the middle line to a point half-way between the gladiolus and the umbilicus.”

In men the anterior margin of the liver often corresponds to the lower margin of the ribs, but in women and children it is usually below the ribs in the line indicated above. Opposite the attachment of the falciform ligament the anterior border often exhibits a deep notch, the umbilical notch (incisura umbilicalis), which is the anterior end of the fossa venae umbilicalis. Another notch, sometimes present, corresponds to the fundus of the gall-bladder, and is known as the notch of the gall-bladder (incisura vesicae felleae).

The left extremity of the inferior margin of the liver is thin and flattened from above downward. The margin passes posteriorly around the free end of the left lobe and terminates posteriorly at the oesophageal groove.

Fissures.—Five fissures are seen upon the under and posterior surfaces of the liver, which serve to divide it into five lobes. They are: the umbilical fissure, the fissure of the ductus venosus, the transverse fissure, the fissure for the gall-bladder, and the fissure for the postcava. They are arranged in the form of the letter H. The left limb of the H is known as the longitudinal fissure. The right limb is formed in front by the fissure for the gall-bladder, and behind by the fissure for the postcava; these two fissures are separated from each other by the caudate lobe. The connecting bar of the H is the transverse or portal fissure. It separates the quadrato lobe in front from the caudate and Spigelian lobes behind.

The Longitudinal Fossa or Fissure (fossa longitudinalis sinistra).—The longitudinal fissure is a deep groove, which extends from the notch on the anterior margin of the liver to the upper border of the posterior surface of the organ. It separates the right and left lobes; the transverse fissure (Fig. 951) joins it, at right angles, and divides it into two parts. The anterior part is called the umbilical fossa or fissure (fossa venae umbilicalis) (Fig. 951); it is deeper than the posterior, and lodges the umbilical vein in the foetus, and its remains (the round ligament) in the adult; the posterior part contains the ductus venosus, and is known as the fissure of the ductus venosus. This fissure lies between the quadrate lobe and the left lobe of the liver, and is often partially bridged over by prolongation of the hepatic substance, the pons hepatis.

1 Ambrose Birmingham, in Cunningham’s Text-book of Anatomy.
The Fissure or Fossa of the Ductus Venosus (fossa ductus venosi) (Fig. 951) is the back part of the longitudinal fissure, and is situated mainly on the posterior surface of the liver. It lies between the left lobe and the lobe of Spigelius. It lodges in the foetus the ductus venosus, and in the adult a slender fibrous cord, the obliterated remains of that vessel.

The Transverse or Portal Fissure (porta hepatis) (Fig. 951).—The transverse or portal fissure is a short but deep fissure, about two inches in length, extending transversely across the under surface of the left portion of the right lobe, nearer to its posterior surface than its anterior border. It joins, nearly at right angles, with the longitudinal fissure, and separates the quadrate lobe in front from the caudate and Spigelian lobes behind. By the older anatomists this fissure was considered the gateway (porta) of the liver; hence the large vein which enters at this fissure was called the portal vein (Fig. 952). Besides this vein, the fissure transmits the hepatic artery and nerves, and the hepatic duct and lymphatics. At their entrance into the fissure, the hepatic duct lies in front and to the right, the hepatic artery to the left, and the portal vein behind and between the duct and artery.

The Fossa or Fissure for the Gall-bladder (fossa vesicae felleae).—The fossa or fissure for the gall-bladder is a shallow, oblong fossa, placed on the under surface of the right lobe, parallel with the longitudinal fissure. It extends from the anterior free margin of the liver, which is notched for its reception, to the right extremity of the transverse fissure.

The Fissure or Fossa for the Postcava (fossa venae cavae) (Fig. 951).—The fissure or fossa for the postcava is a short, deep fissure, in some cases a complete canal, in consequence of the substance of the liver occasionally surrounding the postcava. It extends obliquely upward from the lobus caudatus, which separates it from the transverse fissure, on the posterior surface of the liver, and separates the Spigelian from the right lobe. On slitting open the postcava the orifices of the hepatic veins will be seen opening into this vessel at its upper part, after perforating the floor of this fissure.

Lobes.—The lobes of the liver, like the ligaments and fissures, are five in number—the right lobe, the left lobe, the lobus quadratus, the lobus Spigelli, and the lobus caudatus, the last three being merely parts of the right lobe.
The Right Lobe (lobus hepatis dexter) (Figs. 949 and 951).—The right lobe is much larger than the left; the proportion between them being as six to one. It occupies the right hypochondrium, and is separated from the left lobe, on its upper and anterior surfaces by the falciform ligament; on its under and posterior surfaces by the longitudinal fissure; and in front by the umbilical notch. It is of a somewhat quadrilateral form, its under and posterior surfaces being marked by three fissures—the transverse fissure, the fissure for the gall-bladder, and the fissure for the postcava, which separate its left part into three smaller lobes—the lobus Spigelii, lobus quadratus, and lobus caudatus. On it are seen four shallow impressions: one in front, for the hepatic flexure of the colon; a second behind, for the right kidney; a third internal, between the last-named and the gall-bladder, for the second part of the duodenum; and a fourth on its posterior surface, for the suprarenal capsule.

The Lobus Quadratus or Square Lobe (Figs. 951 and 952) is situated on the under surface of the right lobe, is bounded in front by the inferior margin of the liver; behind, by the transverse fissure; on the right, by the fissure of the gall-bladder; on the left, by the umbilical fissure.

The Lobus Spigelii (lobus caudatus [Spigelii]) (Figs. 951 and 952) is situated upon the posterior surface of the right lobe of the liver. It looks directly backward, and is nearly vertical in direction. It is bounded, above, by the upper layer of the coronary ligament; below, by the transverse fissure; on the right, by the fissure for the postcava; and on the left, by the fissure for the ductus venosus. Its left upper angle forms part of the groove for the oesophagus. What is here called the lobus Spigelii, Spalteholz calls the lobus caudatus of Spigelius.

The Lobus Caudatus or Tuberculum Caudatum (processus caudatus) (Fig. 951), or tailed lobe, is a small elevation of the hepatic substance extending obliquely outward, from the lower extremity of the Spigelian lobe to the under surface of the right lobe. It is situated behind the transverse fissure, and separates the fissure for the gall-bladder from the commencement of the fissure for the postcava. What is here called the lobus caudatus, Spalteholz calls the processus caudatus of the lobus caudatus of Spigelius.

The Left Lobe (lobus hepatis sinister) (Figs. 949 and 951).—The left lobe is smaller and more flattened than the right. It is situated in the epigastric and left hypochondriac regions. Its upper surface is slightly convex; its under surface is concave, and presents a shallow depression for the stomach, the gastric impression. This is situated in front of the groove for the oesophagus, and is separated from the longitudinal fissure by the omental tuberosity, which lies against the small omentum and lesser curvature of the stomach. The posterior end of the left lobe frequently exhibits a flat projection, composed of connective tissue, and called the appendix fibrosus hepatitis. In the adult, portions only of bile-duets are present in it. In the newborn it is a definite portion of secreting liver substance, which later undergoes connective-tissue transformation.

Ligaments.—The liver is connected to the under surface of the Diaphragm and the anterior walls of the abdomen and the postcava by six ligaments, four of which are peritoneal folds; the other two, which are the round ligament and the ligament of the ductus venosus, are fibrous cords, resulting from the obliteration of foetal vessels. These ligaments are the falciform, two lateral, coronary, round, and the ligament of the ductus venosus. It is also attached to the lesser curvature of the stomach by the gastro-hepatic or small omentum.

The Falciform, Broad or Suspensory Ligament (ligamentum falciforme hepatitis) (Figs. 949, 953, and 954).—The falciform or suspensory ligament is a broad and thin antero-posterior peritoneal fold, falciform in shape, its base being directed downward and backward, its apex upward and backward. It is attached by one margin to the under surface of the Diaphragm, and the posterior surface of the
sheath of the right Rectus muscle to within one inch of the umbilicus; by its hepatic margin it extends from the notch on the anterior margin of the liver, as far back as its posterior surface.

The free edge or base of the falciform ligament reaches from a little above and to the right of the umbilicus to the umbilical fissure on the anterior margin of the liver. This free edge contains between its folds the round ligament of the liver. On the posterior surface of the liver the two peritoneal folds which constitute the falciform ligament separate, the right fold passing into the upper fold of the coronary ligament, the left fold passing into the upper fold of the left lateral ligament.

The Lateral Ligaments (Figs. 949 and 953).—The lateral ligaments are two in number, and are called the right and left lateral ligaments.

The Right Lateral Ligament (ligamentum triangulare dextrum) (Figs. 949 and 953) is in reality the right extremity of the coronary ligament. This ligament is triangular in form, runs from the liver to the Diaphragm, and is formed by the apposition of the upper and lower layers of the coronary ligament. It is attached to the liver between its lateral and inferior surfaces.

The Left Lateral Ligament (ligamentum triangulare sinistrum) (Figs. 949 and 953) is also formed by apposition of the upper and lower layers of the coronary ligament. It is triangular in form, runs from the liver to the Diaphragm, and is longer than the right lateral ligament. It is attached to the upper surface of the left lobe, where it lies, in front of the oesophageal opening in the Diaphragm.

The Coronary Ligament (ligamentum coronarium hepatitis) (Figs. 949 and 953).—The coronary ligament connects the posterior surface of the liver to the Diaphragm. It is formed by the reflection of the peritoneum from the Diaphragm on to the upper and lower margins of the posterior surface of the liver. The coronary ligament consists of two layers, which are continuous on each side with the lateral ligaments, and, in front, with the falciform ligament. Between the layers a large triangular area is left uncovered by peritoneum, and is connected to the Diaphragm by firm areolar tissue.
The Round Ligament (ligamentum teres hepatis) (Figs. 952 and 954).—The round ligament is a fibrous cord resulting from the obliteration of the foetal umbilical vein. It ascends from the umbilicus, in the free margin of the falciform ligament, to the notch in the anterior border of the liver, from which it may be traced along the umbilical fissure on the under surface of the liver, to the left branch of the portal vein.

The Ligament of the Ductus Venosus (ligamentum venosum [Arantii]) is composed of slender bundles of fibrous tissue, and results from the obliteration of the ductus venosus of the foetus. It arises from the left branch of the portal vein, almost opposite the insertion of the round ligament, passes backward in the fissure of the ductus venosus, and, as it emerges from the liver, is attached to the postcava.

Support and Movability of the Liver.—The liver is movable within certain narrow limits. It moves with respiration. On inspiration it moves down with the Diaphragm to distinctly below the costal arch in the right nipple line. Much discussion has taken place as to what supports the liver in place. Symington asserted that the ligaments do not give support, because they lie relaxed. Other observers (Graham, Steele) apparently demonstrate that the peritoneal ligaments do give some support to the liver. The connective tissue which unites the uncovered area of the right lobe of the liver to the Diaphragm and the hepatic veins which join the postcava (Faure) do give distinct support. The chief factor in the support of the liver is the intra-abdominal pressure resulting from the tonic contraction of the abdominal muscles. When abdominal tension is normal the intestines are driven up and become a bed for the liver. Intrahepatic vascular tension aids in supporting the liver (Glénard).

Abnormalities of the Liver.—The liver may be divided into many lobules, and such lobulation is most evident on the parietal surface of the right lobe. Lobulation is probably a pathological change. Occasionally the right lobe is small and the left large.

The editor, in performing an abdominal operation, encountered a liver the left lobe of which was so large and the right so small as to suggest transposition or rotation of the organ. Such a change may result from abnormality of the foetal circulation or from syphilitic disease of the right lobe, producing cicatricial contraction. The left lobe may be very small; sometimes it is rudimentary. When the left lobe is very small an unusual amount of stomach is visible, and the entire gall-bladder can be seen from the front. In such a case the gall-bladder is usually displaced and it may actually "lie with its long axis in the transverse axis of the body."

Atrophy of the left lobe is usually a congenital defect, but may result from syphilis. Small accessory lobes, about one inch in length, are not uncommon, and they are most often met with on the visceral surface of the right lobe. "When markedly pedunculated, they may form accessory livers. The Spigelian lobe is sometimes curiously pedunculated."

Accessory livers are fragments of hepatic tissue or rests, which are entirely separated from the liver. They are seldom met with. When they do exist their most common situation is in the suspensory ligament, but they have been found in the great omentum, in the peritoneum, wall of the gall-bladder, and in other situations. They may be congenital or may be due to atrophy of the pedicle of an accessory lobe or of a pedunculated lobe. Tight lacing alters the shape and position of the liver (Fig. 955). It may flatten the dome and increase the length of the anterior surface, this change being especially obvious in the right lobe, and a costal groove may be formed by the pressure of a rib. "When the elongated right lobe passes over the right kidney, there is atrophy of the hepatic substance.

1 H. D. Rolleston on Diseases of the Liver.
2 Ibid.
3 Ibid.
and thickening of the capsule, which is opaque and forms a hinge-like ligament between the main part of the right lobe above and the constricted lower portion. This lobe is variously termed partial hepatoptosis, constriction lobe, or the sustentacular formation of the right lobe (Hertz). The constriction furrow is produced by the pressure of the corset in front and the resistance of the kidney behind. The constriction lobe tapers to a point, so that the shape of the liver, as seen from the front, is that of a right-angled triangle, with the apex downward.  

The condition resembles Riedel's lobe. The left lobe may also project down, but not so markedly. Tight lacing may cause the entire organ to occupy a level higher than normal. Such a liver is thick and excessively convex above and thin below, and reaches to or laps over the spleen. In severe cases the superior surface is thrown into antero-posterior creases or folds. Linguiform or tongue-like lobe, Riedel's lobe or floating lobe (Fig. 955), may be congenital, may be due to tight lacing, or may arise in cholelithiasis or cholecystitis from the traction of adhesions. Such a lobe comes off from the right lobe. It may be a tapering mass of liver tissue, it may have a thin pedicle of liver tissue, or its pedicle may be merely a double fold of peritoneum. The gall-bladder may lie upon its under surface, or may be placed to the left of it.

**Vessels.**—The blood-vessels connected with the liver are the hepatic artery, the portal vein and the hepatic veins.

The Hepatic Artery and Portal Vein (Figs. 421, 422, 488, and 957), accompanied by numerous lymphatics and nerves, ascend to the transverse fissure between the layers of the gastro-hepatic omentum, and in front of the foramen of Winslow. The hepatic duct, lying in company with them, descends from the transverse fissure between the layers of the same omentum. The relative position of the three structures in the lesser omentum (Fig. 872) is as follows: the hepatic duct lies to the right, the hepatic artery to the left, and the portal vein behind and between the other two. They enter the transverse fissure in the above-described order, but in that fissure undergo rearrangement, the duct being in front, the artery in the

---

1 Rolleston, on Diseases of the Liver.
middle, and the vein behind. The artery, the vein, and the duct divide into a right and left branch and several smaller branches, and within the organ the vessels from the three sources accompany each other and divide at the same points; so each branch of the portal vein is accompanied by a branch of the hepatic artery and of the duct. They are enveloped in a loose areolar tissue, the capsule of Glisson (Fig. 956), which accompanies the vessels in their course through the portal canals in the interior of the organ.

The Hepatic Veins (Fig. 424).—The hepatic veins convey the blood from the liver. They commence in the substance of the liver, in the capillary terminations of the portal vein and hepatic artery; these tributaries, gradually uniting, usually form three veins, which converge toward the posterior surface of the liver and open into the portion of the postcava situated in the groove at the back part of this organ. Of these three veins, one from the right and another from the left lobe open obliquely into the postcava; that from the middle of the organ and lobus Spigeli having a straight course.

The hepatic veins have very little cellular investment; what there is binds their parietes closely to the walls of the canals through which they run; so that, on section of the organ, these veins remain widely open and solitary (Fig. 959), and may be easily distinguished from the branches of the portal vein (Fig. 960),
which are more or less collapsed, and always accompanied by an artery and duct, the hepatic veins are destitute of valves.

**Structure.**—The substance of the liver is composed of lobules held together by extremely fine areolar tissue, and of the ramifications of the portal vein, hepatic duct, hepatic artery, hepatic veins, lymphatics, and nerves, the whole being invested by a serous and a fibrous coat.

**The Serous Coat (tunica serosa).**—The serous coat is derived from the peritoneum, and invests the greater part of the surface of the organ. It is intimately adherent to the fibrous coat.

**The Areolar or Fibrous Coat (capsula fibrosa [Glissoni]).**—The areolar or fibrous coat lies beneath the serous investment and covers the entire surface of the organ. It is difficult of demonstration, excepting where the serous coat is deficient. At the transverse fissure it is thick and evident, is known as the capsule of Glisson, and envelops the vessels which enter the liver and passes with them along the portal canals. The areolar tissue which surrounds and binds together the liver lobules is continuous with the areolar coat.

**The Lobules (lobuli hepatitis) (Fig. 962).**—The lobules form the chief mass of the hepatic substance; they may be seen either on the surface of the organ or by making a section through the gland. They are small granular bodies about the size of a millet-seed, measuring from one-twentieth to one-tenth of an inch in diameter. In the human subject their outline is very irregular, but in some of the lower animals (for example, the pig) they are well defined, and when divided transversely have a polygonal outline. If divided longitudinally they are more or less foliated or oblong. The bases of the lobules are clustered around the smallest radicles of the hepatic veins (sublobular veins), to which each is connected by means of a small branch which issues from the centre of the lobule (intralobular vein). The remaining part of the surface of each lobule is imperfectly isolated from the surrounding lobules by a thin stratum of areolar tissue in which are ducts and a plexus of vessels, the interlobular plexus (Figs. 961 and 962). In some animals, as the pig, the lobules are completely isolated one from another by this interlobular areolar tissue.

If one of the sublobular veins be laid open, the bases of the lobules may be seen through the thin wall of the vein on which they rest, arranged in the form of a tessellated pavement, the centre of each polygonal space presenting a minute aperture, the mouth of an intralobular vein (Fig. 959).

**Microscopic Appearance.**—Each lobule is composed of a mass of cells, hepatic cells (Fig. 958), surrounded by a dense capillary plexus, composed of vessels which penetrate from the circumference to the centre of the lobule, and terminate in a single straight central vein, which runs through its centre, to open at its base into one of the radicles of the hepatic vein. Between the cells are also the minute commencements of the bile-ducts. Therefore in the lobule we have all the essentials of a secreting gland; that is to say: (1) cells, by which the secretion is formed; (2) blood-vessels, in close relation with the cells, containing the blood from which the secretion is derived; and (3) ducts, by which the secretion, when formed, is carried away. Each of these structures will have to be further considered.
(1) The \textbf{Hepatic Cells} are epithelial in nature and of more or less spheroidal form, but may be rounded, flattened, or many-sided from mutual compression. They vary in size from the \(\frac{1}{1000}\) to the \(\frac{1}{2000}\) of an inch in diameter. They consist of a honeycomb network (Klein) without any cell-wall, and contain one or sometimes two distinct nuclei. In the nucleus is a highly refracting nucleolus with granules. Embedded in the honeycomb network are numerous yellow particles, the coloring matter of the bile, and oil-globules. The cells adhere together by their surfaces so as to form rows, which radiate from the centre to the circumference of the lobules.\(^1\) As stated above, they are the chief agents in the secretion of the bile.

(2) \textbf{The Blood-vessels}.—The blood in the capillary plexus around the liver-cells is brought to the liver principally by the portal vein, but also to a certain extent by the hepatic artery. For the sake of clearness the distribution of the blood derived from the hepatic artery may be considered first.

The \textbf{Hepatic Artery}, entering the liver at the transverse fissure with the portal vein and hepatic duct, ramifies with these vessels through the portal canals. It gives off \textit{vaginal branches} which ramify in the capsule of Glisson, and appear to be destined chiefly for the nutrition of the coats of the large vessels, the ducts, and the investing membranes of the liver. It also gives off \textit{capsular branches} which reach the surface of the organ, terminating in the fibrous coat in stellate plexuses. Finally it gives off \textit{interlobular branches} (\textit{rami arteriosi interlobulares}) which form a plexus on the outer side of each lobule, to supply its wall and the accompanying bile-ducts. From this plexus lobular branches enter the lobule and end in the capillary network between the cells. Some anatomists, however, doubt whether it transmits any blood directly to the capillary network.

The \textbf{Portal Vein} also enters at the transverse fissure and runs through the portal canals, enclosed in Glisson’s capsule, dividing into branches in its course, which finally break up into a plexus, the \textit{interlobular plexus}, in the interlobular spaces. In their course these branches receive the vaginal and capsular veins, corresponding to the vaginal and capsular branches of the hepatic artery (Fig. 959).

\[\text{FIG. 959.—Longitudinal section of an hepatic vein. (After Kiernan.)}\]

\[\text{FIG. 960.—Longitudinal section of a small portal vein and canal. (After Kiernan.)}\]

\(^1\) Delpeigne states that there are evidences of the arrangement of these cells in the form of columns, which form tubes with narrow lumina branching from terminal bile-ducts. This branching is evidenced by a diversification of the columns from lines extending between adjacent portal vessels. The columns of cells group around terminal bile-ducts, and not around the so-called intralobular veins. (\textit{Lancet}, 1896, vol. i., p. 1254.)—En. of 15th English edition.
Thus it will be seen that all the blood carried to the liver by the portal vein and hepatic artery, except perhaps that derived from the interlobular branches of the hepatic artery, directly or indirectly finds its way into the interlobular plexus. From this plexus the blood is carried into the lobule by fine branches which pierce its wall and then converge from the circumference to the centre of the lobule, form-

![Diagram of liver structures](image)

**Fig. 961.—Horizontal section of liver (dog.)**

ing a number of converging vessels which are connected by transverse branches (Figs. 961 and 962). In the interstices of the network of vessels thus formed are situated, as before said, the liver-cells; and here it is that the blood is brought into intimate connection with the liver-cells and the bile is secreted. Arrived at the centre of a lobule, all these minute vessels empty themselves into one vein, of considerable size, which runs down the centre of the lobule from apex to base and is called the **intralobular or central vein** (*vein interlobularis*) (Fig. 962). At the base of the lobule this vein opens directly into the **sublobular vein**, with which the lobule is connected, and which, as before mentioned, is a radicle of the hepatic vein. The sublobular veins, uniting into larger and larger trunks, end at last in the hepatic veins, which do not receive any intralobular veins. Finally, the hepatic veins, as mentioned on page 767, converge to form three large trunks which open into the postcava, while that vessel is situated in the fissure appropriated to it at the back of the liver.
(3) The Ducts.—Having shown how the blood is brought into intimate relation with the hepatic cells in order that the bile may be secreted, it remains now only to consider the way in which the secretion, having been formed, is carried away.

Several views have prevailed as to the mode of origin of the hepatic ducts; it seems, however, to be clear that they commence by little passages which are formed between the cells, and which have been termed *intercellular biliary passages*, *bile-capillaries* or *bile-canaliculi* (*ductus biliferi*). These passages are merely little channels or spaces left between the contiguous surfaces of two cells or in the angle where three or more liver-cells meet (Fig. 964), and it seems doubtful whether there is any delicate membrane forming the wall of the channel. Heidenhain, however, thinks they have coats. The channels thus formed radiate to the circumference of the lobule, and, piercing its wall, form a plexus...
(interlobular) between the lobules. From this plexus interlobular ducts (ductus interlobulares) are derived which pass into the portal canals, become enclosed in Glisson's capsule, and, accompanying the portal vein and hepatic artery (Fig. 952), join with other ducts to form two main trunks, the right and left branches of the hepatic duct, which leave the liver at the transverse fissure, and by their union form the hepatic duct.

Structure.—The coats of the smallest biliary ducts, which lie in the interlobular spaces, are a connective-tissue coat, in which are muscle-cells, arranged both circularly and longitudinally, and an epithelial layer, consisting of short columnar cells. In the larger ducts, which lie in the portal canals, there are a number of orifices disposed in two longitudinal rows, which were formerly regarded as the openings of mucous glands, but which are merely the orifices of tubular recesses. They occasionally anastomose, and from the sides of them saccular dilatations are given off.

Lymphatics of the Liver (Fig. 504).—The lymphatics in the substance of the liver commence in lymphatic spaces around the capillaries of the lobules; they accompany the vessels of the interlobular plexus, often enclosing and surrounding them. These unite and form larger vessels, which run in the portal canals, enclosed in Glisson's capsule, and emerge at the portal fissure to be distributed in the manner described. Other superficial lymphatics arise from the superficial lobules, pass under the peritoneum, and form a close plexus, where this membrane covers the liver. The first-named group of lymphatics give origin to the deep collecting trunks, the second to the superficial collecting trunks. According to Poirier, Cunéo and Delamare,¹ one group of deep collecting trunks accompanies the portal vein, there being fifteen to eighteen of them emerging from the transverse fissure. They empty into the glands of the hilum. Another group accompanies the hepatic veins. There are five or six trunks which pass through the Diaphragm and terminate in the glands about the postcava (intrathoracic glands). According to the above-cited authorities, the superficial trunks of the superior surface are divided into posterior, anterior, and superior trunks. Some of the posterior trunks terminate in the glands about the coeliac axis, others in the glands about the lower portion of the postcava in the thorax; others in the glands about the abdominal portion of the oesophagus. The anterior trunks which are limited to the right lobe pass to the glands of the hilum. The superior trunks ascend in the suspensory ligament. Some pass to the glands about the postcava, just above the Diaphragm; others to the hepatic glands. The balance unite to form a very large trunk, which passes through the Diaphragm and divides into branches which enter the glands back of the base of the ensiform cartilage.

Nerves of the Liver.—The nerves of the liver are derived from the left vagus and the solar plexus of the sympathetic. The branches of the vagus ascend from in front of the stomach within the lesser omentum. The sympathetic nerves pass along the hepatic artery from the coeliac plexus. The nerves enter the liver at the transverse fissure and accompany the vessels and ducts to the interlobular spaces. Here, according to Korolkow, the myelinic fibres are distributed almost exclusively to the coats of the blood-vessels; while the amyelinic fibres enter the lobules and ramify between the cells.

The Excretory Apparatus of the Liver.

The excretory apparatus of the liver consists of (1) the hepatic duct, which, as we have seen, is formed by the junction of the two main ducts, which pass out of the liver at the transverse fissure, and are formed by the union of the bile-capillaries; (2) the gall-bladder, which serves as a reservoir for the bile; (3) the

¹ The Lymphatics. Translated and edited by Cecil H. Leaf.
cystic duct, which is the duct of the gall-bladder; and (4) the common bile-duct, formed by the junction of the hepatic and cystic ducts.

The Hepatic Duct (ductus hepaticus) (Figs. 961, 967, and 969).—Two main trunks of nearly equal size issue from the liver at the transverse fissure, one from the right, the other from the left lobe; these unite to form the hepatic duct, which then passes downward and to the right for about an inch and a half or two inches, between the layers of the lesser omentum, where it is joined at an acute angle by the cystic duct, and so forms the ductus communis choledochus. The hepatic duct, as it descends from the transverse fissure of the liver, between the two layers of the lesser omentum, lies in company with the hepatic artery and portal vein (Fig. 957).

The Gall-bladder (vesica fellea) (Figs. 872, 874, 951, 957, and 966).—The gall-bladder is the reservoir for the bile; it is a conical or pear-shaped musculo-membranous sac, lodged in a fossa on the under surface of the right lobe of the liver, and fixed in it by connective tissue, and extending from near the right extremity of the transverse fissure to the anterior border of the organ. It is about four inches in length, one inch in breadth at its widest part, and holds from eight to ten drachms. It is divided into a fundus, body, and neck. The fundus (fundus vesicae felleae), or broad extremity, is directed downward, forward, and to the right, and projects beyond the anterior border of the liver; the body (corpus vesicae felleae) and neck (collum vesicae felleae) are directed upward and backward to the left. The neck of the gall-bladder is on a slightly higher level than the lowest point of the gall-bladder; thus the weight of the bile is away from rather than toward the outlet. The upper surface of the gall-bladder is attached to the liver by connective tissue and vessels. The under surface is covered by peritoneum, which is reflected on to it from the surface of the liver. Occasionally the whole of the organ is invested by the serous membrane, and is then connected to the liver by a kind of mesentery.

Relations.—The body of the gall-bladder is in relation, by its upper surface, with the liver, to which it is connected by areolar tissue and vessels; by its under surface, with the commencement of the transverse colon; and farther back, with the upper end of the descending portion of the duodenum or sometimes with the pyloric end of the stomach or the first portion of the duodenum. The fundus is completely invested by peritoneum; it is in relation, in front, with the abdominal parietes, immediately below the ninth costal cartilage; behind, with the transverse arch of the colon.

The neck is narrow, and curves upon itself like the letter S; at its point of connection with the cystic duct it presents a well-marked constriction.

When the gall-bladder is distended with bile or filled with calculi, the fundus may be felt through the abdominal parietes, especially in an emaciated subject; the relations of this sac will also serve to explain the occasional occurrence of abdominal biliary fistulae, through which biliary calculi may pass out, and of the passage of calculi from the gall-bladder into the stomach, duodenum, or colon, which occasionally happens.
Structure.—The gall-bladder consists of three coats—serous, fibrous and muscular, and mucous.

The External or Serous Coat (tunica serosa vesicae felleae) is derived from the peritoneum; it completely invests the fundus, but covers the body and neck only on their under surfaces.

The Fibro-muscular Coat (tunica muscularis vesicae felleae) is a thin but strong layer which forms the framework of the sac, consisting of dense fibrous tissue which interlaces in all directions and is mixed with plain muscular fibres which are disposed chiefly in a longitudinal direction, a few running transversely.

The Internal or Mucous Coat (tunica mucosa vesicae felleae) is loosely connected with the fibrous layer. It is generally tinged with a yellowish-brown color, and is everywhere elevated into minute rugae, by the union of which numerous meshes are formed, the depressed intervening spaces having a polygonal outline. The meshes are smaller at the fundus and neck, being most developed about the centre of the sac. Opposite the neck of the gall-bladder the mucous membrane projects inward in the form of oblique ridges or folds, forming a sort of screw-like or spiral valve (Fig. 966).

The mucous membrane is covered with columnar epithelium, and secretes an abundance of thick viscid mucus; it is continuous through the hepatic duct with the mucous membrane lining the ducts of the liver, and through the ductus communis choledochus with the mucous membrane of the duodenum.

The Cystic Duct (ductus cysticus).—The cystic duct, the smallest of the three biliary ducts, is about an inch and a half in length. It passes obliquely downward and to the left from the neck of the gall-bladder, and joins the hepatic duct to form the common bile-duct. It lies in the gastro-hepatic omentum in front of the portal vein, the hepatic artery lying to its left side. The mucous membrane lining its interior is thrown into a series of crescentic folds, from five to twelve in number, similar to those found in the neck of the gall-bladder. They project into the duct in regular succession, and are directed obliquely round the tube, presenting much the appearance of a continuous spiral valve (valvula spiralis [Heisteri]) (Fig. 966). When the duct is distended, the spaces between the folds are dilated, so as to give to its exterior a succulated appearance.

The Ductus Communis Choledochus or Common Bile-duct (ductus choledochus) Figs. 966 and 967), the largest of the three,
is the common excretory duct of the liver and gall-bladder. It is about three inches in length, is of the diameter of a goose-quill, and is formed by the junction of the cystic and hepatic ducts.

It descends within the two layers and along the right border of the lesser omentum behind the first portion of the duodenum, in front of the portal vein, and to the right of the hepatic artery (Fig. 872); then passes either between the pancreas and descending portion of the duodenum, or through the head of the pancreas. In fifty-eight dissections Prof. Büngner found that it passed through the pancreas fifty-five times and over the head only three times. Even when it passes through the pancreas it almost always joins the pancreatic duct outside of the gland. It descends by the right side of the pancreatic duct and passes with it obliquely through the wall of the descending portion of the duodenum between the mucous and muscular coats in the submucous tissue for one-half to three-quarters of an inch. The two ducts usually unite just before opening into the duodenum (Figs. 967, 968, and 970), but may remain independent throughout (in about 10 per cent. of individuals). The diverticulum ampulla of Vater (Fig. 967) is the conical cavity formed by the fusion of the two ducts, and is much larger than the opening on the bile-papilla. It averages 3.9 mm. in length. The average diameter of the orifice is 2.5 mm. (Opie). The two ducts open by a common orifice if there is an ampulla, or by two separate orifices if there is no ampulla, upon the summit of a papilla, situated at the inner side of the descending portion of the duodenum, a little below its middle and about three or four inches below the pylorus. Circular muscular fibres, continuous with the longitudinal fibres of the ducts, surround the termination of the two ducts in the ampulla. These fibres constitute the so-called sphincter of Oddi (Fig. 968).

Structure.—The coats of the large biliary ducts are an external or fibrous and an internal or mucous. The fibrous coat is composed of strong fibro-areolar tissues, with a certain amount of muscular tissue arranged, for the most part, in a circular manner around the duct. The mucous coat is continuous with the lining mem-

Fig. 970.—Diagram showing the bile and pancreatic ducts piercing the wall of the duodenum obliquely. (Cunningham.)
brane of the hepatic ducts and gall-bladder, and also with that of the duode-
num; and, like the mucous membrane of these structures, its epithelium is of the
columnar variety. It is provided with numerous mucous glands, which are lobu-
lated and open by minute orifices scattered irregularly in the larger ducts. It is
questionable if the smallest biliary ducts, which lie in the interlobular spaces, have
any coats. Heidenhain thinks they have a connective-tissue coat, in which are
muscle-cells arranged both circularly and longitudinally, and an epithelial layer,
consisting of short columnar cells.

Dimensions of the Bile-ducts.—The hepatic duct is about two inches in length,
and its lumen is one-sixth of an inch in diameter. The cystic duct is about one
and one-half inches in length, and its lumen is one-twelfth of an inch in diameter.
The common duct is about three inches in length, and its lumen is one-quarter of
an inch in diameter. The duodenal opening is smaller than the common duct.
The ducts are capable of considerable distention, but the duodenal opening can-
not be dilated (Hyrtl).

Blood-vessels, Lymphatics, and Nerves of the Gall-bladder and Bile-ducts.—The
cystic artery (Fig. 421), a branch from the right division of the hepatic, supplies the
gall-bladder and cystic duct with blood. It passes along the cystic duct, and on
reaching the gall-bladder divides into an upper branch and a lower branch. The
upper branch lies between the gall-bladder and the liver and sends branches to each.
The lower branch is between the peritoneum and the wall of the gall-bladder.
The cystic veins empty into the portal vein. The common duct receives branches
from the superior pancreatico-duodenal artery. There is a submucous lymphatic net-
work and a muscular lymphatic network. The lymphatics are much less numer-
ous at the fundus of the gall-bladder than at the neck or in the extra-hepatic ducts.
The collecting trunks (Fig. 504) end in glands along the cystic and common ducts
and these glands are in communication with the duodenal lymphatics and the
lymphatics from the head of the pancreas. The nerves of the gall-bladder and
bile-ducts come from the coeliac plexus of the sympathetic. The adjacent peri-
toneum is plentifully supplied with nerves (Robinson).

The Bile (fcl).—The bile is a reddish-brown or greenish fluid. It contains pig-
ments (bilirubin and biliverdin), fats and soaps, cholesterol, sodium salts of glyco-
choleic and taurocholic acid, lecithin, and nucleo-albumin furnished by the mucous
membrane. There are also present CO2; chlorides, carbonates, phosphates, and
sulphates of the alkalies and of calcium, and iron. The amount normally secreted is from one pint to one and one-half pints in the twenty-four hours.

Surface Relations.—The liver is situated in the right hypochondriac and the epigastric
regions, and is moulded to the arch of the Diaphragm. In the greater part of its extent it lies
under cover of the lower ribs and their cartilages, but in the epigastric region it comes in con-
tact with the abdominal wall, in the subcostal angle. The upper limit of the right lobe of the
liver may be defined in the middle line by the junction of the mesosternum with the ensiform
cartilage; on the right side the line must be carried upward as far as the fifth rib cartilage
in the line of the nipple and then downward to reach the seventh rib at the side of the chest.
The upper limit of the left lobe may be defined by continuing this line to the left with an inclina-
tion downward to a point about two inches to the left of the sternum on a level with the sixth
left costal cartilage. The lower limit of the liver may be indicated by a line drawn half an inch
below the lower border of the thorax on the right side as far as the ninth right costal cartilage,
and thence obliquely upward across the subcostal angle to the eighth left costal cartilage. A
slight curved line with its convexity to the left from this point—i.e., the eighth left costal
cartilage—to the termination of the line indicating the upper limit will denote the left margin of
the liver. The fundus of the gall-bladder approaches the surface behind the anterior extremity
of the ninth costal cartilage, close to the outer margin of the Right rectus muscle.

It must be remembered that the liver is subject to considerable alterations in position, and
the student should make himself acquainted with the different circumstances under which this
occurs, as they are of importance in determining the existence of enlargement or other diseases
of the organ.
Its position varies according to the posture of the body. In the erect position in the adult male the edge of the liver projects about half an inch below the lower edge of the right costal cartilages, and its anterior border can be often felt in this situation if the abdominal wall is thin. In the supine position the liver gravitates backward and recedes above the lower margin of the ribs, and cannot then be detected by the finger. In the prone position it falls forward, and can then generally be felt in a patient with loose and lax abdominal walls. Its position varies also with the ascent or descent of the Diaphragm. In a deep inspiration the liver descends below the ribs; in expiration it is raised behind them. Again, in emphysemata, where the lungs are distended and the Diaphragm descends very low, the liver is pushed down; in some other diseases, as phthisis, where the Diaphragm is much arched, the liver rises very high up. Pressure from without, as in tight lacing, by compressing the lower part of the chest, displaces the liver considerably, its anterior edge often extending as low as the crest of the ilium; and its convex surface is often at the same time deeply indented from the pressure of the ribs. Again, its position varies greatly according to the greater or less distortion of the stomach and intestines. When the intestines are empty the liver descends in the abdomen, but when they are distended it is pushed upward. Its relations to surrounding organs may also be changed by the growth of tumors or by collections of fluid in the thoracic or abdominal cavities.

**Surgical Anatomy.**—Movable liver or hepatoptosis is a rare condition, in which the liver moves or can be moved from its normal position. It is due to lessened tone of the abdominal muscles and relaxation of the liver supports. In movable liver the organ may be rotated on its vertical axis or on its transverse axis. Tongue-like lobes have been referred to. On account of its large size, its fixed position, and its friability, the liver is more frequently ruptured than any of the abdominal viscera. The rupture may vary considerably in extent, from a slight scratch to an extensive laceration completely through its substance, dividing it into two parts. Sometimes an internal rupture without laceration of the peritoneal covering takes place, and such injuries are most susceptible of repair; but small tears of the surface may also heal; when, however, the laceration is extensive, death usually takes place from hemorrhage, on account of the fact that the hepatic veins are contained in rigid canals in the liver-substance and are unable to contract, and are moreover unprovided with valves. The liver may also be torn by the end of a broken rib perforating the Diaphragm. The liver may be injured by stabs or other punctured wounds, and when these are inflicted through the chest-wall both pleural and peritoneal cavities may be opened up and both lung and liver be wounded. In cases of wound of the liver from the front, protrusion of a part of this viscus may take place, but can generally easily be replaced. In cases of laceration of the liver, when there is evidence that bleeding is going on, the abdomen must be opened, the laceration sought for, and the bleeding arrested. This may be done temporarily by introducing the forefinger into the foramen of Winslow and placing the thumb on the gastro-hepatic omentum and compressing the hepatic artery and portal vein between the two. Any bleeding points can then be seen. Bleeding is, if possible, arrested by suture ligatures. The edges of a small laceration are simply brought together and sutured by means of a blunt, curved, round needle passed from one side of the wound to the other. All sutures must be passed before any are tied, and this must be done with the greatest gentleness, as the liver substance is very friable. If suture fails the actual cautery may succeed. When the laceration is extensive, the liver is sutured to the abdominal wall to hold it firm when pressure is applied, and then the laceration is packed with a piece of iodine gauze, the gauze of which is allowed to hang out of the external wound. **Abscess of the liver** is of not infrequent occurrence, and may open in many different ways on account of the relations of this viscus to other organs. Thus it may burst into the lung, the pus being coughed up, or into the stomach; the pus perhaps being vomited, it may burst into the colon or into the duodenum, or, by perforating the Diaphragm, it may empty itself into the pleural cavity. Frequently it makes its way forward, and points on the anterior abdominal wall, and finally it may burst into the peritoneal or pericardiac cavity. Abscesses of the liver require opening, and this must be done by an incision in the abdominal wall, in the thoracic wall, or in the lumbar region, according to the direction in which the abscess is tracking. The incision through the abdominal wall is to be preferred when possible. The abdominal wall is incised over the swelling, and unless the peritoneum is adherent, gauze is packed all around the exposed liver surface and the abscess opened, if deeply seated, preferably by the thermocautery. **Hydatid cysts** are more often found in the liver than in any other of the viscera. The reason of this is not far to seek. The embryo of the egg of the tapeworm ischococcus being liberated in the stomach by the disintegration of its shell, bores its way through the gastric walls and usually enters a blood-vessel, and is carried by the blood-stream to the hepatic capillaries, where its onward course is arrested, and where it undergoes development into the fully formed hydatid. **Tumors of the liver** have recently been subjected to surgical treatment by removal of a portion of the organ. The abdomen is opened and the diseased portion of liver exposed; the circulation is controlled by compressing the portal vein and the hepatic artery in the gastro-hepatic omentum and a wedge-shaped portion of liver containing the tumor removed; the divided vessels are ligated and the cut surfaces brought together and sutured in the manner directed above.

When the gall-bladder or one of its main ducts is ruptured, which may occur independently of laceration of the liver, death usually occurs from peritonitis. If the symptoms have led to
THE PANCREAS 1355

the performance of a laparotomy and a small rent is found, it should be sutured; if an extensive opening is found the gall-bladder should be removed. If the cystic duct is torn, its intestinal end must be closed and the gall-bladder removed. In rupture of either of the other ducts, simply provide for free drainage.

The gall-bladder may become distended with bile in cases of obstruction of its duct or of the common bile-duct, or it may become distended from a collection of gall-stones within its interior, thus forming a large tumor. The swelling due to distention with bile is pear-shaped, and projects downward and forward to the umbilicus. It moves with respiration, since it is attached to the liver. To relieve a patient of gall-stones, the gall-bladder must be opened and the gall-stones removed. The operation is performed by an incision two or three inches long in the right semilunar line, commencing at the costal margin. The peritoneal cavity is opened, and the tumor having been found, gauze pads are packed around it to protect the peritoneal cavity, and it is aspirated. When the contained fluid has been evacuated the flaccid bladder is drawn out of the abdominal wound and its wall incised to the extent of an inch; any gall-stones in the bladder are now removed and the interior of the sac sponged dry. If the case is one of obstruction of the duct, an attempt must be made to dislodge the stone by manipulation through the wall of the duct; or it may be crushed from without by the fingers or carefully padded forceps. If this does not succeed, the safest plan is to incise the duct, extract the stone, close the incision in the duct by fine sutures in two layers and employ drainage. After all obstruction has been removed, four courses are open to the surgeon: 1. The wound in the gall-bladder may be at once sewed up, the organ returned into the abdominal cavity, and the external incision closed. 2. The edges of the incision in the gall-bladder may be sutured to the fascia of the external wound, and a fistulous communication established between the gall-bladder and the exterior; this fistulous opening usually closes in the course of a few weeks. 3. The gall-bladder may be connected with the intestinal canal, preferably the duodenum, by means of a lateral anastomosis; this is known as cholecystenterostomy. 4. The gall-bladder may be completely removed (cholecystectomy). Plan 2 is usually followed. Plan 4 is employed when the coats of the gall-bladder are seriously diseased. Plan 2 is employed in obstruction of the common duct by malignant disease.

If a stone blocks the diverticulum of Vater and if the common bile-duct and the pancreatic duct empty into the diverticulum, it is evident that both ducts will be blocked. It has been demonstrated that in such a case the pressure urging the bile onward is sufficient to overcome the pressure in the pancreatic duct and drive bile into the ducts of the pancreas, the result, perhaps, being disastrous inflammation of the pancreas.

Septic trouble arises more rapidly when a stone is blocked in the duct than when stones merely block the gall-bladder, because the first-named part is richer in lymphatics (Murphy).

THE PANCREAS (Figs. 971, 972, 973, 974).

Dissection.—The pancreas may be exposed for dissection in three different ways: 1. By raising the liver, drawing down the stomach, and tearing through the gastro-hepatic omentum and the ascending layer of the transverse mesocolon. 2. By raising the stomach, the arch of the colon, and great omentum, and then dividing the inferior layer of the transverse mesocolon and raising its ascending layer. 3. By dividing the two layers of peritoneum, which descend from the great curvature of the stomach to form the great omentum; turning the stomach upward, and then cutting through the ascending layer of the transverse mesocolon (see Fig. 860).

The Pancreas (παν-κρέας, all flesh) is a compound racemose gland, analogous in its structure to the salivary glands, though softer and less compactly arranged than those organs. It is long and irregularly prismatic in shape, and has been compared to a human or a dog's tongue; it is of reddish-white color. Its right extremity being broad, is called the head. The right half of the head above is continuous with the neck, which connects the head to the main portion of the organ, the body. The neck is a slight constriction or thin part of the gland, placed in front of the portal vein, and connecting the head to the body. The left half of the head is separated from the neck by a notch, the incisura pancreaticus. The body of the gland gradually tapers into an extremity directed to the left, and called the tail. The pancreas is placed transversely across the posterior wall of the abdomen, at the back of the epigastric and left hypochondriac regions. Its length varies from five to six inches, its breadth is an inch and a half, and its thickness from half an inch to an inch, being greater at its right extremity and along
its upper border. Its weight varies from two to three and a half ounces, but it may reach six ounces.

**FIG. 971.**—Position and relations of pancreas.

**FIG. 972.**—The duodenum and pancreas. The liver has been lifted up and the greater part of the stomach removed: a, portal vein; b, hepatic duct; c, cystic duct; d, hepatic artery; e, right suprarenal capsule; f, pyloric orifice; g, right gastro-epiploic artery; h, superior mesenteric vein; i, left crus of diaphragm; j, left suprarenal capsule; k, splenic vein; l, splenic artery; m, duodeno-jejunal junction; A, B, C, D, the four portions of the duodenum. (Testut.)
The Right Extremity or Head of the Pancreas (caput pancreatis) (Fig. 971) is shaped like the head of a hammer, being elongated both above and below; it is flattened from before backward, and conforms to the whole concavity of the duodenum, which is slightly overlapped by it. The anterior surface near its left border exhibits a notch, the incisura pancreatis, which contains the superior mesenteric vessels. The notch marks the separation of the inferior portion of the head, which is known as the uncinate process of Winslow (processus uncinatus [Winslow]), which rests, below, upon the inferior portion of the duodenum, and, above, is pushed up back of the upper portion. The lower end of the head is crossed by the transverse colon and its mesocolon. Behind, the head of the pancreas is in relation with the postcava, the left renal vein, the right crus of the Diaphragm, and the aorta. The common bile-duct descends behind, between the duodenum and pancreas, or in the substance of the gland; and the pancreatico-duodenal artery descends in front between the same parts. The head of the pancreas is closely adherent to the duodenum.

**Fig. 973.—Duodenal orifice of the pancreatic duct and of the canal of Santorini.**

The Neck of the Pancreas is about an inch long, and passes upward and forward to the left, having the first part of the duodenum above it, and the termination of the fourth portion below. It lies in front of the commencement of the portal vein, and is grooved on the right by the gastro-duodenal and superior pancreatico-duodenal arteries. The pylorus lies just above it.

The Body (corpus pancreatis) and Tail (cauda pancreatis) of the Pancreas are somewhat prismatic in shape, and have three surfaces: anterior, posterior, and inferior.

**The Anterior Surface (facies anterior).—**The anterior surface is somewhat concave, and is covered by the posterior surface of the stomach which rests upon it, the two organs being separated by the lesser sac of the peritoneum. At its right extremity there is a well-marked prominence, called by His the omental tuberosity (tuber omentale).

**The Posterior Surface (facies posterior).—**The posterior surface is separated from the vertebral column by the aorta, the splenic vein, the left kidney and its vessels, the left suprarenal capsule, the pillars of the Diaphragm, and the origin of the superior mesenteric artery.

**The Inferior Surface (facies inferior) (Fig. 972).—**The inferior surface is narrow, and lies upon the duodeno-jejunal flexure and on some coils of the jejunum; its left extremity rests on the splenic flexure of the colon.

**The Superior Border (margo superior) (Fig. 972).—**The superior border of the body is blunt and flat to the right; narrow and sharp to the left, near the tail. It commences to the right in the omental tuberosity, and is in relation with the coeliac axis, from which the hepatic artery courses to the right just above the gland, while the splenic branch runs in a groove along this border to the left.
The Anterior Border (margo anterior).—The anterior border is the position where the two layers of the transverse mesocolon separate; the one passing upward in front of the anterior surface, the other backward below the inferior surface (Fig. 866). The lesser end or tail of the pancreas is narrow; it extends to the left as far as the lower part of the inner aspect of the spleen, and its end is directed upward and to the left (Fig. 972).

Birmingham describes the body of the pancreas as projecting forward as a prominent ridge into the abdominal cavity and forming a sort of shelf on which the stomach lies. He says: "The portion of the pancreas to the left of the middle line has a very considerable antero-posterior thickness; as a result the anterior surface is of considerable extent, it looks strongly upward, and forms a large and important part of the shelf. As the pancreas extends to the left toward the spleen it crosses the upper part of the kidney, and is so moulded on to it that the top of the kidney forms an extension inward and backward of the upper surface of the pancreas and extends the bed in this direction. On the other hand, the extremity of the pancreas comes in contact with the spleen in such a way that the plane of its upper surface runs with little interruption upward and backward into the concave gastric surface of the spleen, which completes the bed behind and to the left, and, running upward, forms a partial cap for the wide end of the stomach." An occasional anomaly is a pancreas prolonged in front of the duodenum or actually embracing it (annular pancreas).

Fig. 974.—Transverse section through the middle of the first lumbar vertebra, showing the relations of the pancreas. (Braune.)

Peritoneal Relations (Fig. 866).—The transverse mesocolon is attached to the anterior border of the pancreas, from the tail to the neck of the gland, and the two layers of the mesocolon separate. The anterior layer which comes from the lesser peritoneum covers part of the anterior surface and the superior surface; the posterior layer, which comes from the greater omentum, covers the rest of the anterior surface and the inferior surface. The posterior surface is devoid of peritoneum.

There is in front of the head and at the anterior margin a narrow strip of pancreas, which remains uncovered by peritoneum and which corresponds to the cellular tissue of the mesocolon.

The principal excretory duct of the pancreas, called the **pancreatic duct** or **canal of Wirsung** (ductus pancreaticus [Wirsungii]) (Figs. 969, 971, and 973), from its discoverer, extends transversely from left to right through the substance of the pancreas. In order to expose it, the superficial portion of the gland must be removed. It commences by the junction of the small ducts of the lobules situated in the tail of the pancreas, and, running from left to right through the body, it constantly receives the ducts of the various lobules composing the gland. Considerably augmented in size, it reaches the neck, and turning obliquely downward, backward, and to the right, it comes into relation with the common bile-duct, lying to its left side; leaving the head of the gland, it passes very obliquely through the mucous and muscular coats of the duodenum, and usually terminates by an orifice common to it and the ductus communis choledochus upon the summit of an elevated papilla, situated at the inner side of the descending portion of the duodenum, three or four inches below the pylorus (Figs. 967, 968, and 970).

Sometimes the pancreatic duct and ductus communis choledochus open separately into the duodenum (Fig. 906). In about one-fifth of the subjects there is an accessory duct, which is given off from the canal of Wirsung in the neck of the pancreas and passes horizontally to the right to open into the duodenum about an inch above the orifice of the main duct. This is known as the **duct of Santorini** (ductus pancreaticus accessorius [Santorini]) (Figs. 969, 970, and 973).

The pancreatic duct, near the duodenum, is about the size of an ordinary quill; its walls are thin, consisting of two coats, an external fibrous and an internal mucous; the latter is smooth, and furnished near its termination with a few scattered follicles.

**Structure.**—In structure, the pancreas resembles the salivary glands. It differs from them, however, in certain particulars, and is looser and softer in its texture. It is not enclosed in a distinct capsule, but is surrounded by areolar tissue, which dips into its interior, and connects together the various lobules of which it is composed. Each lobule, like the lobules of the salivary glands, consists of one of the ultimate ramifications of the main duct, terminating in a number of caecal pouches or alveoli, which are tubular and somewhat convoluted. The minute ducts connected with the alveoli are narrow and lined with flattened cells. They are the secreting end tubules. The narrow ducts which come from the end tubules are lined with flat epithelial cells. The alveoli are almost completely filled with secreting cells, so that scarcely any lumen is visible. In the centre of the end tubules flat cells are frequently found. They are continuations into the tubules of the duct epithelium. These cells are known as the **centro-acinar cells of Langerhans**. The true secreting cells which line the wall of the alveolus are very characteristic. They are columnar or rounded in shape and present two zones: an outer one clear and finely striated next the basement-membrane, and an inner granular one next the lumen. The highly refracting granules are known as **zymogen granules**. During digestion the granules gradually disappear and the cells become clear. During fasting the granular zone occupies more than one-half of the cell (Szymonowicz). In some secreting cells of the pancreas is a spherical mass, staining more easily than the rest of the cells; this is termed the **paranucleus**, and is believed to be an extension from the nucleus. The connective tissue among the gland tubules and alveoli presents in certain parts collections of cells, which are termed **inter-alveolar cell-islets, intertubular cell-masses** or **islands of Langerhans**. Opie points out that they are most common in the splenic end of the pancreas. The cells of the islands are smaller than the secreting cells of the alveoli, and are arranged in layers with intervening spaces. The islands are surrounded by
fine connective tissue. The spaces in the islands contain capillaries. There are no ducts in the islands of Langerhans. Their function is to furnish the internal secretion of the pancreas.

Blood-vessels, Lymphatics, and Nerves.—The arteries of the pancreas come from the superior pancreatico-duodenal branch of the gastro-duodenal; the inferior pancreatico-duodenal branch of the superior mesenteric; the inferior pancreatic branch of the superior mesenteric; pancreatic branches of the hepatic and pancreatic branches of the splenic. In a few cases a large artery, the \textit{pancreatica magna}, accompanies the pancreatic duct. In most cases there is no such vessel. The veins are the anterior pancreatico-duodenal branch of the superior mesenteric; the posterior pancreatico-duodenal branch and other pancreatic branches of the portal; and pancreatic branches of the splenic. The lymphatics arise in a network about the lobules. Numerous collecting trunks pass to the surface of the pancreas, anastomose with each other, and enter into glands about the pancreas. The \textit{splenic glands} receive most of the trunks. Others are received by glands along the aorta (Sappey), glands at the origin of the superior mesenteric artery, and glands along the pancreatico-duodenal vessels.\(^1\) The \textit{nerves} come from the coeliac, superior mesenteric, and splenic plexuses.

The Pancreatic Juice.—The pancreatic juice is a clear, somewhat viscid alkaline liquid. Its specific gravity is about 1030. The solid matter consists chiefly of proteids, and amounts to about 10 per cent. of a sample of the juice.\(^2\) The juice contains a ferment which breaks up fat, a ferment which converts starch into sugar, a ferment which curdles milk, and a ferment which digests protein material.

Surface Form.—The pancreas lies in front of the second lumbar vertebra, and can sometimes be felt, in emaciated subjects, when the stomach and colon are empty, by making deep pressure in the middle line about three inches above the umbilicus.

Surgical Anatomy.—Of late years our knowledge of the structure, functions, and diseases of the pancreas has been notably increased, and surgeons have begun to operate for certain pancreatic diseases. It is occasionally the seat of cancer, which usually affects the head or duodenal end, and therefore often speedily involves the common bile-duct, leading to persistent jaundice. Cancer of the pancreas may be primary or secondary. \textit{Primary sarcoma} is very unusual; secondary sarcoma is more common, but cancer is far commoner than either form of sarcoma. \textit{Adenoma} may also occur. Cases are on record of the successful removal of tumors of the pancreas, but the operations are very dangerous, are extremely difficult, and are seldom attempted. The pancreas may be the seat of \textit{syphilitic or tuberculous disease}. As a result of pancreatic injury, there may be \textit{effusion into the lesser peritoneal cavity}. The lesser cavity becomes distended, and the fluid of this \textit{pseudo-cyst} may contain pancreatic juice (Jordan Lloyd). True \textit{cysts} of the pancreas are occasionally found. Pancreatic cysts may result from blocking of the duct, from epithelial proliferation, from traumatism and hemorrhage, or from hydatid disease. \textit{Congenital cysts} may occur, and \textit{cystic carcinoma} is sometimes encountered. Cysts of the pancreas may present in the epigastric region above and to the right of the umbilicus. The fluid in these cysts contains some of the pancreatic secretion. A pancreatic cyst is best treated by opening the abdomen, suturing the cyst to the skin, opening the cyst and providing for drainage. Complete extirpation of the cyst is invariably difficult and is usually impossible. It has been said that the pancreas is the only abdominal viscus which has never been found in a hernial protrusion; but even this organ has been found, in company with other viscera, in rare cases of \textit{diaphragmatic hernia}. The pancreas has been known to become invaginated into the intestine, and portions of the organ have sloughed off. In cases of \textit{excision of the pylorus} great care must be exercised to avoid wounding the pancreas, as the escape of the pancreatic fluid may be attended with serious and even with fatal results, peritonitis and \textit{fat necrosis}, and gangrene being caused.

\textit{Rupture of the pancreas} as a solitary result of traumatism is very unusual, but is more common in violent injuries which rupture the liver and spleen as well. An injury which lacerates the pancreas and permits blood and pancreatic juice to flow into the lesser peritoneal cavity is usually rapidly fatal, but may not be. The foramen of Winslow may be occluded by inflammation, and a pseudo-cyst may form. In severe laceration of the pancreas alone, it would be proper to open the abdomen, ligature bleeding vessels, suture the pancreas, and drain the lesser peritoneal cavity posteriorly. A \textit{gunshot wound of the pancreas} requires posterior drainage. Every effort must

\(^1\) Poirier, Cunéo, and Delamare on the \textit{Lymphatics}. Edited and translated by Cecil H. Leaf.

\(^2\) Robson and Moynihan on Diseases of the Pancreas.
be made in a pancreatic wound to rapidly get rid of pancreatic fluid by drainage from the
wound area, as this fluid is extremely irritant and may cause gangrene.

Inflammation of the pancreas is due to infection. Occasionally it seems to follow the entrance
of bile into the pancreatic duct, because of plugging of the ampulla with a calculus (Halsted,
Opie). Hemorrhage into the pancreas is frequent in acute pancreatitis, and fat necrosis is common
in the fat of the mesentery, subperitoneal tissue, omentum, and other parts. Acute pancreatitis
may be recovered from if the abdomen is opened, the pancreas incised, and drainage employed.
In chronic interstitial pancreatitis of the head of the pancreas the gall-duct is apt to become
blocked, and the disease is frequently mistaken for cancer. Cure may follow opening and drain-
age of the gall-bladder.

THE SPLEEN (LIEN) (Figs. 971, 972, 974).

The spleen belongs to that class of bodies which are known as ductless glands. It
is probably related to the blood-vascular system, but in consequence of its
anatomical relationship to the stomach and its physiological relationship to the
liver it is convenient to describe it in this section. It is situated principally in the
posterior portion of the left hypochondriac region, its upper and inner extremity
extending into the epigastric region; lying between the fundus of the stomach
and the Diaphragm. If the abdomen is opened a spleen of ordinary size is not
visible from the front, as it is placed between the left kidney, Diaphragm, and
stomach. It moves with the respiratory movements and with the movements of
the stomach. It is the largest of the so-called ductless glands, and varies greatly
in size. Usually it measures some five inches in length. It is of an oblong,
flattened form, soft, of very brittle consistence, highly vascular, and of a dark-
purpleish color.

Surfaces. The External or Phrenic Surface (facies diaphragmatica).—The external
or phrenic surface is convex, smooth, and is directed upward, backward, and
to the left, except at its upper end, where it is directed slightly inward. It is in
relation with the under surface of the Diaphragm, which separates it from the
eighth, ninth, tenth, and eleventh ribs of the left side, and in part from the lower
border of the left lung and pleura. It is
to be remembered that not only are the
peritoneum and the Diaphragm between
the spleen and the ribs, but also the cavity
of the left pleura and a portion of the left
lung.

The Internal Surface.—The internal sur-
face is concave, and divided by a ridge into an anterior or larger, and a posterior or
smaller portion.

The Anterior Portion of the internal sur-
face or the gastric surface (facies gastrica), which is directed forward and inward, is
broad and concave, and is in contact with the posterior wall of the great end of the
stomach; and below this with the tail of the pancreas. It presents near its inner
border a long fissure, termed the hilum
(hilus lienis). This is pierced by several
irregular apertures, for the entrance and
exit of vessels and nerves.

The Posterior Portion of the internal sur-
face or the renal surface (facies renalis)
is directed inward and downward. It is
somewhat flattened, does not reach as high

---

Fig. 975.—The spleen, showing its gastric and
renal surfaces. (Testut.)
as the gastric surface, is considerably narrower than the latter, and is in relation with the upper part of the outer surface of the left kidney and occasionally with the left suprarenal capsule.

The upper end of the spleen (extremitas superior) is directed inward, toward the vertebral column, where it lies on a level with the eleventh thoracic vertebra. The lower end (extremitas inferior), sometimes termed the basal surface, is flat, triangular in shape, and rests upon the splenic flexure of the colon and the phreno-colic ligament, and is generally in contact with the tail of the pancreas. The anterior border (margo anterior) is free, sharp, and thin, and is often notched, especially below. It separates the phrenic surface from the gastric surface. The posterior border (margo posterior) is more rounded and blunter than the anterior. It separates the renal portion of the internal surface from the phrenic surface. It corresponds to the lower border of the eleventh rib and lies between the Diaphragm and left kidney. The internal border is the name sometimes given to the ridge which separates the renal and gastric portions of the internal surface.

The spleen is surrounded by peritoneum, except at the hilum and the serous membrane, is firmly adherent to its capsule, and is held in position by two folds of this membrane: one, the lienorenal ligament (ligamentum phrenicolienale) (Figs. 870 and 873), is derived from the layers of peritoneum forming the greater and lesser sacs, where they come into contact between the left kidney and the spleen. Between its two layers the splenic vessels pass; the second, the gastro-splenic omentum (ligamentum gastrolienale), also formed of two layers, derived from the greater and lesser sacs, respectively, where they meet between the spleen and stomach (Fig. 873). Between these two layers run the vasa brevia of the splenic artery and vein. The spleen is also supported by the phrenocolic ligament (ligamentum phrenicocolicum), upon which its lower end rests.

The size and weight of the spleen are liable to very extreme variations at different periods of life, in different individuals, and in the same individual under different conditions. In the adult, in whom it attains its greatest size, it is usually about five inches in length, three inches in breadth, and an inch or an inch and a half in thickness, and weighs about seven ounces. At birth, its weight, in proportion to the entire body, is almost equal to what is observed in the adult, being as
1 to 350; while in the adult it varies from 1 to 320 to 1 to 400. In old age, the organ not only decreases in weight, but decreases considerably in proportion to the entire body, being as 1 to 700. The size of the spleen is increased during and after digestion, and varies considerably according to the state of nutrition of the body, being large in highly fed, and small in starved animals. In intermittent and other fevers it becomes much enlarged, weighing occasionally from eighteen to twenty pounds.

Frequently in the neighborhood of the spleen, and especially in the gastro-splenic and great omenta, small nodules of splenic tissue may be found, either isolated, or connected to the spleen by thin bands of splenic tissue. Every such nodule is known as a *supernumerary* or *accessory spleen* (*lien accessorius*). Accessory spleens vary in size from that of a pea to that of a plum.

**Support and Movability of the Spleen.**—The spleen is normally movable within certain narrow limits. It moves with respiration and with stomach movements. It is supported by ligaments (p. 1362). An unduly movable spleen is called a *movable spleen*. In order that a spleen shall become unduly movable, the ligaments must stretch, and this stretching is often effected when the organ is greatly enlarged, but even an apparently normal spleen may become movable. Movable spleen is usually associated with movable left kidney.

**Structure.**—The spleen is invested by two coats—an *external serous* and an *internal fibro-elastic coat*.

The **External or Serous Coat** (*tunica serosa*).—The external or serous coat is derived from the peritoneum; it is thin, smooth, and in the human subject is intimately adherent to the fibro-elastic coat. It invests the entire organ, except at the places of its reflection on to the stomach and Diaphragm and at the hilum.

The **Fibro-elastic Coat** (*tunica albuginea*).—The fibro-elastic coat forms the framework of the spleen. It is composed of connective tissue containing muscle-cells and elastic fibres, and it invests the organ as a *capsule*, and at the hilum is reflected inward upon the vessels in the form of sheaths. From these sheaths, as well as from the inner surface of the fibro-elastic coat, numerous small fibrous bands, *trabeculae* (*trabeculae lienis*) (Figs. 976 and 977), are given off in all directions; these uniting, constitute the framework of the spleen. This framework resembles a sponge-like material, consisting of a number of small spaces or areolae formed by the trabeculae, which are given off from the inner surface of the capsule, or from the sheaths prolonged inwardly on the blood-vessels. The spaces or areolae contain the adenoid material known as *splenic pulp* (*pulpa lienis*).

The proper coat, the sheaths of the vessels and the trabeculae, consist of a dense mesh of white and yellow elastic fibrous tissues, the latter decidedly predominating. It is owing to the presence of this tissue that the spleen possesses a considerable amount of elasticity, which allows of the very great variations in size that it presents under certain circumstances. In addition to these constituents of this tunic, there is found in man a small amount of non-stripped muscular fibre, and in some mammalia (e. g., dog, pig, and cat) a very considerable amount, so that the trabeculae appear to consist chiefly of muscular tissue. It is probably because of this muscular structure that the spleen exhibits, when acted upon by the galvanic current, faint traces of contractility.

The proper substance of the spleen or splenic-pulp is a soft mass of a dark reddish-brown color, resembling grumous blood. When a thin section is examined under a microscope, it is found to consist of a number of branching cells and an intercellular substance. The cells are connective-tissue corpuscles, and have been named the *sustentacular* or *supporting cells of the pulp*. The processes of these branching cells communicate with each other, thus forming a delicate reticulated tissue in the interior of the areolae formed by the trabeculae of the capsule; so that each primary space may be considered to be divided into a
number of smaller spaces by the junction of these processes of the branching corpuscles. These secondary spaces contain blood, in which, however, the white corpuscles are found to be in larger proportions than in ordinary blood. The sustentacular cells are either small uni-nucleated or larger multi-nucleated cells; they do not stain deeply with carmine, like the cells of the Malpighian bodies, presently to be described (W. Müller), but like them they possess amoeboid movements (Cohnheim). In many of them may be seen deep red or reddish-yellow granules of various sizes which present the characters of the hematin of the blood. Sometimes, also, unchanged blood-disks are seen included in these cells, but more frequently blood-disks are found which are altered both in form and color. In fact, blood-corpuscles in all stages of disintegration may be noticed to occur within them. Klein has recently pointed out that sometimes these cells in the young spleen contain a proliferating nucleus; that is to say, the nucleus is of large size, and presents a number of knob-like projections, as if small nuclei were budding from it by a process of gemmation. This observation is of importance, as it may explain one possible source of the colorless blood-corpuscles.

The interspaces or areolae formed by the framework of the spleen are thus filled by a delicate reticulum of branched connective-tissue corpuscles, the interstices of which are occupied by blood, and in which the blood-vessels terminate in the manner now to be described.

**Blood-vessels of the Spleen.**—The splenic artery (Fig. 974) is remarkable for its large size in proportion to the size of the organs, and also for its tortuous course. It divides into six or more branches, which enter the hilum of the spleen and ramify throughout its substance, receiving sheaths from the involution of the external fibrous tissue. Similar sheaths also invest the nerves and veins.

Each branch runs in the transverse axis of the organ from within outward, diminishing in size during its transit, and giving off in its passage smaller branches, some of which pass to the anterior, others to the posterior part. These ultimately leave the trabecular sheaths, and terminate in the proper substance of the spleen in small tufts or pencils of minute arterioles, which open into the interstices of the reticulum formed by the branched sustentacular cells (Figs. 977, 978, and 979). Each of the larger branches of the artery supplies chiefly that region of the organ in which the branch ramifies, having no anastomosis with the majority of the other branches.
The arterioles (Fig. 979), supported by the minute trabeculae, traverse the pulp in all directions in bundles or pencilli of straight vessels. Their external coat, on leaving the trabecular sheaths, consists of ordinary connective tissue, but it gradually undergoes a transformation, becomes much thickened, and is converted into a lymphoid material. This change is effected by the conversion of the connective tissue into a lymphoid tissue, the bundles of connective tissue becoming looser and laxer, their fibrils more delicate, and containing in their interstices an abundance of lymph-corpuscles (W. Müller). This lymphoid material is supplied with blood by minute vessels derived from the artery with which they are in contact, and which terminates by breaking up into a network of capillary vessels.

The altered coat of the arterioles, consisting of lymphoid tissue (Fig. 979), presents here and there thickenings of a spheroidal shape, the Malpighian bodies of the spleen (noduli lymphatici lienales [Malpighii]) (Fig. 978). These bodies vary in size from about the $\frac{1}{10}$ of an inch to the $\frac{1}{25}$ of an inch in diameter. They are merely local expansions or hyperplasias of the lymphoid tissue of which the external coat of the smaller arteries of the spleen is formed. They are most frequently found surrounding the arteriole, which thus seems to tunnel them, but occasionally they grow from one side of the vessel only, and present the appearance of a sessile bud growing from the arterial wall. Klein, however, denies this, and says it is incorrect to describe the Malpighian bodies as isolated masses of adenoid tissue, but that they are always formed around an artery, though there is generally a greater amount on one side than on the other, and that, therefore, in transverse sections the artery in the majority of cases is found in an eccentric position. These bodies are visible to the naked eye on the surface of a fresh section of the organ, appearing as minute dots of semi-opaque whitish color in the dark substance of the pulp. In minute structure they resemble the adenoid tissue of lymphatic glands, consisting of a delicate reticulum in the meshes of which lie ordinary lymphoid cells.

The reticulum of the tissue is made up of extremely delicate fibrils, and is comparatively open in the centre of the corpuscle, becoming closer at the periphery of the body. The cells which it encloses, like the supporting cells of the pulp, are possessed of amoeboid movements, but when treated with carmine become deeply stained, and can thus easily be recognized from those of the pulp.

The arterioles terminate in capillaries, which traverse the pulp in all directions; their walls become much attenuated, lose their tubular character, and the cells of the lymphoid tissue of which they are composed become altered; presenting a branched appearance and acquiring processes which are directly connected with the processes of the sustentacular cells of the pulp (Fig. 979). In this manner the capillary vessels terminate, and the blood flowing through them finds its way into the interstices of the reticulated tissue formed by the branched connective-tissue corpuscles of the splenic pulp. Thus the blood passing through the spleen is brought into intimate relation with the elements of the pulp, and no doubt undergoes important changes.

After these changes have taken place the blood is collected from the interstices of the tissue by the rootlets of the veins (Fig. 976), which commence much in the

---

1 According to Klein, it is the sheath of the small vessel which undergoes this transformation, and forms a solid mass of adenoid tissue which surrounds the vessel like a cylindrical sheath. (Atlas of Histology, p. 424.)
same way as the arteries terminate. Where a vein is about to originate the connective-tissue corpuscles of the pulp arrange themselves in rows in such a way as to form an elongated space or sinus. They become changed in shape, being elongated and spindle-shaped, and overlap each other at their extremities. They thus form a sort of endothelial lining of the path or sinus, which is the radicle of a vein. On the outer surface of these cells are seen delicate transverse lines or markings which are due to minute elastic fibrillae arranged in a circular manner around the sinus. Thus the channel obtains a continuous external investment, and gradually becomes converted into a small vein, which after a time presents a coat of ordinary connective tissue, lined by a layer of fusiform endothelial cells which are continuous with the supporting cells of the pulp. The smaller veins unite to form larger ones which do not accompany the arteries, but soon enter the trabecular sheaths of the capsule, and by their junction form from six or more branches which emerge from the hilum and, uniting, form the splenic vein, the largest radicle of the portal vein (Figs. 971 and 975).

The veins are remarkable for their numerous anastomoses, while the arteries hardly Anastomose at all.

The lymphatics originate in two ways—i.e., from the sheaths of the arteries and in the trabecule. The former trunks are the deep collecting trunks, and accompany the blood-vessels; the latter pass to the superficial lymphatic plexus, which may be seen on the surface of the organ. The two sets communicate in the interior of the organ. The deep trunks at the hilum number from five to ten, and terminate in the splenic glands. The superficial trunks also pass to the hilum and terminate in the splenic glands.

The nerves are derived from the splenic plexus, which is part of or connected with the solar plexus. The nerves enter the spleen with the vessels.

**Surface Form.**—The spleen is situated under cover of the ribs of the left side, being separated from them by the Diaphragm, and above by a small portion of the lower margin of the left lung and pleura. Its position corresponds to the eighth, ninth, tenth, and eleventh ribs. It is placed very obliquely. “It is oblique in two directions—viz., from above downward and outward, and also from above downward and forward” (Cunningham). “Its highest and lowest points are on a level respectively with the ninth dorsal and first lumbar spines; its inner end is distant about an inch and a half from the median plane of the body, and its outer end about reaches the mid-axillary line” (Quain).

**Surgical Anatomy.**—Injury of the spleen is less common than that of the liver, on account of its protected situation and connections. It may be ruptured by direct or indirect violence, torn by a broken rib, or injured by a punctured or gunshot wound. When the organ is enlarged the chance of rupture is increased. The great risk is hemorrhage, owing to the extreme vascularity of the organ, and the absence of a proper system of capillaries. The injury is not, how-
ever, necessarily fatal, and this would appear to be due in a great measure to the contractile power of its capsule, which narrows the wound and thus antagonizes the escape of blood. In cases in which the symptoms suggest such an injury and indicate danger to life, laparotomy must be performed; and if the hemorrhage cannot be arrested by ordinary surgical methods the spleen must be removed. The spleen may become displaced, producing great pain from stretching of the vessels and nerves, and this dislocation may render necessary removal of the organ. The spleen may become enormously enlarged in certain diseased conditions, such as ague, leukemia, syphilis, valvular disease of the heart, or without any obtainable history of previous disease. It may also become enlarged in lymphadenoma as a part of a general blood disease. In these cases the mass may fill the abdomen and extend into the pelvis, and may be mistaken for ovarian or uterine disease.

The spleen is sometimes the seat of cystic tumors, especially hydatids, and of abscess. These cases require treatment by incision and drainage; and in abscess great care must be taken if there are no adhesions between the spleen and abdominal cavity, to prevent the escape of any of the pus into the peritoneal cavity. If possible, the operation should be performed in two stages. Sarcoma and carcinoma are occasionally found in the spleen, but very rarely as a primary disease. In movable spleen, if the organ is normal, follow the advice of Rydygier and loosen the parietal peritoneum to make a pocket, place the spleen in the pocket, and pass sutures through the parietal peritoneum and the splenic ligaments. A movable diseased spleen should be removed.

Extrirpation of the spleen has been performed for wounds or injuries, floating spleen, simple hypertrophy, and leukæmic enlargement; but in the latter case the operation is now regarded as unjustifiable, as it is practically certain to terminate fatally. The incision is best made in the left semilunar line: the spleen is isolated from its surroundings, and the pedicle transfixed and ligatured in two portions, before the tumor is turned out of the abdominal cavity, if this is possible, so as to avoid any traction on the pedicle, which may cause tearing of the splenic vein and which inevitably induces grave shock. In applying the ligatures the surgeon must not include the tail of the pancreas, and in lifting out the organ care must be taken to avoid rupturing the capsule.
THE ORGANS OF VOICE AND RESPIRATION.

THE LARYNX.

The larynx is the organ of voice, placed at the upper part of the air-passage. It is situated between the trachea and base of the tongue, at the upper and forepart of the neck, where it forms a considerable projection in the middle line. On either side of it lie the great vessels of the neck; behind, it forms part of the boundary of the pharynx, and is covered by the mucous membrane lining that cavity. Its vertical extent corresponds to the fourth, fifth, and sixth cervical vertebrae, but it is placed somewhat higher in the female and also during childhood. In infants between six and twelve months of age Symington found that the tip of the epiglottis was a little above the level of the cartilage between the odontoid process and body of the axis, and that between infancy and adult life the larynx descends for a distance equal to two vertebral bodies and two intervertebral disks. The movements of the head affect the position of the larynx. When the head is drawn back, the larynx is lifted, and when the chin approaches the chest the larynx is depressed. During swallowing the larynx moves distinctly; during singing it moves slightly. The larynx is suspended by the stylo-hyoid ligament, the
muscles of the upper border of the hyoid bone, the Stylo-pharyngeus and Palato-pharyngeus muscles. According to Sappey, the average measurements of the adult larynx are as follows:

<table>

</table>

Until puberty there is no marked difference between the larynx of the male and that of the female. In the latter its further increase in size is only slight, whereas in the former it is great; all the cartilages are enlarged, and the thyroid becomes prominent as the pomum Adami in the middle line of the neck, while the length of the glottis is nearly doubled.

The larynx is broad above, where it presents the form of a triangular box, flattened behind and at the sides, and bounded in front by a prominent vertical ridge. Below, it is narrow and cylindrical. It is composed of cartilages, which are connected together by ligaments and moved by numerous muscles. It is lined by mucous membrane, which is continuous above with that lining the pharynx and below with that of the trachea.

In the median line of the neck the larynx has in front of it the skin and cervical fascia. There is often a bursa between the skin and fascia over the most prominent part of the larynx. It is called the bursa subcutanea prominentiae laryngae. It is present particularly in men, and is seldom found in the young or in women. The larynx is covered on each side by the thyroid gland, and the Sterno-hyoid, Sterno-thyroid, Thyro-hyoid, and Omo-hyoid muscles, and the Inferior constrictors of the pharynx. Posterior is the laryngeal portion of the pharynx.

**The Cartilages of the Larynx (cartilagines laryngis).**—The cartilages of the larynx are nine in number, three single, and three pairs:

- Thyroid.
- Cricoid.
- Epiglottis.
- Two Arytenoid.
- Two Cornicula Laryngis.
- Two Cuneiform.

**The Thyroid Cartilage (cartilago thyroidea)** (Figs. 981 and 982).—The thyroid cartilage (from thyros, a shield) is hyaline cartilage and is the largest cartilage of the larynx. It is at the anterior and upper portion of the larynx. It consists of two lateral lamellae or alae, united at an acute angle in front, forming a vertical projection in the middle line, which is prominent above and called the pomum Adami (prominentia laryngae). This projection is subcutaneous, is more distinct in the male than in the female, and is often separated from the integument by a bursa, the bursa subcutanea prominentiae laryngae.

Each lamella is quadrilateral in form. Its outer surface (Fig. 981) presents an oblique ridge (linea obliqua), which passes downward and forward from a tubercle situated near the root of the superior cornu, the superior tubercle (tuberculum thyroideum superius), to a small tubercle near the anterior part of the lower border, the inferior tubercle (tuberculum thyroideum inferius). This ridge gives attachment to the Sterno-thyroid and Thyro-hyoid muscles, and the portion of cartilage included between it and the posterior border gives attachment to part of the Inferior constrictor muscle. Just below each superior tubercle there is often an opening, the thyroid foramen (foramen thyroideum).

The anterior borders of the alae of the thyroid cartilage which are continuous below are separated above by a V-shaped notch, the thyroid notch (incisura thyroidea [superior]).
The Inner Surface (Fig. 982) of each ala is smooth, slightly concave, and covered by mucous membrane above and behind; but in front, in the receding angle formed by their junction, are attached the epiglottis, the true and false vocal cords, the Thyro-arytenoid and Thyro-epiglottidean muscles, and the thyro-epiglottidean ligament.

The Upper Border or Margin of the Thyroid Cartilage (Fig. 982) is sinuously curved, being concave at its posterior part, just in front of the superior cornu, then rising into a convex outline, which dips in front to form the sides of the thyroid notch, in the middle line, immediately above the pomum Adami. This border gives attachment throughout its whole extent to the thyro-hyoid or hyothyroid membrane.

The Lower Border or Margin (Fig. 982) is nearly straight in front, but behind, close to the cornu, it is concave. It is connected to the cricoid cartilage, in and near the median line, by the middle portion of the crico-thyroid membrane (membrana cricothyreoidea); and, on either side, by the Crico-thyroid muscle.

The Posterior Borders (Fig. 982) are thick and rounded, and each terminates above, in a superior cornu (cornu superius), and below, in an inferior cornu (cornu inferius). The two superior cornua are long and narrow, directed upward, backward, and inward, and terminate in conical extremities, which give attachment to the lateral thyro-hyoid ligaments. The two inferior cornua are short and thick; they pass downward, with a slight inclination forward and inward, and each presents on its inner surface a small oval articular facet for articulation with the side of the cricoid cartilage (Fig. 981). The posterior border receives the insertion of the Stylo-pharyngeus and Palato-pharyngeus muscles on each side.

During infancy the alae of the thyroid cartilage are joined to each other by a narrow, lozenge-shaped strip, named the intrathyroid cartilage. This strip extends from the upper to the lower border of the thyroid cartilage in the middle line, and is distinguished from the alae by being more transparent and more flexible.

The Cricoid Cartilage (cartilago cricoidea) (Figs. 981, 982, and 984).—The cricoid cartilage is so called from its resemblance to a signet ring (στιγμή, a ring). It is smaller, but thicker and stronger than the thyroid cartilage, and forms the lower and back part of the cavity of the larynx. It is hyaline cartilage and consists of two parts: a quadratus portion, situated behind, and a narrow ring or arch, one-fourth or one-fifth the depth of the posterior part, situated in front. The posterior square portion rapidly narrows at the sides of the cartilage, at the expense of the upper border, into the anterior portion.

Its Posterior Portion or Lamina (lamina cartilaginis cricoidea) is very deep and broad, and measures from above downward about an inch (2 to 3 cm.); it presents, on its posterior surface, in the middle line, a vertical ridge for the attachment of the longitudinal fibres of the oesophagus; and on either side a broad depression for the Crico-arytenoides posticus muscle.

Its Anterior Portion or Arcus (arcus cartilaginis cricoidea) is narrow and convex, and measures vertically about one-fourth or one-fifth of an inch (5 to 7 cm.); it affords attachment externally in front and at the sides to the Crico-thyroid muscles, and, behind, to part of the Inferior constrictor.
At the point of junction of the posterior quadrate portion with the rest of the cartilage is a small round elevation, for articulation with the inferior cornu of the thyroid cartilage.

The **Lower Border** of the cricoid cartilage is horizontal, and connected to the upper ring of the trachea by fibrous membrane (Figs. 981 and 983).

Its **Upper Border** is directed obliquely upward and backward, owing to the great depth of the posterior surface. It gives attachment, in front, to the middle portion of the crico-thyroid membrane; at the sides, to the lateral portion of the same membrane and to the lateral Crico-arytenoid muscle; behind, it presents, in the middle, a shallow notch, and on each side of this is a smooth, oval surface, directed upward and outward, for articulation with the arytenoid cartilage.

The **Inner Surface** of the cricoid cartilage is smooth, and lined with mucous membrane.

The **Arytenoid Cartilages** (cartilagines arytaenoidae) (Figs. 982, 983, and 989).—The arytenoid cartilages are so called from the resemblance they bear, when approximated, to the mouth of a pitcher (*ὁρτάζων*, a pitcher). They are two in number, and situated at the upper border of the cricoid cartilage, at the back of the larynx in the interval between the posterior borders of the alae of the thyroid cartilages. Each cartilage is in form a three-sided pyramid, and presents for examination three surfaces, a base, and an apex.

The **Posterior Surface** is triangular, smooth, concave, and gives attachment to the transverse portion of the Arytenoid muscle.

The **Anterior or External Surface** is somewhat convex and rough. It presents, near its apex, a small elevation, the **colliculus**; from this a **ridge** (crista arcuata) passes backward and then forward and downward into a sharp-pointed process, the **vocal process**. This ridge separates a deep depression above, the **fovea triangularis**, from a broader and shallower depression below, the **fovea oblonga**. A short distance above the base a small tubercle gives origin to the ligament of the false vocal cord, the superior thyro-arytenoid ligament. To the outer part of the ridge, as well as the surface above and below, is attached the Thyro-arytenoid muscle.

The **Internal Surface** is narrow, smooth, and flattened, covered by mucous membrane, and forms the lateral boundary of the respiratory part of the glottis.
The **Base (basis)** of each cartilage is broad, and presents a concave smooth surface, for articulation with the cricoid cartilage. Two of its angles require special mention: the **external angle**, which is short, rounded, and prominent, projects backward and outward, and is termed the **muscular process (processus muscularis)**, from receiving the insertion of the Posterior and Lateral crico-arytenoid muscles. The **anterior angle**, also prominent, but more pointed, projects horizontally forward, and gives attachment to the inferior thyro-arytenoid ligament, the supporting ligament of the true vocal cord. This angle is called the **vocal process (processus vocalis)**.

The **Apex** of each cartilage is pointed, curved backward and inward, and surmounted by a small conical, cartilaginous-nodule, the **corniculum laryngis**, articulated with or united to the arytenoid cartilage.

The **Cuneiform Cartilages or Cartilages of Santorini** (cartilagines cuneilatae) (Figs. 982 and 988).—The cuneiform cartilages are two small conical nodules, consisting of white fibro-cartilage, which articulate with the summit of the arytenoid cartilages and serve to prolong them backward and inward. To them are attached the aryteno-epiglottidean folds. They are sometimes united to the arytenoid cartilages.

The **Cuneiform Cartilages or Cartilages of Wrisberg** (cartilagines cuneiformes) (Figs. 982 and 984).—The cuneiform cartilages are two small, elongated, cartilaginous bodies, placed one on each side, in the fold of mucous membrane which extends from the apex of the arytenoid cartilage to the side of the epiglottis, and is called the aryteno-epiglottidean fold (pleca arypepiglottica) (Fig. 984); they give rise to small whitish elevations on the inner surface of the mucous membrane, just in front of the arytenoid cartilages.

The **Epiglottis or the Cartilage of the Epiglottis** (cartilago epiglottica) (Figs. 980, 982, 983, 984, 985, and 988).—The epiglottis is a thin, flexible lamella of fibro-cartilage, of a yellowish color, shaped like a leaf, and placed behind the tongue in front of the superior opening of the larynx. Its free extremity, which is directed upward, is broad and rounded, and often notched; its attached part (petiolus epiglottidis) is long, narrow, and connected to the receding angle between the alee of the thyroid cartilage, just below the median notch, by a long, narrow ligamentous band, the **thyro-epiglottic ligament (Fig. 985)**. It is also connected to the posterior surface of the body of the hyoid bone by an elastic ligamentous band, the **hyo-epiglottic ligament**.

Its **Anterior or Lingual Surface** is curved forward, toward the tongue, and covered at its upper, free part by mucous membrane, which is reflected on to the sides and base of the organ, forming a median and two lateral folds, the **glosso-epiglottidean folds** (Fig. 984). The **median glosso-epiglottidean fold** contains the elastic **glosso-epiglottidean ligament (ligamentum glossopiglotticum)**. Each lateral glosso-epiglottidean fold runs from the front and side of the base of the epiglottis to the side of the tongue. The depression between the epiglottis and the base of the tongue on each side of the median fold is named the **vallecula epiglottica**. The lower part of the anterior surface of the epiglottis lies behind the hyoid bone, the thyro-hyoid membrane, and upper part of the thyroid cartilage, but is separated from these structures by a mass of fatty tissue.

Its **Posterior or Laryngeal Surface** is smooth, concave from side to side, concavo-convex from above downward; its lower part projects backward as an elevation, the **tubercle or cushion (tuberculum epiglotticum)(Fig. 983)**; when the mucous membrane is removed, the surface of the cartilage is seen to be studded with a number of small mucous glands, which are lodged in little pits upon its surface. To its sides the **aryteno-epiglottidean folds** are attached (Fig. 984).

**Structure.**—The cuneiform cartilages, the epiglottis, and the apices of the arytenoids are composed of yellow elastic cartilage, which shows little tendency to calcification; on the other hand, the thyroid, cricoid, and the greater part of the
arytenoids consist of hyaline cartilage, and become more or less ossified as age advances. Ossification commences about the twenty-fifth year in the thyroid cartilage, somewhat later in the cricoid and arytenoids; by the sixty-fifth year these cartilages may be completely converted into bone. The cornicula laryngis consist of white fibro-cartilage, which becomes osseous about the seventieth year.

**Ligaments, Joints, and Membranes of the Larynx.**—The ligaments of the larynx are extrinsic—i.e., those connecting the thyroid cartilage and epiglottis with the hyoid bone, and the cricoid cartilage with the trachea; and intrinsic, those which connect the several cartilages of the larynx to each other.

The ligaments connecting the thyroid cartilage with the hyoid bone are three in number—the thyro-hyoid membrane, and the two lateral thyro-hyoid ligaments. The Thyro-hyoid or Hyo-thyroid Membrane or Ligament (membrana hyothyreoidea) (Fig. 985) is a broad, fibro-elastic, membranous layer, attached below to the upper border of the thyroid cartilage, and above to the posterior border of the body and greater cornua of the hyoid bone, passing behind the postero-inferior surface of the hyoid, and being separated from this surface by a synovial bursa (bursa m. sternohyoiden), which facilitates the upward movement of the larynx during deglutition. The membrane is thicker in the middle line than at either side. This thickening is due to elastic fibres, and constitutes the middle thyro-hyoid ligament (ligamentum hyothyreoideum medium). On each side the posterior extremity of the membrane is thickened by elastic fibres, constituting the lateral thyro-hyoid ligament (ligamentum hyothyreoideum laterale). The thyro-hyoid membrane is pierced on each side by the superior laryngeal vessels and the internal laryngeal nerve. The anterior surface of the thyro-hyoid membrane is in relation with the Thyro-hyoid, Sterno-hyoid, and Omo-hyoid muscles and with the body of the hyoid bone. The two lateral ligaments are rounded, elastic cords, which pass between the superior cornua of the thyroid cartilage and the extremities of the greater cornua of the hyoid bone. A small cartilaginous nodule (cartilago triticia), sometimes bony, is frequently found in each.

The Membrana Quadrangularis is an elastic membrane containing numerous glands. The fibres of the membrane run in part downward and in part downward and backward. The membrane on each side arises in front and above at the lateral margin of the cartilage of the epiglottis, below at the posterior surface of the angle of the thyroid cartilage and becomes attached behind to the cornicula laryngis and to the inner margins of the arytenoid cartilages. The membranes converge below and medianward. The ligamentum ventriculare is the superior end of the membrane (Spalteholz). The fibres constituting the ligamentum ventriculare are given off at the thyroid cartilage above the ligamentum vocale and pass horizontally backward to the medial margin of the fovea triangularis of the arytenoid cartilage. The epiglottis is connected to the tongue by the three glosso-epiglottidean folds of mucous membrane, which may also be considered as extrinsic ligaments of the epiglottis.

The Glosso-epiglottidean Folds or Ligaments (plicae epiglotticae) (Fig. 984) number three. The middle glosso-epiglottidean fold (plica glossoepiglottica mediana) passes from the middle of the anterior free surface of the epiglottis to the base of the tongue. It contains the glosso-epiglottic ligament. The lateral glosso-epiglottidean or the pharyngo-epiglottidean fold (plica glossoepiglottica lateralis) on each side passes from the side of the epiglottis to the side of the base of the tongue and to the pharyngeal wall. On each side between the median and lateral folds is a depression, the vallecula epiglottica.

The Hyo-epiglottic Ligament (ligamentum hyoepiglotticum) is an elastic band, which extends from the anterior surface of the epiglottis, near its apex, to the

2 Ibid.
upper border of the body of the hyoid bone. The epiglottis is attached to the thyroid cartilage, below and behind the superior thyroid notch, by the strong and elastic *thyro-epiglottic ligament* (ligamentum thyreoepiglotticum) (Fig. 985). Between the epiglottis, the hyo-epiglottic ligament, and the thyro-hyoid membrane is a triangular space containing fat on each side of the median line.

The ligaments connecting the thyroid cartilage to the cricoid are also three in number—the *crico-thyroid membrane* and the *capsular ligaments*.

The **Crico-thyroid Membrane** (cornu elasticum) (Figs. 971 and 988) is an elastic membrane which passes radially from the posterior surface of the angle of the thyroid cartilage to the upper margin of the arch of the cricoid cartilage and to the vocal processes of the arytenoid cartilages. It is composed mainly of yellow elastic tissue. It consists of three parts, a central triangular portion and two lateral portions. The central part (ligamentum cricothyreoideum medium) is thick and strong, narrow above and broadening out below. It connects together the contiguous margins of the thyroid and cricoid cartilages. It is convex, concealed on each side by the Crico-thyroid muscle, but subcutaneous in the middle line; it is crossed horizontally by a small anastomotic arterial arch, formed by the junction of the two *crico-thyroid arteries*. The lateral portions are thinner and lie close under the mucous membrane of the larynx. They extend from the superior border of the cricoid cartilage to the inferior margin of the true vocal cords with which they are continuous. On each side are the uppermost fibres from the inferior thyro-arytenoid ligament (ligamentum vocale).

The lateral portions are lined internally by mucous membrane, and are separated from the thyroid cartilage by the lateral Crico-arytenoid and Thyr-o-arytenoid muscles. This membrane and the muscles just mentioned reduce greatly the interior of the larynx. The crico-thyroid membrane with the membrana quadrangularis constitute the *membrana elastica laryngis*.

The **Crico-arytenoid Articulation** (articulatio cricoarytaenoidea) (Fig. 981), on each side of the inferior cornu of the thyroid, with the cricoid cartilage on each side. A loose *synovial membrane* (capsula articularis cricoarytaenoidea) encloses the articulation.

The synovial capsule is strengthened by the ligamenta ceratocricoida, which pass from the lesser cornu of the thyroid to the lamina of the cricoid cartilage.

The **Crico-arytenoid Articulation** (articulatio cricoarytaenoidea) (Fig. 982) on each side is between the articular surface of the arytenoid cartilage and the arytenoid articular surface of the cricoid cartilage.

The ligaments connecting the arytenoid cartilages to the cricoid are on each side a *capsular ligament* (capsula articularis cricoarytaenoidea) and a *posterior crico-arytenoid ligament* (ligamentum cricoarytaenoideum posterius). The capsular ligaments are thin and loose capsules attached to the margin of the articular
surfaces; they are lined internally by synovial membrane. The posterior crico-arytenoid ligaments extend from the cricoid to the inner and back part of the base of the arytenoid cartilage.

The **Crico-tracheal Ligament** (*ligamentum cricotracheale*) connects the cricoid cartilage with the first ring of the trachea. It resembles the fibrous membrane which connects the cartilaginous rings of the trachea to each side.

There is on each side an articulation between the arytenoid cartilage and the **cartilage of Santorini** (*synchondrosis aryconiculata*). The cartilage of Santorini is somewhat movable and is fixed to the arytenoid by lax connective tissue. From each cartilage of Santorini a band of connective tissue runs down to the lamina of the cricoid cartilage and to the pharyngeal mucous membrane. Beneath the arytenoid muscles the ligaments from the two sides join and pass down together. Thus is formed a Y-shaped ligament called the **ligamentum corniculopharyngeum**. The portion between the cricoid cartilage and the mucous membrane of the pharynx is sometimes called the **ligamentum cricopharyngeum**.

**Interior of the Larynx** (Figs. 983, 984, and 985).—The **cavity of the larynx** (*cavum laryngis*) extends from the superior aperture of the larynx to the lower border of the cricoid cartilage. It is divided into two parts by the projection inward of the true vocal cords, between which is a narrow triangular fissure or chink, the **rima glottidis**. It is further subdivided by the false vocal cords. So we consider the larynx as divided into a portion above the false cords, a portion between the false and true vocal cords, and a portion below the true cords. The entrance of the first compartment is the superior aperture of the larynx.

**The Superior Aperture of the Larynx** (*adiitus laryngis*).—The superior aperture of the larynx (Figs. 983 and 984) is a triangular or cordiform opening, wide in front, narrow behind, and sloping obliquely downward and backward. It is bounded, in front, by the epiglottis; behind, by the apices of the arytenoid cartilages and the cornicula laryngis; and laterally, by a fold of mucous membrane, enclosing ligamentous and muscular fibres, stretched between the sides of the epiglottis and the apices of the arytenoid cartilages; these are the **aryteneo-epiglottidean folds** (Figs. 984 and 985), on the margins of which the cuneiform cartilages form more or less distinct whitish prominences.

The small gap between the cartilages of Santorini is called the **incisura interarytanoidea**. On the pharynx, on either side of the posterior portion of the superior aperture of the larynx, is a recess, called the **sinus pyriformis**.

**Upper Compartment or Vestibule of the Laryngeal Cavity** (*vestibulum laryngis*) (Figs. 983 and 985).—The vestibule is the portion between the superior opening and the false vocal cords. It is much narrower below than above. It is bounded anteriorly by the mucous membrane-covered epiglottis. The lower part of the epiglottis exhibits a prominence called the **cushion or tubercle** (Fig. 983). The lateral wall of the vestibule on each side is the **aryteneo-epiglottidean fold** (Fig. 985), which extends from the summit of the arytenoid cartilage forward, upward, and outward to the margin of the epiglottis, and which contains fibres of the Thyro-epiglottideus and Arytenoideus muscles (*musculus arytenoepiglottidean*). Near the posterior end of the fold are two trivial elevations: the anterior elevation is caused by the prominence of the cuneiform cartilage, and is called the **cuneiform tubercle of Wrisberg** (*tuberculum cuneiforme [Wrisbergi]*); the posterior elevation is caused by the anterior margin of the arytenoid cartilage and the cartilage of Santorini, and is called the **cornical tubercle of Santorini** (*tuberculum corniculatum [Santorini]*). Between these elevations is a groove, the **filtrum ventriculi of Merkel**, which passes into the space between the false and true vocal cords. The anterior elevation passes into the false vocal cord, the posterior elevation into the true vocal cord. The posterior portion of the laryngeal vestibule is the narrow space between the upper portions of the arytenoid cartilages.
The Middle Compartment of the Larynx (Figs. 983 and 985).—This lies between the false vocal cords above and the true vocal cords below. It is the smallest of the laryngeal compartments. It opens into the vestibule by way of the gap between the false vocal cords, which is called the false glottis; it opens into the lower compartment of the larynx by way of the space between the true vocal cords, the true glottis.

The True Glottis.—The true glottis is the apparatus for producing tone and is formed by the true vocal cords.

The Chink of the Glottis (rima glottidis) (Figs. 983 and 984).—The chink of the glottis is the elongated fissure or chink between the inferior or true vocal cords in front, and between the bases and vocal processes of the arytenoid cartilages behind. It is therefore frequently subdivided into an anterior, interligamentous or vocal portion, the glottis vocalis (pars intermembranacea), and a posterior, intercartilaginous or respiratory portion, the glottis respiratoria (pars intercartilaginea). Posteriorly it is limited by the mucous membrane passing between the arytenoid cartilages. The vocal portion averages about three-fifths of the length of the entire aperture. It is the narrowest part of the cavity of the larynx, and its level corresponds to the bases of the arytenoid cartilages. Its length, in the male, measures rather less than an inch (20 to 25 mm.); in the female it is shorter by 5 or 6 mm., or three lines. The width and shape of the rima glottidis vary with the movements of the vocal cords and arytenoid cartilages during respiration and phonation. In the condition of rest—i.e., when these structures are uninfluenced by muscular action, as in quiet respiration, the glottis vocalis is triangular, with its apex in front and its base behind, the latter being represented by a line about 8 mm. long, connecting the anterior extremities of the vocal processes, while the inner surfaces of the arytenoids are parallel to each other, and hence the glottis respiratoria is rectangular. During extreme adduction of the cords, as in the emission of a high note, the glottis vocalis is reduced to a linear slit by the apposition of the cords, while the glottis respiratoria is triangular, its apex corresponding to the anterior extremities of the vocal processes of the arytenoids, which are approximated by the inward rotation of the cartilages. Conversely in extreme abduction of the cords, as in forced inspiration, the arytenoids and their vocal processes are rotated outward, and the glottis respiratoria is triangular in shape, but with its apex directed backward. In this condition the entire glottis is somewhat lozenge-shaped, the sides of the glottis vocalis diverging from before backward, those of the glottis
respiratoria diverging from behind forward, the widest part of the aperture corresponding with the attachment of the cords to the vocal processes. 1

The Superior or False Vocal Cords (plicae ventriculares) (Figs. 983, 984, and 985), so called because they are not directly concerned in the production of the voice. Each is a thick fold of mucous membrane, enclosing a narrow band of fibrous tissue, the superior thyro-arytenoid ligament, which is attached in front to the angle of the thyroid cartilage immediately below the attachment of the epiglottis, and behind to the anterior surface of the arytenoid cartilage. The lower border of this ligament, enclosed in mucous membrane, forms a free crescentic margin, which constitutes the upper boundary of the ventricle of the larynx. The false vocal cord contains the lower part of the membrana quadrangularis with the ligamentum ventriculare, the muscle ventricularis, and laryngeal glands.

The Inferior or True Vocal Cords (plicae vocales) (Figs. 983, 984, 985, and 989), so called from their being concerned in the production of sound. Each is a strong band, the inferior thyro-arytenoid ligament (ligamentum vocale), covered on its surface by a thin layer of mucous membrane. Each ligament consists of a band of yellow elastic tissue, attached in front to the depression between the alae of the thyroid cartilage, and behind to the anterior angle of the base of the arytenoid. This angle is called the vocal process. Its lower border is continuous with the thin lateral part of the crico-thyroid membrane. Its upper border forms the lower boundary of the ventricle of the larynx. Externally, the Thyro-arytenoideus muscle lies parallel with it. It is covered internally by mucous membrane, which is extremely pale, thin, and closely adherent to its surface. The upper margin of the true vocal cord is covered with mucous membrane, and is the lower boundary of the ventricle of the larynx. Over the vocal process it is yellowish (macula flava). The true vocal cord contains the upper part of the crico-thyroid membrane with the ligamentum vocale and the muscle vocalis.

1 On the shape of the rima glottidis, in the various conditions of breathing and speaking, see Czermak. On the Laryngoscope, translated for the New Sydenham Society.—Ed. of 15th English edition.
The Ventricile of the Larynx or Laryngeal Sinus (ventriculus laryngis [Morgagnii]) (Figs. 970 and 972) is an oblong fossa, situated between the superior and inferior vocal cords on each side, and extending nearly their entire length. This fossa is bounded, above, by the free crescentic edge of the superior vocal cord; below, by the straight margin of the inferior vocal cord; externally, by the mucous membrane covering the corresponding Thyro-arytenoideus muscle. The anterior part of the ventricle leads up by a narrow opening into a caecal pouch of mucous membrane of variable size, called the laryngeal pouch.

The Laryngeal Sacculæ or Pouch (appendix ventriculi) (Fig. 983), or laryngeal pouch, is a membranous sac, placed between the superior vocal cord and the inner surface of the thyroid cartilage, occasionally extending as far as its upper border or even higher; it is conical in form, and curved slightly backward. On the surface of its mucous membrane are the openings of sixty or seventy mucous glands, which are lodged in the submucous areolar tissue. This sac is enclosed in a fibrous capsule, continuous below with the superior thyro-arytenoid ligament; its laryngeal surface is covered by the Aryteno-epiglottideus inferior muscle (compressor sacculi laryngis of Hilton); while its exterior is covered by the Thyro-arytenoideus and Thyro-epiglottideus muscles. These muscles compress the sacculus laryngis, and discharge the secretion it contains upon the vocal cords, the surfaces of which it is intended to lubricate.

The Lower Compartment of the Larynx (Figs. 983 and 985).—This space is just beneath the true vocal cords and leads into the trachea. It is called the additus glottidis inferior. Above, on cross-section, it is oval; below, it is round. It is bounded by the inner surface of the crico-thyroid membrane and the cricoid cartilage.

Muscles of the Larynx (musculi laryngis).—We do not consider all muscles which are attached to laryngeal cartilages as laryngeal muscles. Some muscles so attached in reality belong to other regions, for instance, the Inferior constrictor, the Stylo-pharyngeus, the Sterno-thyroid, the Thyro-hyoid, and the Palatopharyngeus. The muscles which really belong to the larynx are called intrinsic.

Four muscles of the vocal cords and rima glottidis are paired and one is single.
The paired muscles are the crico-thyroid, the posterior crico-arytenoid, the lateral crico-arytenoid, and the thyro-arytenoid. The single muscle is the arytenoideus.

A Crico-thyroid (m. crico-thyreoides) (Figs. 981, 983, and 986) is placed on each side. It is triangular in form, and situated at the forepart and side of the cricoid cartilage. It arises from the front and lateral part of the cricoid cartilage; its fibres diverge, passing obliquely upward and outward to be inserted into the lower border of the thyroid cartilage and into the anterior border of the lower cornu.

The inner borders of these two muscles are separated in the middle line by a triangular interval occupied by the central part of the crico-thyroid membrane.

The Posterior Crico-arytenoid (m. cricoarytaenoideus posterior) (Figs. 987, 988, and 989), a paired muscle, arises from the broad depression occupying each lateral half of the posterior surface of the cricoid cartilage; its fibres pass upward and outward, converging to be inserted into the outer angle (museum process) of the base of the arytenoid cartilage. The upper fibres are nearly horizontal, the middle oblique, and the lower almost vertical.

The Arytenoideus (Figs. 985, 987, 988, and 989) is a single muscle filling up the posterior concave surface of the arytenoid cartilages. It arises from the posterior surface and outer border of one arytenoid cartilage, and is inserted into the corresponding parts of the opposite cartilage. It consists of three planes of fibres, two oblique and one transverse. The oblique fibres (m. arytaenoideus obliquus), the most superficial, form two fasciculi, which pass from the base of one cartilage to the apex of the opposite one. The transverse fibres (m. arytaenoideus transversus), the deepest and most numerous, pass transversely across between the two cartilages; hence the Arytenoideus was formerly considered as three muscles, the transverse.
verse and the two oblique. A few of the oblique fibres are around the outer margin of the cartilage, and blend with the Thyro-arytenoid in the aryteno-epiglottidean fold, and are called the Aryteno-epiglottideus muscles.

In order to expose the rest of the muscles of the larynx the thyroid cartilage of one side must be removed. Begin by taking away the crico-thyroid muscle, then dividing the lateral thyro-hyoid ligament; disarticulate the inferior cornu of the thyroid cartilage from the cricoid cartilage, then carefully cut through the thyroid cartilage a short distance from its union with its twin. The following muscles will then be exposed after a little cleaning: the Lateral crico-thyroid, the Thyro-arytenoid, the Thyro-epiglottideus.

The Lateral crico-arytenoid (m. cricoarytenoideus lateralis) (Figs. 988 and 989), a paired muscle, is smaller than the preceding, and of an oblong form. It arises from the upper border of the side of the cricoid cartilage, and, passing obliquely upward and backward, is inserted into the muscular process of the arytenoid cartilage in front of the posterior Crico-arytenoid muscle.

The Thyro-arytenoid (m. thyroarytenoideus) (Figs. 988 and 989), a paired muscle, is broad and flat. It lies parallel with the outer side of the true vocal cord. It arises in front from the lower half of the receding angle of the thyroid cartilage, and from the crico-thyroid membrane. Its fibres pass backward and outward, to be inserted into the base and anterior surface of the arytenoid cartilage. This muscle consists of two fasciculi. The inner or inferior fasciculus (m. vocalis), the thicker, is prismatic in shape and is inserted into the vocal process of the arytenoid cartilage, and into the adjacent portion of its anterior surface; it lies parallel with the true vocal cord, to which it is adherent. This fasciculus on its deeper surface gives off some fibres which are attached to the true vocal cord. These are called the ary-vocalis (Ludwig). The outer or superior fasciculus, the thinner, is inserted into the anterior surface and outer border of the arytenoid cartilage above the preceding fibres; it lies on the outer side of the sacculus laryngis, immediately beneath the mucous membrane.

The muscles of the epiglottis are the—

Thyro-epiglottideus. Aryteno-epiglottideus superior.

Aryteno-epiglottideus inferior.

The Thyro-epiglottideus (m. thyroepiglotticus) is a delicate fasciculus, which arises from the inner surface of the thyroid cartilage, just external to the origin of the Thyro-arytenoid muscle, of which it is sometimes described as a part, and spreads over the outer surface of the sacculus laryngis; some of its fibres are lost in the aryteno-epiglottidean fold, while the others are continued forward to the margin of the epiglottis.

The Aryteno-epiglottideus (Figs. 983 and 988) is properly divided into two muscles, a superior and an inferior.

The Aryteno-epiglottideus superior consists of a few delicate muscular fasciculi, which arise from the apex of the arytenoid cartilages, and become lost in the fold of mucous membrane, the aryteno-epiglottidean fold, extending between the arytenoid cartilage and the side of the epiglottis.

The Aryteno-epiglottideus inferior, the Compressor sacculi laryngis of Hilton, arises from the arytenoid cartilage, just above the attachment of the superior vocal cord; passing forward and upward, it spreads out upon the anterior surface of the epiglottis. This muscle is separated from the preceding by an indistinct areolar interval.

1 Henle describes these two portions as separate muscles, under the names of the External and Internal thyro-arytenoid.—Ed. of 15th English edition.
2 Luschka has described a small but fairly constant muscle as the Arytenoideus rectus. It is attached below to the posterior concave surface of the arytenoid cartilage, beneath the Arytenoideus muscle, and, passing upward, emerges at the upper border of this muscle, and is inserted into the posterior surface of the cartilage of Santorini (Anatomy, by Hyrtl, p. 718).—Ed. of 15th English edition.
3 Musculus triticeo-glossus. Bochdalek, Jr. (Prager Vierteljahrschrift, 1866, 2d part) describes a muscle hitherto entirely overlooked, except by Henle, who makes a brief statement in his Anatomy, which arises from the node of cartilage (corpus tritceum) in the posterior thyro-hyoid ligament, and passes forward and upward to enter the tongue along with the Hyo-glossus muscle. He met with this muscle eight times in twenty-two subjects. It occurred in both sexes, sometimes on both sides, at others on one only.—Ed. of 15th English edition.
Actions.—In considering the action of the muscles of the larynx, they may be conveniently divided into two groups, viz.: 1. Those which open and close the glottis. 2. Those which regulate the degree of tension of the vocal cords.

1. The muscles which open the glottis are the two Posterior crico-arytenoids; and those which close it are the Arytenoideus and the two Lateral crico-arytenoids.

2. The muscles which regulate the tension of the vocal cords are the two Cricothyroids, which tense and elongate them, and the two Thyro-arytenoids, which relax and shorten them. The Thyro-epiglottideus is a depressor of the epiglottis, and the Aryteno-epiglottideus, superior and inferior, constrict the superior aperture of the larynx.

The Posterior crico-arytenoids separate the chordae vocales, and consequently open the glottis, by rotating the arytenoid cartilages outward around a vertical axis passing through the crico-arytenoid joints, so that their vocal processes and the vocal cords attached to them become widely separated.

The Lateral crico-arytenoids close the glottis by rotating the arytenoid cartilages inward so as to approximate their vocal processes.

The Arytenoideus muscle approximates the arytenoid cartilages, and thus closes the opening of the glottis, especially at its back part.

The Crico-thyroid muscles produce tension and elongation of the vocal cords. This is effected as follows: the thyroid cartilage is fixed by its extrinsic muscles; then the Crico-thyroid muscles, when they act, draw upward the front of the cricoideal cartilage, and so depress the posterior portion, which carries with it the arytenoid cartilages, and thus elongate the vocal cords.

The Thyro-arytenoid muscles, consisting of two parts having different attachments and different directions, are rather complicated as regards their action. Their main use is to draw the arytenoid cartilages forward toward the thyroid, and thus shorten and relax the vocal cords. But, owing to the connection of the inner portion with the vocal cord, this part, if acting separately, is supposed to modify its elasticity and tension, and the outer portion, being inserted into the outer part of the anterior surface of the arytenoid cartilage, may rotate it inward, and thus narrow the rima glottidis by bringing the two cords together.

The Thyro-epiglottidei may depress the epiglottis; they assist in compressing the sacculi laryngis. The Aryteno-epiglottideus inferior constricts the superior aperture of the larynx, when it is drawn upward, during deglutition. The aryteno-epiglottideus inferior, together with some fibres of the Thyro-arytenoidei, compress the sacculus laryngis.

The Mucous Membrane of the Larynx is continuous above with that lining the mouth and pharynx, and it is prolonged through the trachea and bronchi into the lungs. It lines the posterior surface and the anterior part of the upper surface of the epiglottis, to which it is closely adherent. In the rest of the larynx, above the true vocal cords, it is lax and rests upon a considerable submucous layer. The mucous membrane, with the submucous coat, ligamentous and muscular fibres, forms the aryteno-epiglottidean folds, which folds are the lateral boundaries of the superior aperture of the larynx. It lines the whole of the cavity of the larynx; forms by its reduplication the chief part of the superior or false vocal cord; and, from the ventricle, is continued into the sacculus laryngis. It is then reflected over the true vocal cords, where it is thin and very intimately adherent; covers the inner surface of the crico-thyroid membrane and cricoid cartilage; and is ultimately continuous with the lining membrane of the trachea. The forepart of the anterior surface and the upper half of the posterior surface of the epiglottis, the upper part of the aryteno-epiglottidean folds, and the true vocal cords are covered by stratified squamous epithelium; the rest of the laryngeal mucous membrane is covered by columnar ciliated cells.

The mucous membrane above the rima glottidis is extremely sensitive, and during life the lightest touch of a foreign body produces cough.

Glands.—The mucous membrane of the larynx is furnished with numerous muciparous glands, the orifices of which are found in nearly every part; they are very numerous upon the epiglottis, being lodged in little pits in its substance; they are also found in large numbers along the posterior margin of the aryteno-epiglottidean fold, in front of the arytenoid cartilages, where they are termed the
arytenoid glands. They exist also in large numbers upon the inner surface of the sacculus laryngis. None are found on the surface of the true vocal cords.

Vessels and Nerves.—The arteries of the larynx (Fig. 990) are the laryngeal branches derived from the superior and inferior thyroid. The superior laryngeal artery from the superior thyroid courses along by the internal laryngeal nerve; the inferior laryngeal artery from the inferior thyroid courses along with the recurrent laryngeal nerve. The veins accompany the arteries; those accompanying the superior laryngeal artery join the superior thyroid vein which opens into the internal jugular vein; while those accompanying the inferior laryngeal artery join the inferior thyroid vein which opens into the innominate vein. The laryngeal lymphatics arise from a network in the mucous membrane. This network is divisible into two portions, a superior and an inferior, which are to be regarded as almost independent areas. The superior region includes all of the "laryngeal mucous membrane above the glottis, epiglottis, aryteno-epiglottidean folds, interarytenoid region, and superior vocal cords." The inferior area is the laryngeal mucous membrane below the glottis. The lymphatics of one-half of the larynx do not communicate with those of the other half in the median line in front, but do in the median line behind. The efferent vessels from the superior network accompany the superior laryngeal artery, pierce the thyro-hyoid membrane, and divide into three sets. One or two lymphatic vessels pass upward and terminate in a gland slightly below the posterior belly of the Digastric muscle. A group of vessels passes horizontally outward to terminate in the glands situated on the internal jugular vein on a level with the bifurcation of the common carotid artery. Another group descends and empties into the internal jugular group of glands at a lower level than the horizontal vessels. Trunks from the inferior network of the laryngeal mucous membrane form two groups. The anterior or supraracricoid group consists of three trunks which pass through the crico-thyroid membrane, to empty into the pre-laryngeal glands, the pre-tracheal gland, and the middle and lower deep cervical glands. The posterior group consists of

---

1 Philip R. W. De Santi in the Lancet, June 18, 1904.
2 Poirier, Cunéo, Most, De Santi.
of "from three to five trunks, which pass over the crico-tracheal fascia at the junction of the lateral and posterior aspects of the trachea," and terminate in the recurrent glands about the recurrent laryngeal nerve. The nerves are derived from the internal and external laryngeal branches of the superior laryngeal nerve, from the inferior or recurrent laryngeal, and from the sympathetic. The internal laryngeal nerve is almost entirely sensor, but some motor filaments are said to be carried by it to the Arytenoideus muscle. It divides into a branch which is distributed to both surfaces of the epiglottis, a second to the aryteno-epiglottidean folds, and a third, the largest, which supplies the mucous membrane over the back of the larynx and communicates with the recurrent laryngeal. The external laryngeal nerve supplies the Crico-thyroid muscle. The recurrent laryngeal passes upward under the lower border of the Inferior constrictor, and enters the larynx between the cricoid and thyroid cartilages. It supplies all the muscles of the larynx except the Crico-thyroid and part of the Arytenoideus. The sensor branches of the laryngeal nerves form subepithelial plexuses, from which fibres ascend to end between the cells covering the mucous membrane.

Over the posterior surface of the epiglottis, in the aryteno-epiglottidean folds, and less regularly in some other parts, taste-buds, similar to those in the tongue, are found.

THE TRACHEA AND BRONCHI (Fig. 991).

The trachea or windpipe is a cartilaginous membranous, elastic, cylindrical tube, flattened posteriorly, which extends from the lower part of the larynx, on a level with the sixth cervical vertebra, to opposite the body of the fourth, or sometimes of the fifth, thoracic vertebra, where it divides (bifurcato tracheae) into two bronchi, one for each lung. This point is at the level of the spine of the fourth thoracic vertebra. The trachea is found to be more deeply placed the lower down it is examined. It is in the median line, deviating below a very little to the right side. When a cross-section is made of the trachea it is seen that its anterior and lateral walls are rounded, but its posterior wall is flat (Fig. 995). The largest diameter of the tube is the middle; from this point the diameter diminishes toward the bronchi and toward the laryngeal end. The trachea measures about four inches and a half in length; its diameter from side to side is from three-quarters of an inch to an inch, being always greater in the male than in the female.

Relations.—The anterior surface of the trachea is convex, and covered in the neck, from above downward, by the isthmus of the thyroid gland, the inferior thyroid veins, the arteria thyroididea ima (when that vessel exists), the Sterno-hyoid and Sterno-thyroid muscles, the cervical fascia, and more superficially, by the anastomosing branches between the anterior jugular veins: in the thorax it is covered from before backward by the first piece of the sternum, the remains of the thymus gland, the left innominate vein, the arch of the aorta, the innominate and left common carotid arteries, and the deep cardiac plexus. Posteriorly, it is in relation with the oesophagus; laterally, in the neck, it is in relation with the common carotid arteries, the lateral lobes of the thyroid gland, the inferior thyroid arteries, and recurrent laryngeal nerves; and, in the thorax, it lies in the upper part of the interpleural space, that is, in the superior mediastinum, and is in relation on the right to the pleura and right vagus, and near the root of the neck to the innominate artery; on its left side are the recurrent laryngeal nerve, the aortic arch, the left common carotid and subclavian arteries.

The Right Bronchus (bronchus dexter).—The unbranched portion of the right bronchus is wider, shorter, and more vertical in direction than the left, is about an inch in length, and enters the hilum of the right lung opposite the fifth thoracic

1 De Santi, in the Lancet, June 18, 1904.
vertebra. It forms an angle to the median plane of about 29 degrees. The vena azygos major arches over it from behind; and the right pulmonary artery lies below and then in front of it. About three-quarters of an inch from its commencement it gives off a branch to the upper lobe of the right lung. This is termed the eparterial branch \((\text{ramus bronchialis eparterialis})\), because it is given off above the right pulmonary artery. The bronchus now passes below the artery, and is known as the hyparterial branch \((\text{ramus bronchialis hyparterialis})\). It divides into two branches for the middle and lower lobes.

If a transverse section of the trachea is made a short distance above its point of bifurcation, and a bird's-eye view taken of its interior (Fig. 995), the septum placed at the bottom of the trachea and separating the two bronchi will be seen to occupy the left of the median line, and the right bronchus appears to be a more direct continuation than the left, so that any solid body dropping into the trachea would naturally be directed toward the right bronchus. This tendency is aided by the larger size of the right tube as compared with its fellow. This fact
serves to explain why a foreign body in the trachea more frequently falls into the right bronchus than into the left.\(^1\)

**The Left Bronchus (bronchus sinister).**—The left bronchus is smaller and longer than the right, being nearly two inches in length. It forms an angle to the median plane of about 46 degrees. It is slightly curved and enters the root of the left lung, opposite the sixth thoracic vertebra, about an inch lower than the right bronchus. It passes beneath the arch of the aorta, crosses in front of the oesophagus, the thoracic duct, and the descending aorta, and has the left pulmonary artery lying at first above, and then in front of it. The left bronchus has no branch corresponding to the eparterial branch of the right bronchus, and therefore it has been supposed by some that there is no upper lobe to the left lung, but that the so-called upper lobe corresponds to the middle lobe of the right lung. The left bronchus does have an hyparterial branch.

When the main or stem bronchus enters the lung on each side it appears to divide into nearly equal branches at the root of the lung, but a somewhat similar arrangement to what is found in many animals may be made out where each main bronchus passes downward and backward toward the extremity of the lower lobe, and ends near the posterior surface of the base of the lung, a portion of pulmonary substance which is between the Diaphragm and the wall of the chest. It gives off four branches, or *lateral bronchi* (rami bronchiales), at intervals in two directions, dorsally and ventrally, and, in addition, accessory branches, which arise from the front of the bronchus and pass mesally and dorsally into the inferior lobe. In the right bronchus the first ventral branch supplies the middle lobe, the other three and all the dorsal going to the lower lobe; in the left bronchus, the first ventral branch supplies the middle lobe, the other three and all the dorsal going to the lower lobe; in the left bronchus, the first central supplies the superior lobe, and all the others, both ventral and dorsal, go to the lower lobe. The dorsal and ventral branches divide into smaller branches, and these again into smaller branches or *bronchioles* (Fig. 994). Each bronchioles divides into minute branches (*bronchiolae respiratorii*) (Fig. 994), the walls of which show numerous areas of bulging called *alveoli* (Fig. 994). From the bronchiolae respiratorii come the terminal branches of the bronchi. These terminal branches are the *alveolar ducts* (ductuli alveolares), and they are bulged by numerous alveoli (Fig. 994). They connect by openings at their termination with several cavities of irregular form, which are called *atria*. Each atrium is connected with several or many larger cavities, known as *sacculi alveolares, air-cells*, or *air-sacs* (*infundibula*). The entire surface of the air-sacs is filled with small cavities, the *pulmonary alveoli* (alveoli pulmonis). An alveolar duct with its branches forms a *pulmonary lobule* (lobulus pulmonis) (Fig. 993).

**Structure of the Trachea.**—The trachea is composed of imperfect cartilaginous rings, fibrous membrane, muscular fibres, mucous membrane, and glands.

**The Cartilages.**—The cartilages vary from sixteen to twenty in number; each forms an imperfect ring, which surrounds about two-thirds of the cylinder of the

---

\(^1\) Reigel asserts that the entrance of a foreign body into the *left* bronchus is by no means so infrequent as is generally supposed. See also Med.-Chir. Transactions, vol. lxxi., p. 121.—Ed. of 15th English edition.
trachea, being imperfect behind, where the tube is completed by fibrous membrane. The cartilages are placed horizontally above each other, separated by narrow membranous intervals. They measure about two lines in depth, and half a line in thickness. Their outer surfaces are flattened, but internally they are convex, from being thicker in the middle than at the margins. Two or more of the cartilages often unite, partially or completely, and are sometimes bifurcated at their extremities. They are highly elastic, but sometimes become calcified in advanced life. In the right bronchus the cartilages vary in number from six to eight; in the left, from nine to twelve. They are shorter and narrower than those of the trachea. The peculiar cartilages are the first and the last.

The First Cartilage is broader than the rest, and sometimes divided at one end; it is connected by fibrous membrane with the lower border of the cricoid cartilage, with which or with the succeeding cartilage it is sometimes blended.

The Last Cartilage is thick and broad in the middle, in consequence of its lower border being prolonged into a triangular hook-shaped process which curves downward and backward between the two bronchi. It terminates on each side in an imperfect ring which encloses the commencement of the bronchi. The cartilage above the last is somewhat broader than the rest at its centre.

The Fibrous Membrane.—The cartilages are enclosed in an elastic fibrous membrane which forms a double layer, one layer, the thicker of the two, passing over the outer surface of the ring, the other over the inner surface; at the upper and lower margins of the cartilages these two layers blend together to form a single membrane, which connects the rings one with another. They are thus, as it were, embedded in the membrane. In the space behind, between the extremities of the rings, the membrane forms a single distinct layer.

The Muscular Fibres.—The muscular fibres are disposed in two layers, longitudinal and transverse.
The **Longitudinal Fibres** are the most external, and consist merely of a few scattered longitudinal bundles of fibres.

The **Transverse Fibres** constitute the **Trachealis muscle of Todd and Bowman**. The most internal form a thin layer which extends transversely between the ends of the cartilages and the intervals between them at the posterior part of the trachea. The muscular fibres are of the unstriped variety.

**The Mucous Membrane.**—The mucous membrane is continuous above with that of the larynx, and below with that of the bronchi. Microscopically, it consists of areolar and lymphoid tissue, and presents a well-marked basement-membrane, supporting a layer of columnar, ciliated epithelium, between the deeper ends of which are smaller triangular cells, the bases of which, often branched, are attached to the basement-membrane. These triangular cells are mucus-secreting, and may be seen as goblet-cells or chalice-cells when their contents have been discharged. In the deepest part of the mucous membrane, and especially between the mucous and submucous layers, longitudinally arranged fibres are very abundant and form a distinct layer.

**The Tracheal Glands (glandulae tracheales).**—The tracheal glands are found in great abundance at the posterior part of the trachea. They are racemose glands, and consist of a basement-membrane lined by columnar mucus-secreting cells. They are situated at the back of the trachea, outside the layer of muscular tissue, between it and the outer fibrous layer. Their excretory ducts pierce the muscular and inner fibrous layers, and pass through the submucous and mucous layers to open on the surface of the mucous membrane. Some glands of smaller size are also found at the sides of the trachea, between the layers of fibrous tissue connecting the rings, and others immediately beneath the mucous coat. The secretion from these glands serves to lubricate the inner surface of the trachea.

**Vessels and Nerves.**—The trachea is supplied with blood by the inferior thyroid arteries. The **veins** terminate in the thyroid venous plexus. The **nerves** are derived from the vagus and its recurrent branches and from the sympathetic.
THE TRACHEA AND BRONCHI

Lymphatic Glands.—The trachea is surrounded by lax connective tissue which contains numerous lymph glands, known as the peritracheo-bronchial glands. They are divided into four groups (Baréty). A group to the right side, in the angle between the trachea and right bronchus and ascending to the region of the subclavian vessels. A group to the left side, in the angle formed by the trachea and left bronchus, and ascending to about the arch of the aorta and the recurrent laryngeal nerve. The two groups just described are usually called tracheal glands (lymphoglandulacœ tracheales). A third group is in the angle formed by the bifurcation of the trachea. These constitute the bronchial glands (lymphoglandulacœ bronchiales). They number ten or twelve (Cunéo). A fourth group, the interbronchial glands, are found in angles of bifurcation of the larger bronchi in the lung parenchyma. Very early in life the peritracheo-bronchial glands become dark or even black from the deposition of carbonaceous substance brought by the leukocytes from the bronchial tubes. This condition is called anthracosis.

Surface Form.—In the middle line of the neck some of the cartilages of the larynx can readily be distinguished. In the receding angle below the chin the hyoid bone can easily be made out, and a finger’s breadth below it is the pomum Adami, the prominence between the upper borders of the two alae of the thyroid cartilage. About an inch below this, in the middle line, is a depression corresponding to the crico-thyroid space, in which the operation of laryngotomy is performed. This depression is bounded below by a prominent arch, the anterior ring of the cricoid cartilage, below which the trachea can be felt, though it is only in the emaciated adult that the separate rings can be distinguished. The lower part of the trachea is not easily made out, for as it descends in the neck it takes a deeper position, and is farther removed from the surface. The level of the vocal cords corresponds to the middle of the anterior margin of the thyroid cartilage.

With the laryngoscope, the following structures can be seen: The base of the tongue and the upper surface of the epiglottis, with the glosso-epiglottic ligaments; the superior aperture of the larynx, bounded on either side by the aryteno-epiglottidean folds, in which may be seen two rounded eminences corresponding to the cornicula and euneiform cartilages. Beneath these, the true and false vocal cords, with the ventricle between them. Still deeper, the cricoid cartilage and some of the anterior parts of the rings of the trachea, and sometimes, in deep inspiration, the bifurcation of the trachea.

Surgical Anatomy.—Foreign bodies often find their way into the air-passages. These may be either large soft substances, as a piece of meat, which may become lodged in the upper aperture of the larynx or in the rima glottidis, and cause speedy suffocation unless rapidly got rid of, or unless an opening is made into the air-passages below, so as to enable the patient to breathe. Smaller bodies, frequently of a hard nature, such as cherry- or plum-stones, small pieces of bone, buttons, etc., may find their way through the rima glottidis into the trachea or bronchus, or may become lodged in the ventricle of the larynx. The dangers then depend not so much upon the mechanical obstruction as upon the spasm of the glottis which they excite from reflex irritation. When lodged in the ventricle of the larynx, they may produce very few symptoms beyond sudden loss of voice or alteration in the voice sounds, immediately following the inhalation of the foreign body. When, however, they are situated in the trachea, they are constantly striking against the vocal cords during expiratory efforts, and produce attacks of dyspnea from spasm of the glottis. When lodged in the bronchus, they usually become fixed there, and, occluding the lumen of the tube, cause a loss of the respiratory murmur on the affected side, which is, as stated above, more often the right.

Beneath the mucous membrane of the upper part of the air-passages there is a considerable amount of submucous tissue which is liable to become much swollen from effusion in inflammatory affections, constituting the disease known as "edema of the glottis." This effusion does not extend below the level of the true vocal cords, on account of the fact that the mucous membrane is closely adherent to these structures, without the intervention of any submucous tissue. So that, in cases of this disease in which it is necessary to open the air-passages to prevent suffocation, the operation of laryngotomy is sufficient.

Chronic laryngitis is an inflammation of the mucous glands of the larynx, which occurs in those who speak much in public, and is known as "clergyman's sore throat." It is due to the dryness induced by the large amount of cold air drawn into the air-passages during prolonged speaking, which incites increased activity in the mucous glands to keep the parts moist, and this eventually terminates in inflammation of these structures.

Ulceration of the larynx may occur from syphilis; either as a superficial ulceration, or from the softening of a gumma; from tuberculous disease (laryngeal phthisis), or from malignant disease (epithelioma).
The air-passages may be opened surgically in two different situations: through the crico-thyroid membrane (laryngotomy), or in some part of the trachea (tracheotomy); and to these some surgeons have added a third method, by opening the crico-thyroid membrane and dividing the cartilage with the upper ring of the trachea (laryngo-tracheotomy).

Laryngotomy is anatomically the more simple operation: it can readily be performed, and should be employed in those cases where the air-passages require opening in an emergency for the relief of some sudden obstruction to respiration. The crico-thyroid membrane is very superficial, being covered only in the middle line by the skin, superficial fascia, and the deep fascia. On each side of the middle line it is also covered by the Sterno-hyoid and Sterno-thyroid muscles, which diverge from each other at their upper parts, leaving a slight interval between them. On these muscles rest the anterior jugular veins. The only vessel of any importance in connection with this operation is the crico-thyroid artery, which crosses the crico-thyroid membrane, and which may be wounded, but rarely gives rise to any trouble. The operation is performed thus: the head being thrown back and steadied by an assistant, the finger is passed over the front of the neck, and the crico-thyroid depression felt for. A vertical incision is then made through the skin, in the middle line over this spot, and carried down through the fascia until the crico-thyroid membrane is exposed. A cross-cut is then made through the membrane, close to the upper border of the cricoid cartilage, so as to avoid, if possible, the crico-thyroid artery, and a tracheotomy tube is introduced. It has been recommended, as a more rapid way of performing the operation, to make a transverse instead of a longitudinal cut, through both the superficial and deep structures, and thus to open at once the air-passages. It will be seen, however, that in opening in this way the anterior jugular veins would be in danger of being wounded.

Tracheotomy may be performed either above or below the isthmus of the thyroid body, or this structure may be divided and the trachea opened behind it.

The isthmus of the thyroid gland usually crosses the second and third rings of the trachea; along its upper border is frequently to be found a large transverse communicating branch between the superior thyroid veins; and the isthmus itself is covered by a venous plexus formed between the thyroid veins of the opposite sides. Theoretically, therefore, it is advisable to avoid dividing this structure in opening the trachea.

Above the isthmus the trachea is comparatively superficial, being covered by the skin, superficial fascia, deep fascia, Sterno-hyoid and Sterno-thyroid muscles, and a second layer of the deep fascia, which, attached above to the lower border of the hyoid bone, descends beneath the muscles to the thyroid body, where it divides into two layers and enclose the isthmus.

Below the isthmus the trachea lies much more deeply, and is covered by the Sterno-hyoid and the Sterno-thyroid muscles and a quantity of loose areolar tissue in which is a plexus of veins, some of them of large size; they converge to two trunks, the inferior thyroid veins, which descend on either side of the median line on the front of the trachea and open into the innominate veins. In the infant the thymus gland ascends a variable distance along the front of the trachea, and opposite the episternal notch the windpipe is crossed by the left innominate vein. Occasionally, also, in young subjects, the innominate artery crosses the tube obliquely above the level of the sternum. The thyroidea ima artery, when that vessel exists, passes from below upward along the front of the trachea.

From these observations it must be evident that the trachea can be more readily opened above than below the isthmus of the thyroid body.

Tracheotomy above the isthmus is performed thus: the patient should, if possible, be laid on his back on a table in a good light. A pillow is to be placed under the shoulders and the head thrown back and steadied by an assistant. The surgeon standing on the right side of his patient makes an incision from an inch and a half to two inches in length in the median line of the neck from the top of the cricoid cartilage. The incision must be made exactly in the middle line, so as to avoid the anterior jugular veins, and after the superficial structures have been divided the interval between the Sterno-hyoid muscles must be found, the raphe divided, and the muscles drawn apart. The lower border of the cricoid cartilage must now be felt for, and the upper part of the trachea exposed from this point downward in the middle line. Bose has recommended that the layer of fascia in front of the trachea should be divided transversely at the level of the lower border of the cricoid cartilage, and, having been seized with a pair of forceps, pressed downward with the handle of the scalpel. By this means the isthmus of the thyroid gland is depressed, and is saved from all danger of being wounded, and the trachea is cleanly exposed. The trachea is now transfixed with a sharp hook and drawn forward in order to steady it, and is then opened by inserting the knife into it and dividing the two or three upper rings from below upward. If the trachea is to be opened below the isthmus, the incision to expose it must be made from a little below the cricoid cartilage to the top of the sternum.

In the child the trachea is smaller, more deeply placed, and more movable than in the adult. In fat or short-necked people, or in those in whom the muscles of the neck are prominently developed, the trachea is more deeply placed than in others.

A portion of the larynx or the whole of it has been removed or malignant disease, laryngectomy.
Some surgeons do preliminary tracheotomy, insert a Trendelenburg cannula to prevent the flow of blood downward into the lungs, and then remove the larynx. Other surgeons do not employ preliminary tracheotomy.

Perier's method of laryngectomy is as follows: Make a vertical incision in the median line from the level of the hyoid bone to below the level of the cricoid cartilage. Make a transverse incision at each end of the vertical incision. This makes an I-shaped wound.

Separate the soft parts from the larynx and upper part of the trachea, and separate these two structures from the oesophagus. After arresting bleeding, divide the trachea below the cricoid cartilage, introduce a special cannula, complete the removal of the larynx, suture the opening of the trachea to the lower angle of the wound, and close the rest of the wound after securing drainage. In malignant disease of the larynx the associated lymphatic glands must be removed.

Partial laryngectomy, according to Sir F. Semon, is the removal of not less than one wing of the thyroid cartilage. Removal of a lesser piece of the thyroid or of a bit of the arytenoid or cricoid he considers with the operation of thyrotomy.

**THE PLEURAE** (Figs. 997, 998, 999, 1000, 1001).

Each lung is invested, upon its external surface, by an exceedingly delicate serous membrane, the pleura, which encloses the organ as far as its root, and is then reflected upon the inner surface of the thorax. The portion of the serous membrane investing the surface of the lung and dipping into the fissures between its lobes is called the pulmonary pleura or the visceral layer of the pleura (*pleura pulmonalis*) (Fig. 997), while that which lines the inner surface of the chest is called the parietal layer of the pleura (*pleura parietalis*) (Fig. 997). The two layers join at the hilum of the lung. The space between these two layers is called the **cavity of the pleura** (*cavum pleurae*), and contains a very little clear fluid. It must be borne in mind that in the healthy condition the two layers are in contact, and there

is no real cavity until the lung becomes collapsed and separates from the wall of the chest. Each pleura is therefore a shut sac, one occupying the right, the other the left half of the thorax, and they are perfectly separate from each other.
The two pleurae do not meet in the middle line of the chest, excepting anteriorly opposite the second and third pieces of the sternum—a space being left between them, which contains all the viscera of the thorax excepting the lungs; this is the mediastinum.

**Reflections of the Pleurae** (Fig. 997). **The Pleura Pulmonalis** (Fig. 997).—The pleura pulmonalis is closely attached to the surface of the lung and enters into the depths of the interlobar fissures. It leaves the lung surface at the hilum, covers the root of the lung for a little way (Fig. 1004 and 1005), and then passes into the mediastinal pleura. Between the hilum and the mediastinal pleura there is a thickened pleural fold, triangular in outline, and called the ligamentum pulmonale or the ligamentum latum pulmonis (Figs. 1004 and 1005). It is formed by the two layers of
the pulmonary pleura coming in contact below the root of the lung. This fold passes from the lower part of the inner pulmonary surface to the pericardium, and the lower border is free or attached to the diaphragmatic pleura. In the right lung the origin of this ligament is in front of the groove for the azygos vein; in the left lung it is in front of the groove for the thoracic aorta.

The Pleura Parietalis.—The pleura parietalis is a continuous membrane, but for convenience is divided into the **cervical pleura**, costal pleura, mediastinal pleura, and diaphragmatic pleura.

The Cervical Pleura or Dome of the Pleura or Cupola (cupula pleurae) (Fig. 1000) is the dome-shaped roof of the cavity of the pleura. It projects above the apex of the lung to the neck of the first rib. As the first rib is placed obliquely, the dome of the pleura reaches from one to one and one-half inches above the anterior extremity of the first rib, and from one-half an inch to one inch above the clavicle. On the outer side of the cervical pleura are the Scalenus anticus and medius muscles. Just below the apex, on the anterior and inner surface, is a groove for the subclavian artery, which vessel passes over it in an arch (Fig. 998). A little below the groove for the subclavian artery is a broader and shallower groove for the innominate and subclavian veins. Above the subclavian artery and in front and above the cervical pleura are the cords of origin of the brachial plexus and the inferior cervical ganglion (Fig. 998). The dome is strengthened and kept in place by Sibson’s aponeurosis or the vertebro-pleural ligament (Figs. 999 and 1000). This comes from a little piece of muscle, the Scalenus minimus muscle, which originates from the transverse process of the seventh cervical vertebra, broadens and becomes aponeurotic as it descends, and is inserted into the inner margin of the first rib (Figs. 998 and 999). It is also strengthened by the costo-pleural ligament (Fig. 999), from the inner surface of the neck of the first rib to the pleura, and by fibrous bands which pass to the tissue about the subclavian sheath, trachea, and oesophagus (Fig. 999).

The Costal Pleura (pleura costalis) (Fig. 997) is the shortest portion of the pleura and is connected to the parts it covers by the **endothoracic fascia** (fascia
endothoracica), a layer of connective tissue which is much thicker back of the rib cartilages than it is posteriorly. The costal pleura covers the inner surface of part of the sternum, the costal cartilages, ribs, and intercostal muscles, and the sides of the bodies of the thoracic vertebrae. This layer is loosely attached except as it passes from the heads of the ribs to the vertebrae, where it is firmly adherent.

The Medias 

tinal Pleura (pleura mediastinalis) (Fig. 999) covers the septum of the mediastinum, which intervenes between the two pleural cavities. The mediastinal pleura extends from the inner surface of the anterior wall of the thorax to the vertebrae. It is continuous in front and back with the costal pleura of the same side, the lines of junction being known, respectively, as the anterior line of pleural reflection and the posterior line of pleural reflection. Below the mediastinal pleura passes into the diaphragmatic pleura of the same side. The portion of the mediastinal pleura which fuses with the parietal layer of the pericardium is called the pericardial pleura (pleura pericardiaca).

Above the root of the lung the mediastinal pleura passes back directly to the vertebrae. “In this region the left mediastinal pleura is applied to the arch of the aorta and the phrenic and vagus nerves; to the left innominate vein, the left superior intercostal vein, and the left common carotid and left subclavian arteries; to the oesophagus and the thoracic duct. The right mediastinal pleura, on the other hand, is applied, above the level of the root of the lung, to the upper part of the aorta and right innominate vein; to the right innominate artery; to the vena cava major, as it hooks forward above the bronchus; to the vagus and phrenic nerves; and to the right side of the trachea.” Upon the pericardium the phrenic nerve is covered by the pleura. Back of the root of the lung and the pulmonary ligament, the right mediastinal pleura passes back to the vertebrae to the left of the oesophagus; the left mediastinal pleura passes back over the descending aorta, and just above the Diaphragm and in front of the aorta over the lower end of the oesophagus.

The Diaphragmatic Pleura (pleura diaphragmatica) (Figs. 1001 and 1002) covers the upper surface of the Diaphragm outside of the base of the pericardium, but does not completely cover it; for it does not pass into the interval between the wall of the thorax and Diaphragm, and before this point is reached becomes continuous with the costal pleura.

The reflection to the costal pleura begins by the sternum, at the lower margin of the sixth rib; takes place at the junction of the cartilage of the rib with the seventh rib; posteriorly, it takes place at the lower margin of the twelfth thoracic vertebra.

In the front of the chest, where the parietal layer of the pleura is reflected backward to the pericardium, the two pleural sacs are in contact for a considerable extent. At the upper part of the chest, behind the manubrium, they are not in contact; the point of reflection being represented by a line drawn from the sternoclavicular articulation to the mid-point of the junction of the manubrium to the body of the sternum. From this point the two pleurae descend in close contact to the level of the fourth costal cartilages. Here the line of reflection on the right side is continued downward in nearly a straight line to the lower end of the gladiolus and then turns outward behind the costal cartilage of the sixth rib, continuing to descend and to run outward, it passes behind the descending part of the seventh costal cartilage, and meets the axillary line at the junction of the eighth rib with the cartilage. The line of reflection continues to descend till it reaches its lowest point at the tenth rib. This point is in the axillary line, while on the left side the line of reflection diverges outward, so that opposite the seventh cartilage it is about three-quarters of an inch from the left border of the sternum. It, however, always extends considerably farther over the pericardium than the corresponding lung. From this joint the reflections of the two sides are practically

1 Cunningham’s Text-book of Anatomy.
the same. The lower limit of the pleura is on a considerably lower level than the lower limit of the lung, but does not extend to the attachment of the Diaphragm, so that below the line of reflection of the pleura from the chest wall on to the Diaphragm the latter is in direct contact with the rib cartilages and the Internal intercostal muscles. In ordinary inspiration the thin margin of the base of the lung does not extend as low as the line of pleural reflection, with the result that the costal and diaphragmatic pleura are here in contact, the narrow slit between the two being termed the phrenico-costal sinus (sinus phrenicocostalis) (Fig. 1001). A similar condition exists behind the sternum and rib cartilages, where the anterior thin margin of the lung falls short of the line of pleural reflection, and where the slit-like cavity between the two layers of pleura forms what is sometimes called the costo-mediastinal sinus (sinus costomediastinalis).

Along the line of reflection of the diaphragmatic pleura a dense fascia passes from the costal cartilages and the uncovered portion of the Diaphragm to the costal pleura. This serves to hold it in place. It is named by Cunningham the phrenico-pleural fascia.

The inner surface of the pleura is smooth, polished, and moistened by a serous fluid; its outer surface is intimately adherent to the surface of the lung, and to the pulmonary vessels as they emerge from the pericardium; it is also adherent to the upper surface of the Diaphragm; throughout the rest of its extent it is somewhat thicker, and may be separated from the adjacent parts with extreme facility.

The right pleural sac is shorter, wider, and reaches higher in the neck than the left.

Structure of the Pleura.—The pleura is composed of connective tissue containing much elastic tissue, its free surface being covered with flat endothelial cells. It is fastened to adjacent structures by subserous areolar tissue. The subserous tissue of the visceral pleura is continuous with the areolar tissue of the lung.

Vessels and Nerves.—The arteries of the pleura are derived from the intercostal, the internal mammary, the musculo-phrenic, thymic, pericardiac, and bronchial. The veins correspond to the arteries. The lymphatics are very numerous in the pleura and subserous tissue. Many of them are in direct communication with the pleural cavity by stomata between the endothelial cells. Stomata are absent in the mediastinal pleura and over the ribs (Dyskowsky). The lymphatics of the visceral layer empty into the superficial pulmonary trunks; the lymphatics of the costal pleura empty into the intercostal trunks; of the diaphragmatic pleura, into the diaphragmatic trunks; of the mediastinal pleura, into the posterior mediastinal glands. The nerves are derived from the phrenic and sympathetic (Luschka). Kölliker states that nerves accompany the ramifications of the bronchial arteries in the pleural pulmonalis.

Surgical Anatomy.—In operations upon the kidney it must be borne in mind that the pleura may sometimes extend below the level of the last rib, and may therefore be opened in these operations, especially when the last rib is removed, in order to give more room. It is best to keep the incision at least one inch below the last rib, enlarging the wound afterward, when the finger can be introduced as a guide.

In wounds of the Diaphragm the pleura may be injured. In operations about the root of the neck, especially in the removal of glands and the ligation of the first part of the subclavian artery, the pleura may be injured.

Punctured wounds of the root of the neck are apt to reach the pleura.

Empyema is a surgical disease. In acute empyema the treatment is drainage. A portion of the fifth or sixth rib in the axillary line is removed by subperiosteal resection, the pleura is opened, and a tube is introduced. In chronic empyema the lung is contracted and adherent and cannot expand; hence drainage will not cure it. It is necessary to perform multiple rib resection in order to permit the chest-wall to sink in and obliterate the cavity, which, as the lung is unable to expand, it cannot do. The necessary operation may be the operation of Estlander, or the operation of Scheide, or the operation of Fowler (page 168).

1 Poirier, Cunéo, and Delamare on the Lymphatics. Translated and edited by Cecil H. Leaf.
If a large wound admits suddenly a quantity of air into the pleura, dangerous or fatal pneumothorax arises, and the lung collapses. This is usually met during operations by using the Fell-O’Dwyer apparatus for artificial respiration as advised by Mats. This apparatus keeps the lung expanded, in spite of the entrance of air into the pleural sac. A surgeon can open the pleura widely without any fear of the lung collapsing if he operates in a Sauerbruch chamber. The pressure within this chamber is negative. The patient’s head is outside of the chamber, his body is within it. The bronchioles are distended by the animal inhaling air at the ordinary pressure, but the exposed lung is subjected to negative pressure, hence the lung does not collapse in spite of a large wound in the pleura. In surgical pneumothorax the lung may be sutured to the chest-wall, so as to block the opening. Sometimes, in order to arrest dangerous pulmonary bleeding, a surgeon deliberately induces pneumothorax, in hope that the collapse of the lung will arrest bleeding.

When an abscess of the liver is posterior and on the dorsum, transpleural hepotomy is performed. A portion of the tenth and eleventh ribs below the angle of the scapula is removed. As a rule, the pleura is found obliterated at this point. If it is opened, it is at once sutured or closed with gauze packing. The exposed Diaphragm is incised, and, as it is usually adherent to the liver, the abscess cavity is entered. If it is not adherent, the liver is exposed and the abscess sought for with an aspirating-needle.

**THE MEDIASTINAL SPACE, INTERPLEURAL SPACE OR MEDIASTINUM.**

The mediastinum is the space left in the median portion of the chest by the non-approximation of the two pleure. It extends from the sternum in front to the spine behind. Within it are the contents of the thorax excepting the lungs. The mediastinum may be divided for purposes of description into two parts—an upper portion, above the upper level of the pericardium, which is named the superior mediastinum (Struthers); and a lower portion, below the upper level of the pericardium. This lower portion is again subdivided into three—that part which contains the pericardium and its contents, the middle mediastinum; that part which is in front of the pericardium, the anterior mediastinum; and that part which is behind the pericardium, the posterior mediastinum.

**The Superior Mediastinum** (Fig. 1003).—The superior mediastinum is that portion of the interpleural space which lies above the upper level of the pericardium between the manubrium sterni in front and the upper thoracic vertebrae behind. It is bounded below by a plane passing backward from the junction of the manubrium and gladiolus sterni to the lower part of the body of the fourth thoracic vertebra, and laterally by the lungs and pleurae. It contains the origins of the Sterno-hyoid and Sterno-thyroid muscles and the lower ends of the Longus colli muscles; the arch of the aorta; the innominate, the thoracic portion of the left carotid and subclavian arteries; the upper half of the precava and the innominate veins, and the left superior intercostal vein; the vagus, cardiac, phrenic, and left recurrent laryngeal nerves; the trachea, oesophagus, and thoracic duct; the remains of the thymus gland and some lymphatic glands.

**The Anterior Mediastinum** (Fig. 997).—The anterior mediastinum is bounded in front by the sternum, on each side by the pleura, and behind by the pericardium. It is narrow above, but widens out a little below, and, owing to the oblique course taken by the left pleura, it is directed from above obliquely downward and to the left. Its anterior wall is formed by the left Triangularis sterni muscle and the fifth, sixth, and seventh left costal cartilages. It contains a quantity of loose areolar tissue, some lymphatic vessels which ascend from the convex surface of the liver, two or three lymphatic glands (anterior mediastinal glands), and the small mediastinal branches of the internal mammary artery.

**The Middle Mediastinum** (Fig. 997).—The middle mediastinum is the broadest part of the interpleural space. It contains the heart enclosed in the pericardium, the ascending aorta, the lower half of the precava, with the vena azygos major opening into it, the bifurcation of the trachea and the two bronchi,
the pulmonary artery dividing into its two branches and the right and left pulmonary veins, the phrenic nerves, and some bronchial lymphatic glands.

The Posterior Mediastinum (Figs. 997 and 1001).—The posterior mediastinum is an irregular triangular space running parallel with the vertebral column; it is bounded in front by the pericardium and roots of the lungs, behind by the vertebral column from the lower border of the fourth thoracic vertebra, and on either side by the pleura. It contains the descending thoracic aorta, the greater and lesser azygos veins, the vagus and splanchnic nerves, the oesophagus, thoracic duct, and some lymphatic glands.

Blood-vessels.—The areolar tissue of the anterior mediastinum receives numerous mediastinal branches from the internal mammary artery. The areolar tissue
of the posterior mediastinum receives mediastinal branches from the descending thoracic aorta. The lowest mediastinal vessels lie upon the Diaphragm and are called superior phrenic arteries. The precava and internal mammary veins receive mediastinal branches.

The **anterior mediastinal lymphatic glands** are in the upper portion of the anterior mediastinum. They are five or six in number and are placed in front of the transverse arch of the aorta. Chains of glands run up from them to the root of the neck. On the right side glands are in front of the right innominate vein, between the artery and vein and behind the artery. On the left side they are around the left common carotid and left subclavian arteries.

The **posterior mediastinal glands** are around the oesophagus, particularly in front of it. The **peritracheo-bronchial glands** have been described.

**THE LUNGS (PULMONES)** (Figs. 997, 1004, 1005, 1006, 1007, 1008, 1009).

The lungs are the essential organs of respiration; they are two in number, placed one on each side of the chest, separated from each other by the heart and other contents of the mediastinum. A healthy lung hangs free within the pleural cavity. It is suspended by the root and by the ligamentum pulmonis. In many cases examined the lung does not hang free, but, as a result of former pleurisy, an area of the pulmonary pleura is adherent to the parietal pleura. Each lung is conical in shape, and presents for examination an **apex**, a **base**, two **borders**, and two **surfaces**.

**The Apex** (**apex pulmonis**).—The apex forms a tapering cone which extends into the root of the neck about an inch to two inches above the level of the anterior extremity of the first rib. The brachial plexus is in close proximity to this portion of the lung.

**The Base** (**basis pulmonis**).—The base is broad, concave, and rests, by its **diaphragmatic surface** (**facies diaphragmatica**), upon the convex surface of the
Diaphragm, which separates the right lung from the upper surface of the right lobe of the liver and the left lung from the upper surface of the left lobe of the liver, the fundus of the stomach, and the spleen; its circumference is thin, and

projects for some distance into the phrenico-costal sinus of the pleura, between the lower ribs and the costal attachment of the Diaphragm, extending lower down externally and behind than in front.
Surfaces. The External, Costal, or Thoracic Surface (facies costalis) (Figs. 1008 and 1009).—The external, costal, or thoracic surface is smooth, convex, of considerable extent, and corresponds to the form of the cavity of the chest, being deeper behind than in front. In a hardened specimen this surface has grooves and bulgings on it corresponding to the ribs and intercostal spaces.

The Inner or Mediastinal Surface (facies mediastinalis) (Figs. 1004 and 1005).—The inner or mediastinal surface is concave. It presents in front a depression corresponding to the convex surface of the pericardium, and behind a deep fissure, the hilum (hilus pulmonalis). In the hilum lie the bronchi, vessels, nerves, and lymph-nodes, which together constitute the root of the lung. On the inner and anterior surface, a little below the apex, is a groove, the subclavian groove (sulcus subclavius), for the subclavian artery. A little lower is a broader and shallower groove for the innominate and subclavian veins. The pleura lies between the lungs and these vessels. In front of the hilum and below it is a depression for the heart (impressio cardiaca). It is deeper on the left than on the right side. On the right side it passes into the groove from the precava and the vena azygos major. On the left side, behind the hilum, is a groove for the thoracic aorta; on the right side a groove for the oesophagus.

Borders. The Inferior Border (margo inferior).—The inferior border is the line of junction of the costal and diaphragmatic surfaces. Posteriorly, it is rounded and broad, and is received into the deep concavity on either side of the spinal column. It is much longer than the anterior border, and projects, below, into the phrenico-costal sinus.

The Anterior Border (margo anterior).—The anterior border is thin and sharp, overlaps the front of the pericardium, and is projected into the costo-medi-
astinal sinus of the pleura. The anterior border of the right lung is almost vertical; that of the left presents, below, an angular notch, the *incisura cardiaca*,

![Diagram of pulmonary veins](image)

**Fig. 1007.**—Pulmonary veins, seen in a dorsal view of the heart and lungs. The lungs have been pulled away from the median line, and a part of the right lung has been cut away to display the air-ducts and blood-vessels. (Testut.)

![Diagram of right lung](image)

![Diagram of left lung](image)

**Fig. 1008.**—The right lung. The outer or costal surface. (Toldt.)
**Fig. 1009.**—The left lung. The outer or costal surface. (Toldt.)

into which the heart and pericardium are received. A projection from the upper lobe comes forward beneath the cardiac notch; it is called the *lingula pulmonis*.

**The Lobes of the Lungs** (Figs. 1008 and 1009).—Each lung is divided into two lobes, an *upper* (*lobus superior*) and a *lower* (*lobus inferior*), by a long and deep
fissure (*incisura interlobaris*), which extends from the upper part of the posterior border of the organ about three inches from its apex, downward and forward to the lowest part of the lung just external to its anterior border. This fissure penetrates nearly to the root. The upper lobe is the smaller; the lower lobe is the larger. In the right lung the upper lobe is partially subdivided by a second and shorter fissure, which extends almost horizontally forward from the middle of the preceding to the anterior margin of the organ, marking off a small triangular portion, the middle lobe (*lobus medius*).

The right lung is the larger and heavier; it is broader than the left, owing to the inclination of the heart to the left side; it is also shorter by an inch, in consequence of the Diaphragm rising higher on the right side to accommodate the liver.

**The Root of the Lung** (*radix pulmonis*) (Figs. 1004, 1005, 1006, and 1007).—A little above the middle of the inner surface of each lung, and nearer its posterior than its anterior border, is its root, by which the lung is connected to the heart and the trachea. The root is formed by the bronchial tube, the pulmonary artery, the pulmonary veins, the bronchial arteries and veins, the pulmonary plexus of nerves, lymphatics, bronchial glands, and areolar tissue, all of which are enclosed by a reflection of the pleura. The root of the right lung lies behind the precava and ascending portion of the aorta, and below the vena azygos major. The root of the left lung passes beneath the arch of the aorta and in front of the descending aorta; the phrenic nerve and the anterior pulmonary plexus lie in front of each, and the vagus and posterior pulmonary plexus behind each.

The chief structures composing the root of each lung are arranged in a similar manner from before backward on both sides—viz., the two pulmonary veins in front; the pulmonary artery in the middle; and the bronchus, together with the bronchial vessels, behind. From above downward, on the two sides, their arrangement differs, thus; on the right side their position is—bronchus, pulmonary artery, pulmonary veins; but on the left side their position is—pulmonary artery, bronchus, pulmonary veins. It should be noted that the entire right bronchus does not lie above the right pulmonary artery, but only its eparterial branch (see p. 1385), which passes to the upper lobe of the right lung; the divisions of the bronchus for the middle and lower lobes lie below the artery.

The true weight of the human lungs as ascertained in the bodies of criminals executed by electricity, in which the mode of death is attended by a nearly bloodless condition of the lungs, is 215 grams (7.4 ounces) for the left lung and 240 grams (8.4 ounces) for the right lung (E. A. Spitzka, *Amer. Jour. of Anat.*, iii., 1, p. v.). Ordinarily, with the vascular channels more or less filled with blood and serum, the two lungs together weigh about 42 ounces, the right lung being 2 ounces heavier than the left, but much variation is met with according to the amount of blood or serous fluid they may contain. The lungs are heavier in the male than in the female. The specific gravity of the lung-tissue varies from 0.345 to 0.746.

The color of the lungs at birth is a pinkish-white; in adult life a dark slate-color, mottled in patches; and as age advances this mottling assumes a black color. The coloring matter consists of granules of a carbonaceous substance deposited in the areolar tissue near the surface of the organ. It increases in quantity as age advances, and is more abundant in males than in females. The posterior surface of the lung is usually darker than the anterior.

The surface of the lung is smooth, shining, and marked out into numerous polyhedral spaces, indicating the lobules of the organ; the area of each of these spaces is crossed by numerous lighter lines.

The substance of the lung is of a light, porous, spongy texture; it floats in water and crepitates when handled, owing to the presence of air in the tissue; it is also highly elastic; hence the collapsed state of these organs when they are removed from the closed cavity of the thorax.

**The Foetal Lung.**—After respiration has been established, the lung fills the pleural cavity. In the foetus, as the lung has never been distended with air
and has never received a large amount of blood, it is gathered into a small mass at the back of the thorax. It will sink in water and feels solid to the touch.

**Structure.**—The structure of the lung is such that the blood brought by the pulmonary artery comes into close relation with the air which enters from the bronchioles. The blood gives materials to the air, and the air gives elements to the blood, and the process of respiration causes the dark blood brought from the heart by the pulmonary artery to return to the heart as red blood in the pulmonary vein. The lungs are composed of an **external serous coat**, a **subserous areolar tissue**, and the **pulmonary substance or parenchyma**.

**The Serous Coat.**—The serous coat is thin, transparent, and invests the entire organ as far as the root. It is known as the pulmonary pleura (p. 1392).

**The Subserous Areolar Tissue.**—The subserous areolar tissue contains a large proportion of elastic fibres; it invests the entire surface of the lung, and extends inward between the lobules, and at the hilum forms the pulmonary scaffold or framework.

**The Parenchyma.**—The parenchyma is composed of **lobules** which, although closely connected together by an interlobular areolar tissue, are quite distinct from one another, and may be teased asunder without much difficulty in the fetus. The lobules vary in size; those on the surface are large, of pyramidal form, with the bases turned toward the surface; those in the interior are smaller and of various forms. Each lobule is composed of one of the ramifications of a bronchial tube and its terminal air-cells, and of the ramifications of the pulmonary and bronchial vessels, lymphatics, and nerves, all of these structures being connected together by areolar tissue.

**The Bronchus** (pp. 1384 and 1386) (Figs. 993, 994, and 995).—The bronchus, upon entering the substance of the lung, divides and subdivides bipinately, throughout the entire organ. Sometimes three branches arise together, and occasionally small lateral branches are given off from the sides of a main trunk. Each of the smaller subdivisions of the bronchi enters a pulmonary lobe, and is termed a **lobular bronchial tube** or **bronchiole** (bronchioli). Each bronchiole divides into minute branches (bronchioli respiratorii), the walls of which now begin to present irregular dilatations, **bronchial alveoli**. These are present at first sparingly and on one side of the tube only, but as it proceeds onward these dilatations become more numerous and surround the tube on all sides, so that it loses its cylindrical character. The terminal branches come from the bronchioli respiratorii. These terminal branches are called the **alveolar ducts** or **alveolar passages** (ductuli alveolares). The alveolar ducts show numerous alveoli (Fig. 994) and join with cavities called **atria**. Each atrium joins several larger cavities, the **air-cells** or **air-sacs** (infundibula). The numerous small cavities on the surface of the air-sacs are the **pulmonary alveoli** (alveoli pulmonis). The bronchiole now becomes widened out and terminates in an irregular cul-de-sac, the **air cell**, **air sac** alveolus or infundibulum. The walls of the infundibulum are closely beset in all directions by **pulmonary alveoli** or **pulmonary air cells**. Professor Gerrish remarks that the first of the alveoli seen on the bronchioles before the coreal ends are formed would seem an effort on the part of nature to form an infundibulum before all the necessary conditions are favorable.

**Changes in the Structure of the Bronchi in the Lungs.**—Within the lungs the bronchial tubes are circular, not flattened (Fig. 995), and present certain peculiarities of structure.

**In the Lobes of the Lungs.**—In the lobes of the lungs the following changes take place: The **cartilages** are not imperfect rings, but consist of thin laminae, of varied form and size, scattered irregularly along the sides of the tube, being most distinct at the points of division of the bronchi. They may be traced into tubes, the diameter of each of which is only one-fourth of a line. Beyond this point the tubes are wholly membranous. The **fibrous coat** is continued into the
smallest ramifications of the bronchi. The **muscular coat** is disposed in the form of a continuous layer of annular fibres, which may be traced upon the smallest bronchial tubes, and consists of the unstriped variety of muscular tissue. The **mucous membrane** lines the bronchi and their ramifications throughout, and is covered with columnar ciliated epithelium.

**In the Lobules of the Lung.**—In the lobular bronchial tubes and in the infundibula the following changes take place: The **muscular tissue** begins to disappear, so that in the infundibula there is scarcely a trace of it. The **fibrous coat** becomes thinner, and degenerates into areolar tissue. The **epithelium** becomes non-ciliated and flattened. This occurs gradually; thus, in the lobular bronchioles patches of non-ciliated flattened epithelium may be found scattered among the columnar ciliated epithelium; then these patches of non-ciliated flattened epithelium become more and more numerous, until in the infundibula and air-cells all the epithelium is of the non-ciliated pavement variety. In addition to these flattened cells, there are small polygonal granular cells in the air-sacs, in clusters of two or three, between the others.

The air-cells are small, polyhedral recesses composed of a fibrillated connective tissue and surrounded by a few involuntary muscular and elastic fibres. Free in their cavity are to be seen under the microscope granular, rounded, ameoboid cells (cosinophile leukocytes), often containing carbonaceous particles. The air-cells are well seen on the surface of the lung, and vary from $\frac{1}{20}$ to $\frac{1}{10}$ of an inch in diameter, being largest on the surface at the thin borders and at the apex, and smallest in the interior.

**Mucous Glands.**—In the larger bronchi the mucous membrane contains goblet cells. When the tubes diminish to 1 mm. in diameter the glands grow fewer. In the smaller bronchi there are no mucous glands.

**Vessels of the Lungs.**—The **pulmonary artery** (Figs. 1006 and 1007) conveys the venous blood to the lungs; it divides into branches which accompany the bronchial tubes, and terminates in a dense capillary network upon the walls of the intercellular passages and air-cells. In the lung the branches of the pulmonary artery are usually above and in front of a bronchial tube, the vein below.

The **pulmonary capillaries** form plexuses which lie immediately beneath the mucous membrane in the walls and septa of the air-cells and of the infundibula. In the septa between the air-cells the capillary network forms a single layer. The capillaries form a very minute network, the meshes of which are smaller than the vessels themselves; their walls are also exceedingly thin. The arteries of neighboring lobules are independent of each other, but the veins freely anastomose together.

The **pulmonary veins** commence in the pulmonary capillaries, the radicles coalescing into larger branches, which run along through the substance of the lung, independently from the minute arteries and bronchi. After freely communicating with other branches they form large vessels, which ultimately come into relation with the arteries and bronchial tubes, and accompany them to the hilum of the organ. Finally they open into the left auricle of the heart, conveying oxygenated blood to be eventually distributed to all parts of the body by the aorta.

The **bronchial arteries** supply blood for the nutrition of the lung. The thoracic aorta usually gives off two left bronchial arteries. The single right bronchial artery usually arises from the first right aortic intercostal, but sometimes from the superior left bronchial artery, or from the aorta. In the root of the lung they are posterior to the bronchus, they accompany the bronchial tubes, supply the tubes and pulmonary tissue, and give branches to the walls of the larger pulmonary vessels, the oesophagus, pericardium, and bronchial glands. Those

---

1 The meshes are only 0.002" to 0.008" in width, while the vessels are 0.003" to 0.005" (Köllikker, Human Microscopic Anatomy).—Ed. of 15th English edition.
supplying the bronchial tubes form a capillary plexus in the muscular coat, from which branches are given off to form a second plexus in the mucous coat. This plexus communicates with branches of the pulmonary artery, and empties itself into the pulmonary vein. Others are distributed in the interlobular areolar tissue, and terminate partly in the deep, partly in the superficial, bronchial veins. Lastly, some ramify upon the surface of the lung beneath the pleura, where they form a capillary network. There may be but one bronchial artery; there may be three or four.

The bronchial veins are not found in the walls of the very small bronchi. The small bronchial veins run along by the front and back of the median sized and larger tubes, and from two trunks at the root of each lung. These vessels terminate on the right side in the vena azygos major, and on the left side in the superior intercostal or left upper azygos vein. Tracheal and posterior mediastinal veins open into the bronchial veins. The venous blood from the smaller tubes passes to the pulmonary veins.

The lymphatics begin in networks about the lobules and form networks about the bronchi and beneath the bronchial mucous membrane. The superficial collecting trunks arise about the lobules and beneath the pleura. According to Sappey, the superficial trunks from the upper lobe begin on the costal surface; one set passes around the anterior border, another set around the posterior border, and a third into the incisura interlobaris. The same observer says that the superficial trunks from the middle lobe unites with the trunks from the upper and lower lobes; and the superficial trunks from the lower lobe, like those of the upper lobe, are in three sets. One set passes around the posterior margin, one around the anterior margin, and one into the incisura interlobaris. All of the superficial trunks convey lymph to the glands of the hilum. Some of the deep collecting trunks begin by the sides of the small bronchi; others course along by the pulmonary veins or pulmonary arteries. All of them pass to the glands of the hilum. The glands of the hilum are in communication with the peritracheo-bronchial glands.

Nerves.—The lungs are supplied from the anterior and posterior pulmonary plexuses, formed chiefly by branches from the sympathetic and vagus. The filaments from these plexuses accompany the bronchial tubes, and are lost upon them. Small ganglia are found upon these nerves.

Surface Form.—The apex of the lung is situated in the neck, behind the interval between the two heads of origin of the Sterno-mastoid muscle. The height to which it rises above the clavicle varies very considerably, but is generally about one inch. It may, however, extend as much as an inch and a half or an inch and three-quarters, or, on the other hand, it may scarcely project above the level of this bone. In order to mark out the anterior margin of the lung, a line is to be drawn from the apex-point, one inch above the level of the clavicle, and rather nearer the posterior than the anterior border of the Sterno-mastoid muscle, downward and inward across the sterno-clavicular articulation and first piece of the sternum until it meets, or almost meets, its fellow of the other side opposite the articulation of the manubrium and gladiolus. From this point the two lines are to be drawn downward, one on either side of the mesial line and close to it, as far as the level of the articulation of the fourth costal cartilages to the sternum. From here the two lines diverge; the left is to be drawn at first passing outward with a slight inclination downward, and then taking a bend downward with a slight inclination outward to the apex of the heart, and thence to the sixth costo-chondral articulation. The direction of the anterior border of this part of the left lung is denoted with sufficient accuracy by a curved line with its convexity directed upward and outward from the articulation of the fourth right costal cartilage of the sternum to the fifth intercostal space, an inch and a half below and three-quarters of an inch internal to the left nipple. The continuation of the anterior border of the right lung is marked by a prolongation of its line from the level of the fourth costal cartilages vertically downward as far as the sixth, when it slopes off along the line of the sixth costal cartilage to its articulation with the rib.

The lower border of the lung is marked out by a slightly curved line with its convexity downward from the articulation of the sixth costal cartilage to its rib to the spine of the tenth thoracic vertebra. If vertical lines are drawn downward from the nipple, the mid-axillary line, and the apex of the scapula, while the arms are raised from the sides, they should intersect

1 The Lymphatics, by Poirier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf.
this convex line, the first at the sixth, the second at the eighth, and the third at the tenth rib. It will thus be seen that the pleura extends farther down than the lung, so that it may be wounded, and a wound may pass through its cavity into the Diaphragm, and the abdominal viscera may be injured without the lung being involved.

The posterior border of the lung is indicated by a line drawn from the level of the spinous process of the seventh cervical vertebra, down either side of the spine, corresponding to the costo-vertebral joints as low as the spinous process of the tenth thoracic vertebra. The trachea bifurcates opposite the spinous process of the fourth thoracic vertebra, and from this point the two bronchi are directed outward.

"The position of the great fissure of the lungs may be indicated by a line drawn from the third dorsal spine obliquely downward in such a manner as to reach the sixth rib close to the mid-clavicular line. The interlobar fissure between the upper and middle lobes of the right lung corresponds to a line drawn from the apex of the axilla almost horizontally to the sternum, reaching the latter at about the level of the fourth costal cartilage" (Erendrath).

Surgical Anatomy.—The lungs may be wounded or torn in three ways: (1) By compression of the chest, without any injury to the ribs. (2) By a fractured rib penetrating the lung. (3) By stabs, gunshot wounds, etc.

The first form, where the lung is ruptured by external compression without any fracture of the ribs, is very rare, and usually occurs in young children, and affects the root of the lung—i.e., the most fixed part—and thus, implicating the great vessels, is frequently fatal. It would seem to be a most unusual injury, and the exact mode of its causation is difficult to understand. The probable explanation is that immediately before the compression is applied a deep inspiration is taken and the lungs are fully inflated; owing then to spasm of the glottis at the moment of compression, the air is unable to escape from the lung, the lung is not able to reede, and consequently gives way.

In the second variety, when the wound in the lung is produced by the penetration of a broken rib, both the pleura costalis and the pleura pulmonalis must necessarily be injured, and consequently the air taken into the wounded air-cells may find its way through these wounds into the cellular tissue of the parieties of the chest. This it may do without collecting in the pleural cavity; the two layers of the pleura are so intimately in contact that the air may pass straight through from the wounded lung into the subcutaneous tissue. Emphysema constitutes, therefore, an important sign of injury to the lung in cases of fracture of the ribs. Pneumothorax, or air in the pleural cavity, is much more likely to occur in injuries to the lungs of the third variety; that is to say, from external wounds, from stabs and gunshot injuries, in which cases air passes either from the wound of the lung or from an external wound into the cavity of the pleura during the respiratory movements. In these cases there is generally no emphysema of the subcutaneous tissue unless the external wound is small and valvular, so that the air drawn into the wound during inspiration is then forced into the cellular tissue around during expiration because it cannot escape from the external wound. Occasionally in wounds of the parieties of the chest no air finds its way into the cavity of the pleura, because the lung at the time of the accident protrudes through the wound and blocks the opening. This occurs where the wound is large, and constitutes a so-called hernia of the lung. True hernia of the lung occurs, though very rarely, after wounds of the chest-wall, when the wound has healed and the cicatrix subsequently yields from the pressure of the viscous behind. It forms a globular, elastic, crepitating swelling, which enlarges during expiratory efforts, falls during inspiration, and disappears on holding the breath. Wounds of the lung may produce dangerous or fatal hemorrhage into the pleural sac. In many cases the bleeding is spontaneously arrested; in others the surgeon must interfere to save life. In some cases air has been admitted by intercostal incision and the insertion of a tube, and pulmonary collapse has arrested bleeding. In other cases it is necessary to resect portions of several ribs, and stop bleeding by ligatures or suture ligatures. In one case of a furious secondary hemorrhage following a gunshot wound, the editor resected several ribs, packed the pleural cavity about the lung with sterile gauze, to obtain a base of support, and then arrested the bleeding by packing iodoform gauze against the firmly supported lung. This patient recovered.

Incision of the lung (pneumotomy) is performed for pulmonary abscess (either tuberculous or pyogenic), pulmonary gangrene, hydatid cysts, and bronchiectasis. In pulmonary abscess, locate the area by physical signs and the x-ray, resect a portion of rib over it, and note if the pleura is adherent. If it is adherent, continue the operation. If it is not adherent, insert stitches of catgut through the two layers of pleura and the superficial part of the lung, so as to encircle a considerable area, and then wait several days for adhesions to form. Adhesions protect the pleura from infection, and, by keeping air from the pleural sac, prevent pneumothorax. When ready to continue the operation, locate the abscess with an aspirating-needle and syringe, open it with a cautery at a dull-red heat, and drain by means of a tube.

Pneumothorax is very unsatisfactory in tuberculous cavities and bronchiectasis. In tuberculosis, excision of the diseased area (pneumectomy) has been employed, but it is not to be advised. Operations upon the lungs can be most safely performed with the patient in a Sauerbruch chamber. The danger of collapse of the lung is thus eliminated.
THE DUCTLESS GLANDS.

THESE glands do not possess excretory ducts. They furnish materials which are added to the blood or lymph as it passes through them. The material from each gland is known as an internal secretion. Some of these secretions are powerful materials and influence profoundly the body nutrition. The ductless glands are usually given as follows: the spleen, the lymphatic glands, the pineal gland, the pituitary body, the suprarenal capsules, the thyroid gland, the para-thyroids, the thymus, the carotid body, and the coccigeal body. The lymphatic glands were described in a special section (p. 772). The lymphatic glands are not considered to be really glands, but, nevertheless, as lymph passes through the lymph glands, it receives a product of the glands, namely, lymphocytes. There is no evidence that the spleen furnishes an active internal secretion, and this organ has been studied with the abdominal viscera. The pineal gland (p. 915) and pituitary body or hypophysis (p. 917) were considered with the brain. The suprarenal capsules (p. 1437) are described with the kidneys. Some glands, for instance, the liver, pancreas, and testicle, have an external secretion and also an internal secretion.

THE THYROID BODY OR GLAND (GLANDULA THYREOIDEA) (Fig. 1010).

The thyroid gland is an extremely vascular body, situated at the front and sides of the neck, and extending upward upon each side of the larynx. It is a single gland, varying greatly in size in different individuals. It is larger relatively in females and in children than in men. It is frequently asymmetrical. In early embryonal life the gland has a duct, the thyro-glossal duct (ductus thyroglossus), which passes from the isthmus of the thyroid to the foramen caecum of the dorsum of the tongue. The lumen of this duct is obliterated early and becomes a cord of epithelium. The lower portion of the duct often remains open for a little way. The upper portion remains as the foramen caecum. The situation of this obliterated foetal duct may be marked by the third or middle lobe of the thyroid gland. The thyroid surrounds the upper portion of the trachea like a horseshoe. It consists of two lateral lobes connected across the middle line by a narrow transverse portion, the isthmus.

The weight of the gland is somewhat variable, but is usually about one ounce. It is somewhat heavier in the female, in whom it becomes enlarged during menstruation and pregnancy. As age advances the weight of the thyroid diminishes.

The color of the thyroid, as seen from the surface, is reddish-blue. The gland is completely surrounded by a closely adherent thin fibrous-tissue capsule of the pretracheal layer of deep cervical fascia. From the inner surface of the capsule come delicate septa, which enter into the thyroid body and separate it into lobes and also separate the lobes into lobules. The blood-vessels lie beneath the capsule. The anterior and lateral portions of the gland are covered by the capsule. "Passing around the side of the gland to its posterior surface, this capsule then splits into two portions. One remains in contact with the gland and invests its posterior surface. The other, the thicker of the two, passes to the posterior surface of the pharynx.
and oesophagus, thus enclosing them with the larynx, trachea, and thyroid gland, in a common sheath.\textsuperscript{1} There is also a layer from the thyroid capsule which passes between the trachea and oesophagus.\textsuperscript{2}

The \textit{lateral lobes} are conical in shape, the apex of each being directed upward and outward as far as the junction of the middle with the lower third of the thyroid cartilage; the base looks downward, and is on a level with the fifth or sixth tracheal ring. The summit of the lateral lobe not unusually is pointed and reaches to the level of the oblique line upon the ala of the thyroid cartilage or even higher. The right is, as a rule, somewhat larger than the left lobe. The lower portion of the gland, when the head is extended, is about one inch above the upper margin of the sternum; when the head is flexed, it is at the level of the upper border of the sternum or even below and behind it. The portion of the lateral lobe above the level of the superior border of the isthmus is called the \textit{upper horn}, the portion below the level of the inferior margin of the isthmus is called the \textit{lower horn}. The lower horn "is usually much smaller than the upper horn; frequently it is altogether absent."\textsuperscript{3}

At the inner and posterior part of each lateral lobe is the \textit{hilum}. At the hilum the inferior thyroid artery passes into the gland. "Here the \textit{recurrent laryngeal nerve} comes into close contact with the gland, lying in the space between it and the trachea and oesophagus.\textsuperscript{4}

The \textit{external} or \textit{superficial surface} is convex, and covered by the skin, the superficial fascia, the deep fascia, the Sterno-mastoid, the anterior belly of the Omo-hyoid, the Sterno-hyoid and Sterno-thyroid muscles, and beneath the last-named muscles by the pre-tracheal layer of the deep fascia, which forms a capsule for the gland.

The \textit{deep} or \textit{internal surface} is moulded over the underlying structures—viz., the thyroid and cricoid cartilages, the trachea, the inferior constrictor and posterior part of the Crico-thyroid muscles, the oesophagus (particularly on the left side of the neck), the superior and inferior thyroid arteries, and the recurrent laryngeal nerves.

The deep surface of each lobe is fixed by bands of fibrous tissue passing from the capsule of the isthmus and lateral lobes to the sides of the cricoid cartilage and the posterior fascia of the trachea. These bands are called the \textit{lateral} or \textit{suspensory ligaments}. Because of this fixation to the larynx and trachea by the capsule and by the lateral ligaments, the thyroid gland moves with the trachea and ascends during the act of swallowing. The recurrent laryngeal nerve on each side is in contact with the outer and posterior surface of the suspensory ligament.

The \textit{anterior border} is thin, and inclines obliquely from above downward and inward toward the middle line of the neck, while the \textit{posterior border} is thick and overlaps the common carotid artery. Each lobe is about two inches in length, its greatest width is about one inch and a quarter, and its thickness about three-

\textsuperscript{3} Loc. cit.
\textsuperscript{4} Ibid.
quarters of an inch. The posterior border is over the common carotid artery and touches the oesophagus and pharynx. The carotid artery usually makes a groove upon the gland.

The Isthmus (isthmus glandulae thyreoidea).—The isthmus connects the lower third of the two lateral lobes; it measures about half an inch in breadth and the same in depth, and usually covers the second and third rings of the trachea, but sometimes also the first and fourth rings. Its situation presents, however, many variations, a point of importance in the operation of tracheotomy. In the middle line of the neck it is covered by the skin and fascia, and close to the middle line, on either side, by the Sterno-hyoid muscle. Across its upper border run branches of the superior thyroid artery and vein; at its lower border is a branch of the inferior thyroid veins. Sometimes the isthmus is altogether wanting, the two lateral lobes being completely separate.

The third, pyramidal or middle lobe is called the pyramid of Lalouette. It is not constant, but is frequently found. Occasionally it arises from the upper part of the isthmus, or from the adjacent portion of either lobe, but most commonly from the left lobe, and ascends in front of the thyroid cartilage in the direction of the middle of the hyoid bone. It may reach the bone or may not reach it. If it reaches the bone it is attached to it. If it does not reach the bone, fibrous tissue, which often contains muscle, is prolonged from the tip of the pyramid to the back of the bone or to the thyro-hyoid membrane. The pyramid is occasionally quite detached, or divided into two or more parts, or altogether wanting.

A few muscular bands, derived from the Thyro-hyoid muscles, are occasionally found attached, above, to the body of the hyoid bone, and below to the isthmus of the gland or its pyramidal process. These form a muscle, which was named by Soemmerring the Levator glandulae thyreoidea.

Accessory Thyroids (glandulae thyreoideaæ accessoriae).—Frequently small isolated masses of thyroid tissue exist. They are found particularly about the lateral lobes of the thyroid gland in the sides of the neck or just above the hyoid bone, and are called accessory thyroids. Accessory thyroids may also exist by the side of the pyramidal lobe or upon the trachea, as low even as the level of the arch of the aorta. John B. Murphy¹ says, the field in which accessory thyroids "may be found can be roughly represented by an inverted trapezoid, the larger base being a line running from one apex of the mastoid process to the other; the smaller base is a line tangential to the arch of the aorta, and the sides are the two sternomastoid muscles." These isolated portions of gland tissue represent isolated portions of the median thyroid rudiment. Sometimes accessory thyroid tissue is found in the root of the tongue or in the interior of the larynx. Berry points out that a distinction must be made between true congenital accessory thyroid and masses of encapsulated thyroid tissue which "have been extruded from the gland," and still retain a connection with the gland. Such masses are false accessory thyroids.

Structure of the Thyroid (Fig. 1011).—The thyroid body is invested by a thin capsule of connective tissue which projects into its substance as a framework and imperfectly divides it into masses of irregular form and size, known as lobules. More slender septa separate the secretory alveoli from one another. When the organ is cut into, it is of a brownish-red color, and is seen to be made up of a number of closed vesicles or alveoli containing a yellow glairy fluid and separated from each other by intermediate connective tissue.

According to Baber, who has published some important observations on the minute structure of the thyroid,² the vesicles of the thyroid of the adult animal are generally closed cavities; but in some young animals (e.g., young dogs) the vesicles are more or less tubular and branched. This appearance he supposes

¹ Journal of the American Medical Association, December 16, 1905.
² Researches on the Minute Structure of the Thyroid Glands, Phil. Trans., part iii., 1881.
to be due to the mode of growth of the gland, and merely indicating that an increase in the number of vesicles is taking place. Each vesicle is lined by a single layer of epithelium, the cells of which are cubical or cylindrical. Between the epithelial cells exists a delicate reticulum. The vesicles are of various sizes and shapes, and contain as a normal product a viscid, homogeneous, semi-fluid, slightly yellowish material which frequently contains blood, the red corpuscles of which are found in it in various stages of disintegration and decolorization, the yellow tinge being probably due to the haemoglobin, which is thus set free from the colored corpuscles. This normal product is known as colloid material, and it is secreted by the epithelium. What part if any the colloid plays in the formation of the internal secretion of the gland is not known. It is quite possible that the colloid corresponds to the external secretion of glands with ducts and that the true internal secretion passes directly into the capillaries which form a network about the alveoli (Szymonowicz), or passes into the lymphatics. In the thyroid gland of the dog, Baber has found large round cells, parenchymatous cells, each provided with a single oval-shaped nucleus, which migrate into the interior of the gland-vesicles. Between the thyroid vesicles in the human being are collections of round cells. They are, in reality, miniature vesicles, and are much more numerous in youth than in old age.

The capillary blood-vessels form a dense plexus in the connective tissue around the vesicles, between the epithelium of the vesicles and the endothelium of the lymph-spaces, which latter surround a greater or smaller part of the circumference of the vesicles. These lymph-spaces empty themselves into lymphatic vessels which run in the interlobular connective tissue, not uncommonly surrounding the arteries which they accompany, and communicate with a network in the capsule of the gland. Small glands may be connected with this network. Baber has found in the lymphatics of the thyroid a viscid material which is morphologically identical with the normal constituent of the vesicle.

**Vessels and Nerves.**—The arteries (Figs. 394 and 395; see also p. 604) supplying the thyroid are the superior thyroid from the external carotid, and the inferior thyroid from the thyroid axis of the first part of the subclavian. Sometimes there is an additional vessel, the thyroidea media or ima, usually arising from the
innominate artery, but sometimes from the arch of the aorta or the common carotid. It ascends upon the front of the trachea. The superior thyroid artery reaches the summit of the upper horn of the gland, and usually at this point gives off a vessel which courses down the posterior surface of the gland. The main trunk passes downward and inward at the junction of the inner and anterior border of the upper horn, giving branches to adjacent structures and sending branches over the anterior surface of the thyroid gland. It reaches the isthmus and crosses the isthmus at its upper border to anastomose with the artery from the other side. The inferior thyroid artery, which is usually larger than the superior, after it has passed posterior to the sheath of the carotid and the sympathetic nerve, reaches the posterior surface of the gland. At this point branches are given off; some pass into the hilum; the others go to the posterior surface of the gland. The relation of the artery to the recurrent laryngeal nerve is very important to the surgeon. "Usually the main trunk of the artery passes behind the nerve; sometimes the artery breaks up before reaching the nerve; in this case one or more of the branches may pass in front of it. Much less commonly the main trunk or all its branches will be found to lie in front of the nerve." 1 If the thyroidea ima is present it goes to the lower part of the gland. The larger branches of the thyroid arteries are beneath the capsule and upon the surface of the gland; smaller branches pass to the interior of the gland. 2 (Berry). The arteries are remarkable for their large size and frequent anastomoses.

The thyroid veins (Figs. 447 and 448; see also p. 731) form a plexus upon the surface of the gland and beneath the capsule. Here and there veins pass through the capsule and go to adjacent venous trunks. Berry, accepting Kocher's description, notes the following veins: The superior thyroid vein runs with the superior thyroid artery and passes to the internal jugular vein. A transverse vein of the upper border of the isthmus joins the two superior thyroid veins. A single vein, the middle thyroid, sometimes emerges from the side of the gland and passes to the internal jugular. Usually, however, instead of this single vein there are two veins, the superior and inferior accessory thyroids. The superior accessory thyroid emerges from the outer side of the upper horn, below the apex, and passes to the internal jugular. The inferior accessory thyroid emerges from the posterior and inferior portion of the gland and passes to the internal jugular. The veins from the lower border of the gland vary greatly. A vein passes vertically down on each side in front of the trachea from the isthmus and from the inner side of the inferior horn. It is called by Kocher the thyroidea ima. The vein of the left side passes to the left innominate; the vein of the right side passes to the right innominate or left innominate. As Berry points out, the vein of one side may be small or may be absent, or the two veins may unite and form one vein which enters the left innominate. An inferior thyroid vein is often present. It is of small size, emerges at the inferior and external part of the gland, and passes to the corresponding innominate vein. 3

The lymphatics are numerous and of large size. Collecting trunks arise from a network within the capsule. Some trunks ascend from the upper margin of the isthmus and reach the gland in front of the larynx; others ascend along the superior thyroid artery and reach the glands at the bifurcation of the carotid. Descending trunks from the lower margin of the isthmus reach the glands in front of the trachea; trunks from the side of the gland descend to the glands about the recurrent laryngeal nerve. 4

The nerves are derived from the middle and inferior cervical ganglia of the sympathetic, and from the inferior laryngeal nerves. Probably there is also a branch from each superior laryngeal nerve.

Surgical Anatomy.—The thyroid gland may be congenitally absent, and when it is the individual suffers from the worst form of cretinism. One lobe may be congenitally absent, but this will provoke no trouble unless the other lobe undergoes atrophy.

1 Diseases of the Thyroid Gland. By James Berry.
2 Ibid.
3 The Lymphatics. By Poirier, Cunéo, and Delamaré. Translated and edited by Cecil H. Leaf.
Complete removal of the thyroid and parathyroids will produce operative myxoedema (cachexia strumipriva), unless accessory thyroids enlarge and perform the functions of the thyroid. The thyroid gland may be congenitally enlarged. The gland tends to atrophy in old age. It is atrophied in myxoedema and cretinism. Some forms of thyroid enlargement are called goitre.

When all parts of the gland enlarge the condition is known as parenchymatous goitre. Adenomatous goitre consists of an adenoma or of adenomata. In cystic goitre there is one or more cysts due to cystic degeneration of adenomata or to fusion of adjacent follicles. A pulsating goitre is one which receives impulses from the carotid pulsations. In a fibroid goitre there is increase of interstitial connective tissue. A goitre which passes back of the sternum is known as substernal or intrathoracic. A goitre may extend back of the trachea or back of the oesophagus.

Exophthalmic goitre, Graves’s disease or Basedow’s disease, is a remarkable disease. Its three chief symptoms are enlargement of the thyroid, or goitre; prominence of the eyeballs, or exophthalmos, and very rapid pulse, or tachyaeardia. Dyspnoea, tremor, and various other symptoms are usually found. The thyroid gland may be the seat of a carcinoma or sarcoma (malignant goitre), syphilis or tuberculous disease, ordinary inflammation, suppuration, or hydatid disease; for the relief of ordinary goitre various methods have been employed. Tapping, injection of astringents, simple incision, and the seton are obsolete. Ligature of the thyroid arteries is rarely performed as a curative measure. The superior and inferior thyroids of one side have been tied in some cases; all four thyroids in other cases. Jaboulay has performed exothyropexy. In this operation the gland is dislocated from its bed, brought out of the wound, and left exposed, in hope that it will atrophy. Division of the isthmus is occasionally practised to relieve dyspnoea. The operation sometimes succeeds, but often fails.

Exirption of one-half or two-thirds of the gland is a very successful operation. Removal of the entire gland will be followed by operative myxoedema. Removal or injury of the parathyroids causes tetany.

In exirpating a lobe of the thyroid by the method until recently in vogue, great care must be taken to avoid tearing the capsules, as if this happens the gland-tissue bleeds profusely. The thyroid arteries should be ligatured on the diseased side before an attempt is made to remove the mass, and in ligaturing the inferior thyroid the position of the recurrent laryngeal nerve must be borne in mind, so as not to include it in the ligature. In order to preserve the parathyroids from injury, C. H. Mayo recommends that after the vessels entering and leaving the thyroid have been double clamped and divided, the entire lobe should be elevated, the capsule split along the side of the gland and pushed back with gauze, and the gland lifted and removed without disturbing the posterior portion of the capsule.

A cystic or solid tumor of the thyroid may be removed by intraglandular enucleation. If operation becomes necessary in exophthalmic goitre, partial extirpation is usually preferred. Bilateral extirpation of the cervical ganglia of the sympathetic (sympathectomy or Jannsen’s operation) has been practised by some surgeons for exophthalmic goitre. The value of the procedure is uncertain.

THE PARATHYROID GLANDS (Fig. 1012).

The parathyroid glands or the epithelial corpuscles of Kohn were first described as anatomical entities by Sandstrom in 1850. Owen had seen the parathyroids in the rhinoceros in 1862, but he did not recognize any peculiarities of structure. Virchow observed them in man in 1863 but he regarded them as lymph-glands or detached portions of thyroid tissue. Gley, in 1891, called attention to glands within the body of the thyroid. In 1895 Kohn affirmed that the parathyroids are separate organs and not a part of the thyroid gland. If the thyroid gland has been carefully detached, two round bodies of small size may be found embedded

---

2 I am indebted to Dr. F. D. Patterson for collecting the literature upon the parathyroids.
upon the trachea or upon the surface of the lateral lobe of the gland, between the terminal branches of the inferior thyroid artery. "These are the parathyroids, about the size of orange-seeds, and brownish-red in color." They are smaller in infants than in adults. Welsh describes them in adults as from 6 to 7 mm. in length, 3 to 4 mm. in breadth, and 1½ to 2 mm. in thickness. These masses are constant in man. There is no record of a case in which they were congenitally absent. Although the parathyroids lie on or in the thyroid, they are always completely separated from it by capsules of connective tissue. Although there are usually four parathyroids, there may be but three, or there may be six or even eight. Parathyroid tissue may exist within the thyroid gland even when the superior parathyroids are present. Accessory parathyroids may be found over a wide area. Rogers and Ferguson found one in the middle of the posterior portion of the pharynx. Ogle found a gland in the thorax which was partly parathyroid. The parathyroids are divided from their situation into external and internal. The former, usually two in number, are situated, one on each side, in relation to the postero-internal surface of the lateral lobe of the thyroid; sometimes they are duplicated. The latter, also usually two in number, are placed one in or on each lateral lobe of the thyroid, generally near its mesal surface.

Structure.—The structure of the parathyroids is different from that of the thyroid. They are composed of solid masses of epithelial cells arranged in a more or less columnar fashion with numerous intervening capillaries. The columns of the parathyroids anastomose. There is a certain type of cell, but the form varies. These variations result from changes due to episodes of rest and activity (Verebely). MacCallum's studies seem to lead to the same conclusion. Thompson states that he finds only one type of cell in the infant gland, and that in the adult there is primarily but one type of cell, the other cells noted being modifications of the principal cell due to degeneration or hyperfunction. There is much lymphoid tissue connected with the columns. The nerves of the parathyroids are derived from the sympathetic system. Each parathyroid gland is supplied by a parathyroid artery. The inferior parathyroid artery is always a branch of the inferior thyroid artery or of the anastomosing channel between the superior and inferior thyroid arteries of one side (Geist). The superior parathyroid artery may be a branch of the superior thyroid (Poole), but it is usually a branch of the inferior thyroid or of the anastomosing channel. Ginsburg has shown that each of the glands has an accessory blood supply by anastomotic channels from the opposite side.

Embryology.—The parathyroids develop chronologically in advance of the thyroid. They are derived from the third and fourth branchial clefts of each side. An independent accessory parathyroid may develop from the fifth cleft (Getzowa, Michand). Some have regarded the parathyroids as embryonic portions of the thyroid, but, as MacCallum says, "there is no histological proof that parathyroid tissue can ever become converted into thyroid tissue." Most observers regard the parathyroids as distinct glands possessed of a special function. Certain it is, as Gley and others have shown, removal of the parathyroids from herbivora leaving the thyroid intact is followed by spasms, tetany, etc., just as complete thyroidectomy is followed by such symptoms in carnivora.

Surgical Anatomy.—Surgeons have become convinced that removal of the parathyroids in man causes tetany, and that damage to them may produce serious symptoms. Because of this danger most surgeons now prefer to remove a goitre from within the capsule of the thyroid gland after the plan of the Mayos, and thus avoiding the parathyroids.

THE THYMUS GLAND (Fig. 1013).

The thymus gland is a temporary organ, attaining its full size at the end of the second year, when it ceases to grow and remains practically stationary until puberty, at which period it rapidly degenerates. It does not entirely disappear, for the shrunken and-degenerated mass, even later in life, maintains a likeness to the original form and retains within its substance small portions of thymus tissue (Waldeyer). If examined when its growth is most active, it will be found to consist of two lateral lobes placed in close contact along the middle line, situated partly in the superior mediastinum, partly in the neck, and extending from the level of the fourth costal cartilage upward as high as the lower border of the thyroid gland. It is covered by the sternum and by the origins of the Sterno-hyoid and Sterno-thyroid muscles. Below, it rests upon the pericardium, being separated from the arch of the aorta and great vessels by a layer of fascia. In the neck it lies on the front and sides of the trachea, behind the Sterno-hyoid and Sterno-thyroid muscles. The two lobes generally differ in size; they are occasionally united so as to form a single mass, and are sometimes separated by an intermediate lobe. The thymus is of a pinkish-gray color, is soft and is lobulated on its surfaces. It is about two inches in length, one and a half inches in breadth below, and about three or four lines in thickness. At birth it weighs about half an ounce.

Structure (Figs. 1014 and 1015).—Each lateral lobe is composed of numerous lobules held together by delicate areolar tissue, the entire gland being enclosed in an investing capsule of a similar but denser structure. The primary lobules vary in size from a pin's head to a small pea, and are made up of a number of small nodules or follicles which are irregular in shape and are more or less fused together, especially toward the interior of the gland. Each follicle consists of a
medullary and cortical portion, which differ in many essential particulars from each other. The cortical portion is mainly composed of lymphoid cells supported by a delicate reticulum. In addition to this reticulum, of which traces only are found in the medullary portion, there is also a network of finely branched cells which is continuous with a similar network in the medullary portion. This network forms an adventitia to the blood-vessels. In the medullary portion there are but few lymphoid cells, but there are, especially toward the centre, granular cells and concentric corpuscles. The granular cells are rounded or flask-shaped masses attached (often by fibrillated extremities) to blood-vessels and to newly formed connective tissue. The concentric corpuscles are composed of a central mass consisting of one or more granular cells, and of a capsule which is formed of epithelioid cells which are continuous with the branched cells forming the network mentioned above.

Each follicle is surrounded by a capillary plexus from which vessels pass into the interior and radiate from the periphery toward the centre, and form a second zone just within the margin of the medullary portion. In the centre of the medulla there are very few vessels, and they are of minute size.

Watney has made the important observation that haemoglobin is found in the thymus either in cysts or in cells situated near to or forming part of the concentric corpuscles. This haemoglobin varies from granules to masses exactly resembling colored blood-corpuscles, oval in the bird, reptile, and fish; circular in all mammals except in the camel. Dr. Watney has also discovered in the lymph issuing from the thymus similar cells to those found in the gland, and, like them, containing haemoglobin either in the form of granules or masses. From these facts he arrives at the physiological conclusion that the thymus is one source of the colored blood-corpuscles.

Vessels and Nerves.—The arteries supplying the thymus are derived from the internal mammary and from the superior and inferior thyroid. The veins terminate in the two innominate veins, and in the internal mammary and the thyroid veins. The lymphatics are of large size, arise in the substance of the gland, and are said to terminate in the internal jugular vein. The nerves are
exceedingly minute; they are derived from the vagus and sympathetic. Branches from the descendens hypoglossi and phrenic reach the investing capsule, but do not penetrate into the substance of the gland.

**THE CAROTID GLAND OR CAROTID BODY (GLOMUS CAROTICUM)**

This body, when present, lies in the carotid bifurcation, to the inner side of the common carotid below the bifurcation, or on the posterior surface of the internal or of the external carotid artery. Gomez finds it "most commonly between the internal and external carotid arteries, resting posteriorly on the bifurcation of the common carotid." It is often absent. Funke found it absent in 7 foetuses out of 8. In 50 human cases examined by Gomez it was absent in 5 cases. In 4 of Gomez's cases it was found only on one side. It lies in fatty tissue and is surrounded by a fibrous capsule which is attached to the carotid sheath, upon which it lies by a short stump known as the ligament of Mayer. The carotid gland is about the size of a grain of corn; it is oval or rounded in shape and reddish-brown in color. The capsule of the gland sends septa inward. The septa divide the organ into follicles or cell-balls. These cell-balls are composed of endothelial cells and are associated with blood capillaries. A branch (or branches) from the carotid artery, upon which the gland

---

1 American Journal of Medical Sciences, July, 1908
lies, enters the carotid gland through the ligament of Mayer. Many nerve filaments surround the carotid gland, and they usually, but not always, form a plexus, known as the inter-carotid plexus. According to Poirier and Charpy these filaments come from the superior cervical ganglion of the sympathetic, the glossopharyngeal, the hypoglossal, the superior laryngeal, and the nervi molles of Haller. (This structure has been recently studied by John Funke, Reclus and Chevasson, Paltauf, Kartschenko, Marchand, and Gomez.)

**Surgical Anatomy.**—Tumors may arise from this structure. Such a tumor is apt to be above the level of the upper margin of the thyroid cartilage, and in most cases it moves with each arterial beat.

**THE COCCYGEAL GLAND OR COCCYGEAL BODY OR LUSCHKA’S GLAND (GLOMUS COCCYGEUM).**

Lying near the tip of the coccyx in a small tendinous interval formed by the union of the Levator ani muscles and just above the coccygeal attachment of the Sphincter ani, is a small conglobate body about as large as a lentil or a pea, first described by Luschka, and named by him the coccygeal gland. Its most obvious connections are with the arteries of the part. It is similar in structure to the carotid body.

**Structure.**—It consists of a congeries of small arteries with little aneurismal dilatations derived from the middle sacral and freely communicating with each other. These vessels are enclosed in one or more layers of polyhedral granular cells, and the whole structure is invested in a capsule of connective tissue which sends in trabeculae, dividing the interior into a number of spaces in which the vessels and cells are contained. Nerves pass into this little body from the sympathetic, but their mode of termination is unknown. Macalister believes the glomerulus of vessels “consists of the condensed and convoluted metameric dorsal arteries of the caudal segments embedded in tissue which is possibly a small persisting fragment of the neurenteric canal.” It resembles the carotid gland in structure, and is probably one of the ductless glands.

**THE PARASYMPATHETIC BODIES (ORGANA PARASYMPATHETICA OF ZUCKERKANDL).**

The parasympathetic bodies were discovered in 1901 by Zucker kendl. They are from one to four in number, situated retroperitoneally, ventrad of the abdominal aorta at the level of the third and fourth lumbar vertebrae. Each parasympathetic body is from 6 to 10 mm. in length and from 2 to 4 mm. in width. These bodies are usually supplied by fine arterial twigs from the aorta. They are best developed in the foetus and in infancy, and in their structure they resemble the carotid and coccygeal bodies.

THE URINARY ORGANS.

THE KIDNEYS (RENES) (Figs. 1016, 1017, 1018).

The Kidneys are large glands. They are two in number, and are situated in the back part of the abdomen, near the spinal column. Their function is to separate from the blood certain materials which, when dissolved in a quantity of water, also separated from the blood by the kidneys, constitute the urine.

They are placed in the loins, one on each side of the vertebral column, behind the peritoneum, and are surrounded by a mass of fat and loose areolar tissue, which constitutes the fatty capsule (capsula adiposa) (Figs. 1021 and 1022). There are two distinct layers in this fatty capsule. The superficial fatty layer is the pararenal fat. Keen calls this layer the transversalis layer of fat, because it is derived from the

---

1 See Gerota, Arch. f. Anatomie, Leipzig, 1895; Zuckerkindl, Medizinische Jahrbücher, Vienna, 1883.
transversalis fascia. The deeper and thicker perirenal layer is the true perinephric fat (Fig. 1022). The deeper layer of fat completely surrounds the kidney, and is somewhat adherent to the fibrous renal capsule. The fat about the kidney does not look like fat in other regions, but is soft, delicate, and of a canary yellow color. These two fatty layers are separated by a layer of connective tissue, which is the posterior layer of the perirenal fascia, and is called by Zuckerkandl the retrorenal fascia (fascia retrorenalis) (Fig. 1021). The true capsule of the kidney (tunica fibrosa) is thin, smooth, and glistening. The inner part of this capsule (tunica muscularis) contains unstriated muscle fibres. The true capsule can be easily separated from the underlying glandular structure. The upper extremity of the kidney is on a level with the upper border of the twelfth thoracic vertebra, the lower extremity on a level with the third lumbar vertebra (Fig. 1019). The right kidney is usually on a slightly lower level than the left, probably on account of the vicinity of the liver. In the female the kidneys are a little lower than in the male.

Each kidney is about four and a half inches in length, two to two and a half in breadth, and rather more than one inch in thickness. The left is somewhat longer, though narrower, than the right. The weight of the kidney in the adult male varies from 4½ ounces to 6 ounces; in the adult female, from 4 ounces to 5½ ounces. The combined weight of the two kidneys in proportion to the body is about 1 in 240.

The kidney has the characteristic form of a "flattened bean" (Spalteholz). It is flattened on its sides and presents at one part of its circumference a hollow. It is larger at its upper than at its lower extremity. The kidney presents for examination two surfaces, two borders, and an upper and lower extremity.

Surfaces. The Anterior Surface (facies anterior) (Figs. 1016 and 1017).—Its anterior surface is convex, looks forward and outward, and is partially covered by peritoneum. The right kidney in its upper three-fourths is in contact with the posterior part of the under surface of the right lobe of the liver. This area of the right kidney is flattened (impressio hepatica). Toward its inner border it is covered by the second part of the duodenum, while its lower and outer part is in relation with the hepatic flexure of the colon. The relation of the second part of the duodenum to the front of the right kidney is a varying one. The left kidney is covered above

---

1 W. W. Keen, in American Medicine, January 31, 1903.
by the posterior surface of the stomach, below the stomach by the pancreas, behind which are the splenic vessels. The region in contact with the stomach is markedly depressed (impressio gastrica). Its lower half is in contact with some of the coils

---

**Fig. 1019.**—Posterior surface of the kidneys. (Poirier and Charpy.)

**Fig. 1020.**—Relation of the kidney to the vertebral column, ribs, muscles, and lumbo-costal ligaments. (Poirier and Charpy.)
of the small intestine and sometimes with the third part of the duodenum. Near its outer border the anterior surface lies behind the spleen and the splenic flexure of the colon.

The kidneys are partly covered in front by peritoneum and partly uncovered. On the right kidney, the hepatic area, that is to say that portion of the kidney which produces the renal impression on the liver, is covered by peritoneum, which therefore separates the kidney from the liver; the duodenal and colic areas are not peritoneal, and these structures are connected to the kidney by loose connective tissue; at the lower and inner extremity is a small area, the mesocolic area, which is covered by a layer of peritoneum of the greater sac and by the colic vessels. On the left kidney the gastric area is covered by the peritoneum of the lesser sac; the pancreatic and colic areas are non-peritoneal; while, as on the right side, at the lower and inner extremity, is an area, mesocolic area, which is covered by the peritoneum of the greater sac and by the colic vessels.

The Posterior Surface (facies posterior) (Fig. 1018).—The posterior surface of the kidney is flatter than the anterior and is directed backward and inward. It is

![Diagram of the kidney showing the layers and fat.]
and when this is the case the perirenal areolar tissue is in immediate apposition with the diaphragmatic pleura. In the lower part of the posterior surface of the kidney is an impression produced by the Quadratus lumborum muscle and called the impressio muscularis. A little internal to this a flattening, caused by the Psoas muscle, is often recognizable. At the upper part of the posterior surface is a sulcus produced by contact with the Diaphragm.

**Borders. The External Border** (margo lateralis) (Figs. 1017 and 1018).—The external border is convex, and is directed outward and backward, toward the postero-lateral wall of the abdomen. On the left side it is in contact, at its upper part, with the spleen (Fig. 1016).

**The Internal Border** (margo medialis) (Figs. 1017 and 1018).—The internal border is concave, and is directed forward, inward, and a little downward. It presents a deep longitudinal fissure, bounded by a prominent overhanging anterior and posterior lip. This fissure is named the hilum (hillus renalis) (Fig. 1023), and allows of the passage of the vessels, nerves, and ureter into and out of the kidney.

**Extremities. The Superior Extremity** (extremitas superior) (Figs. 1017 and 1018).—The superior extremity, directly slightly inward as well as upward, is thick and rounded, and is surmounted by the suprarenal capsule (Fig. 1023), which covers also a small portion of the anterior surface.

**The Inferior Extremity** (extremitas inferior) (Figs. 1017 and 1018).—The inferior extremity, directed a little outward as well as downward, is smaller and thinner than the superior. It extends to within two inches of the crest of the ilium.

At the hilum of the kidney the relative position of the main structures passing into and out of the kidney is as follows: the vein is in front, the artery in the middle, and the duct or ureter behind and toward the lower part (Fig. 1018). By a knowledge of these relations the student may distinguish between the right and left kidney. The kidney is to be laid on the table before the student on its posterior surface, with its lower extremity toward the observer—that is to say, with the ureter behind and below the other vessels; the hilum will then be directed to the side to which the kidney belongs.

**General Structure of the Kidney.**—The kidney is surrounded by a distinct investment of fibrous tissue, which forms the firm, smooth true capsule covering the entire organ. The capsule passes over the margins of the hilum, enters the interior of the kidney, and covers the wall of the sinus. The true capsule is closely and firmly adherent to the renal pelvis where it is attached to the sinus. It closely invests it, but can be easily stripped off, in doing which, however, numerous fine processes of connective tissue which pass to the intrarenal connective tissue and numerous small blood-vessels are torn through. Beneath this fibrous layer a thin wide-meshed network of unstriped muscular fibre forms an incomplete covering to the organ. When the true capsule is stripped off, the surface of the kidney is found to be smooth, even, and of a deep-red color.

In infants fissures extending for some depth may be seen on the surface of the organ, a remnant of the lobular construction of the gland (Fig. 1040). The kidney is dense in texture, but is easily lacerable by mechanical force. In order to obtain a knowledge of the structure of the gland, a vertical section must be made from its convex to its concave border, and the loose tissue and fat removed around the vessels and the excretory duct (Fig. 1023). It will be then seen that the kidney consists of a central cavity surrounded at all parts but one by the proper kidney-substance. This central cavity is called the sinus (sinus renalis), and is lined by a prolongation of the fibrous coat of the kidney, which enters through a longitudinal fissure, the hilum (Fig. 1023), which is situated at that part of the cavity which is not surrounded by kidney structure. Through this fissure the blood-vessels of the kidney and its excretory duct pass, and therefore these structures, upon entering the kidney, are contained within the sinus.
THE URINARY ORGANS (Fig. 1017). The excretory duct or ureter, after entering, dilates into a wide, funnel-shaped sac named the pelvis (pelvis renalis) (Figs. 1023 and 1024). This divides into two or three tubular divisions, which subdivide into several short, truncated branches named calices or infundibula (calyces renales), all of which are contained in the central cavity of the kidney (Figs. 1023 and 1024). The blood-vessels of the kidney, after passing through the hilum, are contained in the sinus or central cavity, lying between its lining membrane and the excretory apparatus, before entering the kidney-substance (Fig. 1024).

This central cavity, as before mentioned, is surrounded on all sides except at the hilum by the substance of the kidney, which is at once seen to consist of two parts—viz., of an external granular investing part, which is called the cortical portion (substantia corticalis); and of an internal part, the medullary portion (substantia medullaris), made up of a number of dark-colored pyramids, with their bases resting on the cortical part and their apices converging toward the centre, where they form prominent papillae, the renal papillae (papillae renales), which project into the interior of the calices (Fig. 1023.)

The cortical substance (Figs 1023 and 1030) is of a bright reddish-brown color, soft, granular, and easily lacerable. It is found everywhere immediately beneath the capsule, and is seen to extend in an arched form over the base of each medullary pyramid. Prolongations of the cortical substance pass between the pyramids toward the renal sinus. These prolongations are the cortical columns or the columns of Bertin (columnae renales) (Fig. 1023, B B). The columns contain blood-vessels, nerves, and lymphatics. The base of each pyramid (basis pyramidis) is known as the intermediate zone. That portion of the cortical substance which stretches from one cortical column to the next, and intervenes between the base of the pyramid and the capsule (marked by the dotted line extending from A to A' in Fig. 1023), is called a cortical arch, the depth of which varies from a third to half an inch.
The medullary substance (Figs. 1023 and 1030), as before stated, is seen to consist of red-colored, striated, conical masses, the pyramids of Malpighi (pyramides renales) (Fig. 1023), the number of which, varying from eight to eighteen, corresponds to the number of lobes of which the organ in the foetal state is composed. The pyramids are composed of straight tubes which pass between the apices of the papillae and the cortical margin. They enter the cortex in masses called the pyramids of Ferrein (see below). The sides of the pyramids of Malpighi are contiguous with the cortical columns, while the apices, known as the papillae of the kidney (Figs. 1023 and 1027), project into the calices of the ureter, each calyx receiving two or three papillae. Radiating from the bases of the pyramids of Malpighi are ridges of cortical substance with distinct depressions between them.

These ridges are the medullary rays (pars radiata) or pyramids of Ferrein (Figs. 1026 and 1030). The labyrinth of the cortex (Fig. 1026) is constituted by the kidney substance between the rays. The pyramids of Ferrein look like direct continuations of the medullary substance, but, in reality, they are in the cortex, and are formed by the straight tubes extending in masses into the cortex. The pyramids of Ferrein are much smaller than the pyramids of Malpighi. In the columns of
Bertin blood-vessels, nerves, and lymphatics pass to and emerge from the sinus by way of small foramina. The summit of a papilla contains a number of orifices of papillary ducts. Such an area is called an area cribrosa (Fig. 1027).

These two parts, cortical and medullary, so dissimilar in appearance, are very similar in structure, being made up of urinary tubes and blood-vessels united and bound together by a connecting matrix or stroma.

**Minute Anatomy.**—The uriniferous tubes, urinary canals or tubuli uriniferi (tubuli renales) (Figs. 1025 and 1030), of which the kidney is for the most part made up, commence in the cortical portion of the kidney. Each tubule begins between the medullary rays (Fig. 1026) in a sac, Bowman's capsule or the Malpighian capsule (see below). The tubules, as a rule, after pursuing a very circuitous course through the cortical and medullary parts of the kidney, finally terminate at the apices of the Malpighian pyramids by open mouths, so that the fluid which they contain is emptied into the dilated extremity of the ureter contained in the sinus of the kidney. If the surface of one of the papillae is examined with a lens, it will be seen to be studded over with a number of small depressions (foramina papillaria), from sixteen to twenty in number, and in a fresh kidney, upon pressure being made, fluid will be seen to exude from these depressions. They are the orifices of the tubuli uriniferi, which terminate in this situation. The tubuli uriniferi being in the cortex as the Malpighian bodies or corpuscles (corpuscula renis) (Figs. 1025, 1026, 1028, and 1031), which are small rounded masses, varying in size, but average, about \( \frac{1}{12} \) of an inch in diameter. They are of a deep-red color, and are found only in the cortical portion of the kidney. Each of these little bodies is composed of two parts—a central glomerulus of vessels, called a Malpighian tuft, and a membranous envelope, the Malpighian capsule or capsule of Bowman (capsula glomeruli), which latter is a small pouch-like commencement of a uriniferous tubule.

The Malpighian Tuft or Vascular Glomerulus (Figs. 1028, 1030, 1035, and 1036) is a network of convoluted capillary blood-vessels held together by scanty connective tissue and grouped into from two to five lobules. This capillary network is derived from a small arterial twig, the afferent vessel, which pierces the wall of the capsule, generally at a point opposite that at which the latter is connected.
with the tube; and the resulting efferent vessel emerges from the capsule at the same point. The afferent vessel is usually the larger of the two (Fig. 1028). The Malpighian or Bowman's capsule (capsula glomeruli) (Figs. 1028, 1029, and 1030), which surrounds the glomerulus, is formed of a hyaline membrane supported by a small amount of connective tissue which is continuous with the connective tissue of the tube. It is lined on its inner surface with a layer of squamous epithelial cells which are reflected from the lining membrane on to the glomerulus at the point of entrance or exit of the afferent and efferent vessels. The whole surface of the glomerulus is covered with a continuous layer of the same cells on a delicate supporting membrane, which with the cells dips in between the lobules of the glomerulus, closely surrounding them. Thus, between the glomerulus and the capsule a space is left, forming a cavity lined by a continuous layer of cells, which varies in size according to the state of secretion and the amount of fluid present in it. The cells, as above stated, are squamous in the adult, but in the foetus and young subject they are polyhedral or even columnar.

The Tubuli Uriniferi, commencing in the Malpighian bodies, in their course present many changes in shape and direction (tubuli renales contorti), and are contained partly in the medullary and partly in the cortical portions of the organ.

At the junction of a tubule with the Malpighian capsule there is a somewhat constricted portion which is termed the neck (Fig. 1031). Beyond this the tubule becomes convoluted, and pursues a considerable course in the cortical structure, constituting the proximal or first convoluted tubule (Figs. 1030 and 1031). After a time the convolutions disappear, and the tubule approaches the medullary portion of the kidney in a more or less spiral manner. This section of the tubule has been called the spiral tube of Schachowa (Fig. 1031). Throughout this portion of their course the tubuli uriniferi have been contained entirely in the cortical structure, and have presented a pretty uniform calibre. They now enter the medullary portion, and suddenly become much smaller, quite straight in direction (tubuli renales recti), and each tubule dips down for a variable depth into the pyramids, constituting the descending limb of Henle's loop (Figs. 1030 and 1031). Bending on itself, it forms a kind of loop near the apex of the pyramid, the loop of Henle, and, reascending, becomes suddenly enlarged and again spiral.
in direction, forming the ascending limb of Henle's loop (Figs. 1030 and 1031), and re-enters the cortical structure. This portion of the tubule does not present a uniform calibre, but becomes narrower as it ascends and irregular or somewhat spiral in outline (Fig. 1031). As a narrow tube it enters the cortex and ascends for a short distance, when it again becomes dilated, irregular, and angular. This section is termed the irregular tubule (Fig. 1031); it terminates in a convoluted tubule which exactly resembles the proximal convoluted tubule; and is called the distal or second convoluted tubule (Figs. 1030 and 1031). This again terminates in a narrow curved or junctional tubule, which enters the straight or collecting tube.

Each straight collecting or receiving tube (Figs. 1030 and 1031) commences by a small orifice on the summit of a papilla, thus opening and discharging its contents into the interior of one of the calices. Traced into the substance of the pyramid, these tubes are found to run from apex to base, dividing dichotomously in their course and slightly diverging from each other. Thus dividing and subdividing, they reach the base of the pyramid, and enter the cortical structure greatly increased in number. Upon entering the cortical portion they continue a straight course for a variable distance, and are arranged in groups, several of these groups corresponding to a single pyramid. The tubes in the centre of the group are the longest, and reach almost to the surface of the kidney, while the external ones are shorter, and advance only a short distance into the cortex. In consequence of this arrangement the cortical portion presents a number of conical masses, the apices of which reach the periphery of the organ, and the bases are applied to the medullary portion. These are termed the medul-

**Fig. 1029.—A section through the cortex of an ape's kidney. A Malpighian corpuscle, together with the beginning of the urinary canal, is shown. X350.**
lary rays or the pyramids of Ferrein (Fig. 1026; also p. 1426). As they run through the cortical portion the straight tubes receive on either side the curved extremity of the convoluted tubes, which, as stated above, commence at the Malpighian bodies. Each collecting tube receives a number of tubules, and several collecting tubes unite together to form a papillary duct (Fig. 1030) and open by a foramen (Fig. 1027) at the surface of the papilla.

It will be seen from the above description that there is a continuous series of tubes from their commencement in the Malpighian bodies to their termination at the orifices on the apices of the pyramids of Malpighi, and that the urine,
the secretion of which commences in the capsule, finds its way through these tubes into the calices of the kidney, and so into the ureter. To recapitulate:

1. The tube first presents a constricted portion, (1) the neck.
2. It forms a wide convoluted tube, the proximal convoluted tube.
3. It becomes spiral, the spiral tubule of Schachowa.
4. It enters the medullary structure as a narrow, straight tube, the descending limb of Henle’s loop.
5. Forming a loop and becoming dilated, it ascends somewhat spirally, and, gradually diminishing in calibre, again enters the cortical structure, the ascending limb of Henle’s loop.
6. It now becomes irregular and angular in outline, the irregular tubule.
7. It then becomes convoluted, the distal convoluted tubule.
8. Diminishing in size, it forms a curve, the curved or junctional tubule.
9. Finally, it joins a straight tube, the straight collecting tube, which is continued downward through the medullary substance and joins other straight tubes to form a papillary duct, which opens in a foramen at the apex of a pyramid.

**The Tubuli Uriniferi: Their Structure** (Figs. 1032, 1033, and 1034).

The tubuli uriniferi consist of basement-membrane lined with epithelium. The
epithelium varies considerably in different sections of the urinary tubes. In the neck the epithelium is continuous with that lining the Malpighian capsule, and, like it, consists of flattened cells with an oval nucleus. The cells are, however, very indistinct and difficult to trace, and the tube has here the appearance of a simple basement-membrane unlined with epithelium. In the proximal convoluted tubule and the spiral tubule of Schachowa the epithelium is polyhedral in shape, the sides of the cells not being straight, but fitting into each other, and in some animals so fused together that it is impossible to make out the lines of junction. In the human kidney the cells often present an angular projection of the surface next the basement-membrane. These cells are made up of more or less rod-like fibres, which rest by one extremity on the basement-membrane, whilst the other projects toward the lumen of the tube. This gives to the cells the appearance of distinct striation. In the descendine limb of Henle's loop the epithelium resembles that found in the Malpighian capsule and the commencement of the tube, consisting of flat transparent epithelial plates with an oval nucleus (Fig. 1032). In the ascending limb, on the other hand, the cells partake more of the character of those described as existing in the proximal convoluted tubule, being polyhedral in shape and presenting the same appearance of striation. The nucleus, however, is not situated in the centre of the cell, but near the lumen (Fig. 1034). After the ascending limb of Henle's loop becomes narrower upon entering the cortical structure, the striation appears to be confined to the outer part of the cell; at all events, it is much more distinct in this situation, the nucleus, which appears flattened and angular, being still situated near the lumen. In the irregular tubule the cells undergo a still further change, becoming very angular, and presenting thick bright rods or markings, which render the striation much more distinct than in any other section of the urinary tubules. In the distal convoluted tubule the epithelium appears to be somewhat similar to that which has been described as existing in the proximal convoluted tubule, but presents a peculiar refractive appearance. In the curved tubule, just before its entrance into the straight collecting tube, the epithelium varies greatly as regards the shape of the cells, some being angular with short processes, others spindle-shaped, others polyhedral.

In the straight tubes the epithelium is more or less columnar; in its papillary portion the cells are distinctly columnar and transparent (Fig. 1033), but as the tube approaches the cortex the cells are less uniform in shape; some are polyhedral, and others angular with short processes.
The Renal Blood-vessels.—The kidney is plentifully supplied with blood by the renal artery (Figs. 1018 and 1024), a large offset of the abdominal aorta. Previously to entering the kidney, each artery divides into four or five branches, which are distributed to its substance. At the hilum these branches lie between the renal vein and ureter, the vein being in front, the ureter behind. Each vessel gives off a small branch to the suprarenal capsules, the ureter, and the surrounding cellular tissue and muscles. It has been pointed out by Hyrtl (p. 680) that the renal artery gives off a branch which divides and supplies the dorsal portion of the kidney and a branch which divides and supplies the ventral portion of the kidney. Between these two vascular systems is a non-vascular zone, called by Robinson the exsanguinated renal zone of Hyrtl. It "is one-half inch dorsal to the lateral longitudinal renal border." Frequently there is a second renal artery, which is given off from the abdominal aorta at a lower level, and supplies the lower portion of the kidney. It is termed the inferior renal artery. The branches of the renal arteries pass to the kidney substance between the pyramids and are known as interlobar arteries (arteriae interlobares renis) (Figs. 1026, 1030, 1037, and 1038). At the junction of the cortical and medullary portions these vessels turn and for a short distance pursue a course parallel to the kidney surface. There are thus formed a series of incomplete vascular arches across the bases of the pyramids, the arcuate arteries (arteriae arciformes) (Figs. 1030, 1035, and 1036). From these arches two sets of vessels come. The vessels of one set go to the periphery and enter the labyrinth, those of the other set pass toward the centre and enter the intermediate zone of the medulla. These last vessels are the arteriolae recti (Figs. 1030, 1035, and 1036). Because of these vessels the kidney exhibits striations on section. Each of the arteriolae recti in the medulla divides into numerous small branches which are nearly parallel to each other and supply the tubules of this region. The arteries which arise from the arches and pass to the periphery are the interlobular arteries (arteriae interlobulares) (Figs. 1030, 1035, 1036, and 1039). They traverse the labyrinth and pass toward the surface of the kidney. A number of short branches, the vasa afferentia, are given off by the interlobular arteries (Figs. 1030, 1035, 1036, and 1039). Each afferent vessel passes to a capsule of Bowman. On reaching the capsule the vessel forms a capillary mass, the glomerulus, which is within the invaginated capsule (Figs. 1030, 1035, and 1039).

Emerging from each glomerulus is a small vessel, the vas efferens (Figs. 1030, 1035, and 1039).
1028, 1030, 1035, and 1039). This vessel divides into capillaries which are distributed to the tubules of the labyrinth and medullary rays. Blood is gathered from the capillaries about the tubules by veins which correspond to the interlobular arteries and arteriolae recti. These veins form a set of arches across the bases of the pyramids. From the arches veins arise and pass between the pyramids to the sinus of the kidney, where they unite and form branches of the renal vein.

**Nerves of the Kidney.**—The nerves of the kidney, although small, are about fifteen in number. They have small ganglia developed upon them, and are derived from the renal plexus, which is formed by branches from the solar plexus, the lower and outer part of the semilunar ganglion and aortic plexus, and from the lesser and smallest splanchnic nerves. They communicate with the spermatic plexus, a circumstance which may explain the occurrence of pain in the testicle in affections of the kidney. So far as they have been traced, they seem to accompany the renal artery and its branches, but their exact mode of termination is not known.

**The Lymphatics.**—The lymphatics consist of a superficial and deep set.

The superficial lymphatics are just beneath the capsule. From them come two sets of collecting trunks (Sappey). One set joins the deep collectors by entering the kidney substance or passing to the hilum. Another set pass into the lymphatics of the fatty capsule.

The deep collectors emerge from the hilum and lie about the renal artery and vein. From the right kidney some of the trunks pass to the glands about the postcava and possibly also in the glands in front of the aorta. Others end in the glands back of the postcava (Stahr).

From the left kidney the trunks pass to the glands which lie along the left side of the abdominal aorta.¹ The lymphatics of the fatty capsule of the kidney pass to the same glands as do the deep collectors of the kidney (Stahr).

**Connective Tissue or Intertubular Stroma.**—Although the tubules and vessels are closely packed, a certain small amount of connective tissue, continuous with the capsule, binds them firmly together. This tissue was first described by Good sir, and subsequently by Bowman. Ludwig and Zawarykin have observed distinct fibres passing around the Malpighian bodies, and Henle has seen them between the straight tubes composing the medullary structure.

**Variations and Abnormalities.**—Congenital absence of the kidney has been observed. Not unusually one kidney is considerably larger than the other; occasionally one is very large and the other is very small, from atrophy, the large organ having become large in response to a functional need, which causes it to compensate for the insufficiency of the small kidney. If a kidney is removed surgically, the other kidney enlarges. As previously stated, the kidneys of the foetus and of the young child show distinct fissures which makes each organ lobulated (Fig. 1040). The adult kidneys frequently exhibit remains of these fissures. A horseshoe kidney is a condition in which the lower poles of the two kidneys are united by kidney structure, the bend of union crossing the middle line. The strip of kidney tissue which effects the junction may be slight in amount,

¹ The Lymphatics. By Poirier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf.
considerable, or extensive. Sometimes the two kidneys are completely fused together into one large organ with two ureters.

**Surface Form.**—The kidneys, being situated at the back part of the abdominal cavity and deeply placed, cannot be felt unless enlarged or misplaced. They are situated on the confines of the epigastric and umbilical regions internally, with the hypochondriac and lumbar regions externally. The left is somewhat higher than the right. According to Morris, the position of the kidney may be thus defined: *Anteriorly:* "1. A horizontal line through the umbilicus is below the lower edge of each kidney. 2. A vertical line carried upward to the costal arch from the middle of Poupart's ligament has one-third of the kidney to its outer side and two-thirds to its inner side—i.e., between this line and the median line of the body." In adopting these lines it must be borne in mind that the axes of the kidneys are not vertical, but oblique, and if continued upward would meet about the ninth dorsal vertebra. *Posteriorly:* The upper end of the left kidney would be defined by a line drawn horizontally outward from the spinous process of the eleventh dorsal vertebra, and its lower end by a point two inches above the iliac crest. The right kidney would be half to three-quarters of an inch below. Morris lays down the following rules for indicating the position of the kidney on the posterior surface of the body: "1. A line parallel with, and one inch from, the spine, between the lower edge of the tip of the spinous process of the eleventh dorsal vertebra and the lower edge of the spinous process of the third lumbar vertebra. 2. A line from the top of this first line outward at right angles to it for two and three-quarter inches. 3. A line from the lower end of the first transversely outward for two and three-quarter inches. 4. A line parallel to the first and connecting the outer extremities of the second and third lines just described."

The hilum of the kidney lies about two inches from the middle line of the back, at the level of the spinous process of the first lumbar vertebra.

**Surgical Anatomy.**—Cases of congenital absence of a kidney, of atrophy of a kidney, and of horseshoe kidney are of great importance, and must be duly taken into account, when nephrectomy is contemplated. A more common malformation is where the two kidneys are fused together. They may be only joined together at their lower ends by means of a thick mass of renal tissue, so as to form a horseshoe-shaped body, or they may be completely united, forming a disk-like kidney, from which two ureters descend into the bladder. These fused kidneys are generally situated in the middle line of the abdomen, but may be misplaced as well.

One or both kidneys may be misplaced as a congenital condition, and remain fixed in this abnormal position. They are then very often misshapen. They may be situated higher or lower than normal or removed farther from the spine than usual or they may be displaced into the iliac fossa, over the sacro-iliac joint, on to the promontory of the sacrum, or into the pelvis between the rectum and bladder or by the side of the uterus. In these latter cases they may give rise to very serious trouble. The kidney may also be misplaced as a congenital condition, but may not be fixed. It is then known as a floating kidney. It is believed to be due to the fact that the kidney is completely enveloped by peritoneum, which then passes backward to the spine as a double layer, forming a mesonephron, which permits of movement taking place. The kidney may also be misplaced as an acquired condition; in these cases the kidney is mobile in the tissues by which it is surrounded, either moving in or moving with its fatty capsule. This condition is known as movable kidney (nephroptosis), and is more common in the female than in the male, and on the right than the left side. If a displaced kidney becomes fixed in an abnormal position, it is said to be dislocated. Movable kidney cannot be distinguished from floating kidney until the kidney is exposed by incision. Other malformations are the persistence of the foetal lobulation; the presence of two pelves or two ureters to the one kidney. In some rare instances a third kidney may be present.

The kidney is embedded in a large quantity of loose fatty tissue, and is but partially covered by peritoneum; hence, rupture of this organ is not nearly so serious an accident as rupture of the liver or spleen, since the extravasation of blood and urine which follows is, in the majority of cases, outside the peritoneal cavity. Occasionally the kidney may be *bruised* by blows in the loin or by being compressed between the lower ribs and the ilium when the body is violently bent forward. This is followed by a little transient *haematuria*, which, however, speedily passes off. Occasionally, when rupture involves the pelvis of the kidney or the commencement of the ureter, this duct may become blocked, and *hydropnephrosis* follows.

The loose cellular tissue around the kidney may be the seat of suppuration, constituting *perinephritic abscess*. This may be due to injury, to disease of the kidney itself, or to extension of inflammation from neighboring parts. The abscess may burst into the pleura, causing empyema; into the colon or bladder; or may point externally in the groin or loin. *Tumors of the kidney,* of which, perhaps, sarcoma in children is the most common, may be recognized by their position and fixity; by the resonant colon lying in front of it; by their not moving with respiration; and by their rounded outline, not presenting a notched anterior margin like the spleen, with which they are most likely to be confounded. The *examination of the kidney* should be bimanual; that is to say, one hand should be placed in the flank and firm pressure made forward, while
the other hand is buried in the abdominal wall, over the situation of the organ. Manipulation of the kidney frequently produces a peculiar sickening sensation and some faintness.

The kidney has, of late years, been frequently attacked surgically. It may be exposed and opened for exploration or the evacuation of pus (nephrotomy); it may be incised for the removal of stone (nephro-lithotomy); it may be sutured when wounded (nephropraxy); it may be fixed in place by sutures (nephropexy) or gauze pads when movable or floating; or it may be removed (nephrectomy).

The kidney may be exposed either by a lumbar or abdominal incision. The operation is best performed by a lumbar incision, except in a case of very large tumor or of wandering kidney with a loose mesonephron, on account of the advantages which it possesses of not opening the peritoneum and of affording admirable drainage. It may be performed either by an oblique a vertical, or a transverse incision. A common incision for exposing the kidney begins an inch below the twelfth rib at the margin of the Erector spinae muscle and passes obliquely downward and forward, exposing the anterior border of the Latissimus dorsi and the posterior border of the Internal oblique. The surgeon divides the posterior leaflet of the lumbar fascia, draws aside or incises the Quadratus lumbarum, and cuts the anterior leaflet of the lumbar fascia and also the transversalis fascia. He opens the fatty capsule down to the kidney and strips it from the true capsule, bringing the kidney outside of the body for inspection. The vertical incision at the edge of the Erector spinae muscle is frequently used. A gridiron or muscle-splitting operation is used by some in order to avoid the division of nerves, vessels, and muscular fibre.

The abdominal operation is best performed by an incision in the linea semilunaris on the side of the kidney to be removed, as recommended by Langenbuch; the kidney is then reached from the outer side of the colon, ascending or descending, as the case may be, and the vessels of the colon are not interfered with. If the incision were made in the linea alba, the kidney would be reached from the inner side of the colon, and the vessels running to supply the colon would necessarily be interfered with. The incision is made of varying length according to the size of the kidney, and commences just below the costal arch. The abdominal cavity is opened. The intestines are held aside, and the outer layer of the mesocolon incised, so that the fingers can be introduced behind the peritoneum and the renal vessels are sought for. These vessels are then to be ligatured: if tied separately, care must be taken to ligature the artery first. The kidney must now be enucleated, and the vessels and the ureter divided, and the latter disinfected and tied, and, if it is thought necessary, stitched to the edge of the wound.

THE URETER (Figs. 1017, 1018, 1019, 1024, 1041, 1042).

The ureters are the two tubes which conduct the urine from the kidneys into the bladder. The ureter commences within the sinus of the kidney by a number of short truncated branches, the calices or infundibula, which unite either directly or indirectly to form a dilated pouch, the pelvis (Fig. 1023), from which the ureter, after passing through the hilum of the kidney, descends to the bladder. The calices are cup-like tubes encircling the apices of the Malpighian pyramids; but inasmuch as one calyx may include two or even more papillae, their number is generally less than the pyramids themselves. The calices vary in number from eight to eighteen. These calices converge into two or three tubular divisions which by their junction form the pelvis or dilated portion of the ureter. The portion last mentioned, where the pelvis merges into the ureter proper, is found opposite the spinous process of the first lumbar vertebra, in which situation it is accessible behind the peritoneum (Fig. 1019).

The Ureter Proper.—The ureter proper is a cylindrical membranous tube, about sixteen inches in length and of the diameter of a goosequill, extending from the pelvis of the kidney to the bladder. Its course is obliquely downward and inward through the lumbar region (pars abdominalis) (Fig. 1042), into the cavity of the pelvis (pars pelvina) (Fig. 1042), where it passes downward, forward, and inward across that cavity to the base of the bladder, into which it then opens by a constricted orifice (orificeum ureteris) (Fig. 1039), after having passed obliquely for nearly an inch between its muscular and mucous coats (Fig. 1041). The lower part of the abdominal portion of the ureter exhibits a spindle-shaped dilatation.

Relations (Fig. 1042).—In its course it rests upon the Psoas muscle, being covered by the peritoneum, and crossed obliquely, from within outward, by the
spermatic vessels; the right ureter is crossed by the branches of the mesenteric arteries, which are distributed to the ascending colon, and the left ureter by those for the descending colon; the right ureter lying close to the outer side of the postcava. Opposite the first piece of the sacrum it crosses either the common or external iliac artery and vein, lying behind the ileum on the right side and behind the sigmoid flexure of the colon on the left side. In the pelvis it enters the posterior false ligament of the bladder, below the obliterated hypogastric artery, the vas deferens in the male passing between it and the bladder. In the female the ureter is to the inner side of the uterine artery at the wall of the pelvis, it passes forward and inward below the posterior layer of the broad ligament running through the parametrium, passing along the side of the neck of the uterus and upper part of the vagina, being in contact with the anterior and lateral vaginal walls and being crossed anteriorly by the uterine artery (Fig. 1115). At the base of the bladder the ureter is situated about two inches from its fellow: lying, in the male, about an inch and a half from the vesical orifice of the urethra, at one of the posterior angles of the trigone (Fig. 1059).

**Structure.**—The ureter is composed of three coats—fibrous, muscular, and mucous.

**The Fibrous Coat** (*tunica adventitia*).—The fibrous coat is the same throughout the entire length of the duct, being continuous at one end with the fibrous capsule of the kidney at the floor of the sinus, while at the other it is lost in the fibrous structure of the bladder.
The Muscular Coat (tunica muscularis).—In the pelvis of the kidney the muscular coat consists of two layers, longitudinal and circular; the longitudinal fibres become lost upon the sides of the papillae at the extremities of the calices; the circular fibres may be traced surrounding the medullary structure in the same situation. In the ureter proper the muscular fibres are very distinct, and are arranged in three layers—an external longitudinal (stratum externum), a middle circular (stratum medium), and an internal layer (stratum internum), less distinct than the other two, but having a general longitudinal direction. According to Kölliker, this internal layer is only found in the neighborhood of the bladder.

The Mucous Coat (tunica mucosa).—The mucous coat is smooth, and presents a few longitudinal folds which become effaced by distention. It is continuous with the mucous membrane of the bladder below, whilst it is prolonged over the papillae of the kidney above. Its epithelium is of a peculiar character, and resembles that found in the bladder. It is known by the name of transitional epithelium. It consists of several layers of cells, of which the innermost—that is to say, the cells in contact with the urine—are quadrilateral in shape, with concave margins on their outer surface, into which fit the rounded ends of the cells of the second layer. These, the intermediate cells, more or less resemble columnar epithelium, and are pear-shaped, with a rounded internal extremity which fits into the concavity of the cells of the first layer, and a narrow external extremity which is wedged in between the cells of the third layer. The external or third layer consists of conical or oval cells varying in number in different parts, and presenting processes which extend down into the basement-membrane.

Vessels and Nerves.—The arteries supplying the ureter are branches from the renal, spermatic, internal iliac, and inferior vesical.

The nerves are derived from the inferior mesenteric, spermatic, and pelvic plexuses.

Surgical Anatomy.—Subcutaneous rupture of the ureter is not a common accident, but occasionally occurs from a sharp, direct blow on the abdomen, as from the kick of a horse. The ureter may be either torn completely across, or only partially divided, and, as a rule, the peritoneum escapes injury. If torn completely across the urine collects in the retroperitoneal tissues; if it is not completely divided, the lumen of the tube may become obstructed and hydro-nephrosis or pyo-nephrosis results. The ureter may be accidentally wounded in some abdominal operations; if this should happen, the divided ends must be sutured together, or, failing to accomplish this, the upper end must be implanted into the bladder or the intestine.

THE SUPRARENAL CAPSULE OR GLAND (GLANDULA SUPRARENALIS) (Figs. 1023, 1043, 1044).

The suprarenal capsules belong to the class of ductless glands. They are two small flattened bodies, of a yellowish color, situated at the back part of the abdomen, behind the peritoneum, and immediately above and in front of the upper end of each kidney; hence their name. The right one (Fig. 1043) is somewhat triangular in shape, bearing a resemblance to a cocked hat; the left (Fig. 1044) is more semilunar, usually larger and placed at a higher level than the right. They vary in size in different individuals, being sometimes so small as to be scarcely detected; their usual size is from an inch and a quarter to nearly two inches in length, rather less in width, and from two to three lines in thickness. Their average weight is from one to one and a half drachms each.

Relations.—The relations of the suprarenal capsules differ on the two sides of the body.

The Right Suprarenal (Fig. 1043).—The right suprarenal is roughly triangular in shape, its angles pointing upward, downward, and outward. It presents two surfaces for examination, an anterior and a posterior. The anterior surface (facies
anterior) presents two areas, separated by a furrow, the hilum (hilus glandulae suprarenalis): one area occupying about one-third of the whole surface, is situated above and internally; it is depressed, uncovered by peritoneum, and is in contact in front with the posterior surface of the right lobe of the liver, and along its inner border with the postcava; the remaining area is elevated, and is divided into a non-peritoneal portion, in contact with the hepatic flexure of the duodenum, and a portion covered by peritoneum forming the hepato-renal fold. The posterior surface (facies posterior) is slightly convex, and rests upon the Diaphragm. The base (basis glandulae suprarenalis) is concave, and is in contact with the upper end and the adjacent part of the anterior surface of the kidney.

The Left Suprarenal (Fig. 1044).—The left suprarenal is crescentic in shape, its concavity being adapted to the upper end of the left kidney. It presents an inner border which is convex, and an outer which is concave; its upper border is narrow, and its lower rounded. Its anterior surface (facies anterior) presents two areas: an upper one, covered by the peritoneum forming the lesser sac, which separates it from the cardiac end of the stomach and to a small extent from the superior extremity of the spleen; and a lower one, which is in contact with the pancreas and splenic artery, and is therefore not covered by the peritoneum. A hilum is present, as in the right suprarenal. Its posterior surface (facies posterior) presents a vertical ridge, which divides it into two areas. The ridge lies in the sulcus between the kidney and crus of the Diaphragm, while the area on either side of it lies on these parts respectively; the outer area, which is thin, resting on the kidney, and the inner and smaller area resting on the left crus of the Diaphragm. The surface of the suprarenal gland is surrounded by areolar tissue containing much fat, and closely invested by a thin fibrous coat, which is difficult to remove, on account of numerous fibrous processes and vessels which enter the organ through the furrows on its anterior surface and base.

Accessory Suprarenal Glands (glandulae suprarenales accessoriae).—Small accessory suprarenals are often to be found in the connective tissue around the suprarenals. The smaller of these, on section, show a uniform surface, but in some of the larger a distinct medulla can be made out.

Structure (Figs. 1045, 1046, and 1047).—On making a perpendicular section (Fig. 1045), the suprarenal gland is seen to consist of two substances—external or cortical and internal or medullary. The former, which constitutes the chief part of the organ, is of a deep-yellow color. The medullary substance is soft, pulpy,
and of a dark-brown or black color, whence the name atrabiliary capsules formerly given to these organs. In the centre is often seen a space, not natural, but formed by breaking down after death of the medullary substance.

The Cortical Portion (substantia corticalis) (Fig. 1045).—The cortical substance consists chiefly of narrow columnar masses placed perpendicularly to the surface. This arrangement is due to the disposition of the capsule, which sends into the interior of the gland processes passing in vertically and communicating with each other by transverse bands so as to form spaces which open into each other. These spaces are of slight depth near the surface of the organ, so that there the section somewhat resembles a net; this is termed the zona glomerulosa; but they become much deeper or longer farther in, so as to resemble pipes or tubes placed endwise,

the zona fasciculata. Still deeper down, near the medullary part, the spaces become again of small extent; this is named the zona reticularis. These processes or trabeculae, derived from the capsule and forming the framework of the spaces, are composed of fibrous connective tissue with longitudinal bundles of unstriped muscular fibres. Within the interior of the spaces are contained groups of polyhedral cells, which are finely granular in appearance, and contain a spherical nucleus, and not infrequently fat-globules. These groups of cells do not entirely fill the spaces in which they are contained, but between them and the trabeculae of the framework is a channel which is believed to be a lymph-path or sinus, and which communicates with certain passages between the cells composing the
group. The lymph-path is supposed to open into a plexus of efferent lymphatic vessels which are contained in the capsule.

The Medullary Portion (substantia medullaris) (Fig. 1045).—In the medullary portion the fibrous stroma seems to be collected together into a much closer arrangement, and forms bundles of connective tissue which are loosely applied to the large plexus of veins of which this part of the organ mainly consists. In the interstices lie a number of cells compared by Frey to those of columnar epithelium. They are coarsely granular, do not contain any fat-molecules, and some of them are branched. Luschka has affirmed that these branches are connected with the nerve-fibres of a very intricate plexus which is found in the oblongata; this statement has not been verified by other observers, for the tissue of the medullary substance is less easy to make out than that of the cortical, owing to its rapid decomposition.

Vessels and Nerves.—The numerous arteries which enter the suprarenal bodies from the sources mentioned below penetrate the cortical part of the gland, where they break up into capillaries in the fibrous septa, and these converge to the very numerous veins of the medullary portion, which are collected together into the suprarenal vein, which usually emerge as a single vessel from the centre of the gland.

The arteries supplying the suprarenal capsules are three in number and of large size; they are derived from the aorta, the phrenic, and the renal; they subdivide into numerous minute branches previous to entering the substance of the gland.

The suprarenal vein returns the blood from the medullary venous plexus, and receives several branches from the cortical substance; it emerges from the hilum and opens on the right side into the postcava, on the left side into the renal vein.

The lymphatics form several collections which are about the beginning of the suprarenal vein. They terminate in the glands to the corresponding side of the aorta.

The nerves are exceedingly numerous, and are derived from the solar and renal plexuses, and, according to Bergmann, from the phrenic and vagus nerves. They enter the lower and inner part of the capsule, traverse the cortex, and terminate about the cells of the oblongata. They have numerous small ganglia developed upon them, from which circumstance the organ has been conjectured to have some function in connection with the sympathetic nerve system.

THE CAVITY OF THE PELVIS.

The cavity of the pelvis is that part of the general abdominal cavity which is below the level of the ilio-pectineal lines and the promontory of the sacrum.

Boundaries.—It is bounded behind by the sacrum, the coccyx, the Pyriformis muscles, and the great sacro-sciatic ligaments; in front and at the sides by the portions of the innominate bones below the ilio-pectineal lines. In front and to the sides the bony sides of the pelvic cavity are partly covered by the internal Obturator muscles, and internal to these muscles by the parietal part of the pelvic fascia. Above, it communicates with the cavity of the abdomen; and below, the outlet is closed by the triangular ligament, the Levatores ani and Coccygei muscles, and the visceral layer of the pelvic fascia, which is reflected from the wall of the pelvis on to the viscera.

Contents.—The viscera contained in this cavity are—the urinary bladder, the rectum, and some of the generative organs peculiar to each sex, and some convolutions of the small intestines. The pelvic viscera are partially covered by the peritoneum, and supplied with blood-vessels, lymphatics, and nerves.
THE URINARY BLADDER (VESICA URINARIA) (Figs. 1050, 1051, 1069, 1070).

The urinary bladder is the reservoir for the urine. It is a musculo-membranous sac situated in the pelvis, behind the pubes, and in front of the rectum in the male, the cervix uteri and vagina intervening between it and that intestine in the female. The shape, position, and relations of the bladder are greatly influenced by age, sex, and the degree of distention of the organ. During infancy it is conical in shape, and projects above the symphysis pubis into the hypogastric region. In the adult, when quite empty and contracted (Figs. 1048 and 1049), it is cup-shaped, and on vertical median section its cavity, with the adjacent portion of the urethra, presents a Y-shaped cleft, the stem of the Y corresponding to the urethra. It is placed deeply in the pelvis, flattened from before backward, and reaches as high as the upper border of the symphysis pubis. When slightly distended, it has a rounded form, and is still contained within the pelvic cavity (Fig. 1049), and when greatly distended (Figs. 1049 and 1051), it is ovoid in shape, rising into the abdominal cavity, and often extending nearly as high as the umbilicus. It is larger in its vertical diameter than from side to side, and its long axis is directed from above obliquely downward and backward, in a line directed from some point between the symphysis pubis and umbilicus (according to its distention) to the end of the coccyx. The bladder, when distended, is slightly curved forward toward the anterior wall of the abdomen, so as to be more convex behind than in front. In the female it is larger in the transverse than in the vertical diameter, and its
capacity is said to be greater than in the male. When moderately distended, it measures about five inches in length, and three inches across, and the ordinary amount which it can contain without serious discomfort is about a pint.

The bladder is divided for purposes of description into a superior, an antero-inferior, and two lateral surfaces, a base or fundus, and a summit or apex.

**Surfaces.** The Superior or Abdominal Surface (Figs. 865, 1051, 1052, and 1070).

—The superior or abdominal surface is entirely free, and is covered throughout by peritoneum. It looks almost directly upward into the abdominal cavity, and extends in an antero-posterior direction from the apex to the base of the bladder. It is in relation with the small intestine and sometimes with the sigmoid flexure, and, in the female, with the uterus. On each side, in the male, a portion of the vas deferens is in contact with the hinder part of this surface, lying beneath the peritoneum.

The Antero-inferior or Pubic Surface (Figs. 1051, 1052, and 1070).—The antero-inferior or pubic surface looks downward and forward. In the undistended condition it is uncovered by peritoneum, and is in relation with the Obturator internus muscle on each side, with the recto-vesical fascia, and anterior true ligaments of the bladder. It is separated from the body of the pubis by a triangular interval, the space of Retzius, occupied by fatty tissue. As the bladder ascends into the abdominal cavity during distention the distance between its apex and the umbilicus is necessarily diminished, and the urachus (Fig. 865 and 1070) is thus relaxed; so that, instead of passing directly upward to the umbilicus, it descends first on the upper part of the anterior surface of the bladder, and then,

---

1 According to Henle, the bladder is considerably smaller in the female than in the male.—Ed. of 15th English edition.
curving upward, ascends on the back of the abdominal wall. The peritoneum, which follows the urachus, thus comes to form a pouch (plica vesicalis transversa) of varying depth between the anterior surface of the viscus and the abdominal wall (Fig. 1052). The fold passes to the neighborhood of the internal abdominal rings. Thus, when the bladder is distended, the upper part of its anterior surface is in relation with the urachus and is covered by peritoneum. The lower part of its anterior surface, a distance of about two inches above the symphysis pubis, is devoid of peritoneum, and is in contact with the abdominal wall.

---

**The Lateral Surfaces.**—The lateral surfaces are covered behind and above by peritoneum, which extends as low as the level of the obliterated hypogastric artery; below and in front of this, these surfaces are uncovered by peritoneum, and are separated from the Levatores ani muscles and walls of the pelvis by a quantity of loose areolar tissue containing fat. In front this surface is connected to the recto-vesical fascia by a broad expansion on either side, the lateral true ligaments. The vas deferens crosses the hinder part of the lateral surface obliquely, and passes between the ureter and the bladder. When the bladder is empty the peritoneum descends on the pelvic wall as low as the lateral border of the bladder and enters a groove known as the paravesical fossa. The lateral surfaces, the pubic surface, and the abdominal surface together constitute the **body of the bladder** (corpus vesicae).

**The Fundus or Base** (fundus vesicae) (Figs. 1052, 1067, and 1070).—The fundus or base is directed downward and backward, and is partly covered by peritoneum.

---

**Fig. 1052.—Vertical median section of the male pelvis.** (Henle.)
and is in part not covered by it. In the male the upper portion, to within about an inch and a half of the prostate, is covered by the recto-vesical pouch of peritoneum (Fig. 868). The lower part is in direct contact with the anterior wall of the second part of the rectum and the vesiculae seminales and vasa deferentia (Figs. 1067 and 1069). The ureters enter the bladder at the upper part of its base, about an inch and a half above the base of the prostate gland (Fig. 1059).

The portion of the bladder in relation with the rectum corresponds to a triangular space, bounded, below, by the prostate gland; above, by the recto-vesical fold of the peritoneum; and on each side, by the vesicula seminalis and vasa deferens. It is separated from direct contact with the rectum by the recto-vesical fascia. When the bladder is very full, the peritoneal fold is raised with it, and the distance between its reflection and the anus is about four inches; but this distance is much diminished when the bladder is empty and contracted. In the female, the base of the bladder is connected to the anterior aspect of the cervix uteri by areolar tissue, and is adherent to the anterior wall of the vagina (Fig. 866). Its upper surface is separated from the anterior surface of the body of the uterus by the utero-vesical pouch of the peritoneum (Fig. 866).

The so-called neck or cervix of the bladder (collum vesicae) is the point of commencement of the urethra; there is, however, no tapering part, which would constitute a true neck, but the bladder suddenly contracts to the opening of the urethra (Fig. 1052). In the male it is surrounded by the prostate gland and its direction is oblique when the individual is in the erect posture (Figs. 1051 and 1052). In the female its direction is obliquely downward and forward.
The Summit or Apex (\textit{vertex vesicae}).—The summit or apex is the portion of the bladder which when that organ is empty or nearly empty is nearest to the upper border of the symphysis. It is directed upward and forward. In a distended bladder the apex is well above the pubes in the abdominal cavity.

The Urachus or Middle Umbilical Ligament (\textit{ligamentum umbilicale medium}) (Fig. 1070).—The urachus is a connective-tissue cord and is the obliterated remains of the tubular canal of the allantois, which existed in the embryo, and a portion of which expanded to form the bladder. It passes upward, from the apex of the bladder, between the transversalis fascia and peritoneum, to the umbilicus, becoming thinner as it ascends. It is composed of fibrous tissue, mixed with plain muscular fibres. The urachus causes the formation of a peritoneal fold, the \textit{plica umbilicalis media} (Fig. 865). On each side of it is placed a fibrous cord, the obliterated portion of the \textit{hypogastric artery}, which, passing upward from the side of the bladder, approaches the urachus above its summit. Over each cord is the fold known as the \textit{plica umbilicalis lateralis} (Fig. 865). In the infant, at birth, the urachus is occasionally found pervious, so that the urine escapes at the umbilicus, and calculi have been found in its canal.

Ligaments.—The bladder is retained in its place by ligaments, which are divided into true and false. The true ligaments are five in number: two anterior, two lateral, and the urachus. The false ligaments, also five in number, are formed by folds of the peritoneum.

The two \textit{anterior true ligaments}, the \textit{pubo-prostatic} or \textit{pubo-vesical} ligaments (\textit{ligamenta puboprostatica}) extend from the back of the \textit{ossa pubis}, one on each side of the symphysis, to the front of the neck of the bladder, over the anterior surface of the prostate gland. These ligaments are formed by the \textit{recto-vesical fascia}, and contain a few muscular fibres prolonged from the bladder.

The two \textit{lateral true ligaments}, formed by expansions from the fascia lining the lateral wall of the pelvis, are broader and thinner than the preceding. They are attached to the lateral parts of the prostate gland and to the sides of the base of the bladder.

The \textit{urachus} or \textit{middle umbilical ligament} is the fibro-muscular cord already mentioned, extending between the summit of the bladder and the umbilicus. It is broad below, at its attachment to the bladder, and becomes narrower as it ascends.
The two posterior false ligaments pass forward, in the male, from the sides of the rectum (plicae rectovesicales); in the female, from the sides of the uterus (plicae rectouterinae) to the posterior and lateral aspect of the bladder; they form in the male the lateral boundaries of the recto-vesical pouch (excavatio rectovesicalis) (Figs. 939 and 1052); they form in the female the lateral boundaries of the pouch or cul-de-sac of Douglas (excavatio rectouterina [Douglasii]) (Figs. 866 and 940). The posterior false ligaments contain the obliterated hypogastric arteries and the ureters, together with vessels and nerves. In the base of each fold is smooth muscle-fibre, the Recto-vesical muscle (m. rectovesicalis).

The two lateral false ligaments are reflections of the peritoneum, from the iliac fossae and lateral walls of the pelvis to the sides of the bladder. Each lateral false ligament (ligamentum umbilicale laterale) passes in front into the plica umbilicalis lateralis over the corresponding hypogastric artery. The two lateral reflections of peritoneum are continuous in front of the apex vesicae, at which point the peritoneum passes upon the urachus.

The superior or anterior false ligament or the suspensory ligament (plica umbilicalis media) is the prominent fold of peritoneum extending from the summit of the bladder to the umbilicus. It is carried off from the bladder by the urachus and the obliterated hypogastric arteries. The peritoneal fold over each obliterated hypogastric artery is called the plica umbilicalis lateralis (Fig. 865), and is the prolongation forward of the ligamentum umbilicale laterale. Besides the true and false ligaments, the bladder receives support from the fibrous tissue and unstriated muscle about the seminal vesicles, and terminations of the ureters and vasa deferentia. In the female the connection with the anterior vaginal wall supports the base of the bladder. In both sexes the most solidly fixed part of the bladder is about the orifice of the urethra.

Structure.—The bladder is composed of four coats—serous, muscular, submucous, and mucous.

The Serous Coat (tunica serosa).—The serous coat is partial, and derived from the peritoneum. It invests the superior surface and the upper part of the lateral surfaces and base, and is reflected from these parts on to the abdominal and pelvic walls.

The Muscular Coat (tunica muscularis) (Figs. 1054, 1055, and 1056).—The muscular coat consists of three layers of unstripped muscular fibre: an external layer, composed of fibres having for the most part a longitudinal arrangement; a middle layer, in which the fibres are arranged, more or less, in a circular manner; and an internal layer, in which the fibres have a general longitudinal arrangement.

The fibres of the external longitudinal layer (stratum externum) arise from the posterior surface of the body of the os pubis in both sexes (m. pubovesicalis), and in the male arise also from the adjacent part of the prostate gland and its capsule. They pass, in a more or less longitudinal manner, up the anterior surface of the bladder, over its apex, and then descend along its posterior surface to its base, where they become attached to the prostate in the male and to the front of the vagina in the female. At the sides of the bladder the fibres are arranged obliquely and intersect one another. The external longitudinal layer has been named the Detrusor urinae muscle.

The middle circular layers (stratum medium) are very thinly and irregularly scattered on the body of the organ, and, though to some extent placed transversely to the long axis of the bladder, are for the most part arranged obliquely. Toward the lower part of the bladder, around the neck and the commencement of the urethra, they are disposed in a thick circular layer, forming the sphincter vesicae, which is continuous with the muscular fibres of the prostate gland.

The internal longitudinal layer (stratum internum) is thin, and its fasciculi have a reticular arrangement, but with a tendency to assume for the most part a longitudinal direction. Two bands of oblique fibres, originating behind the orifices of the ureters, converge to the back part of the prostate gland, and are inserted, by
means of a fibrous process, into the middle lobe of that organ. They are the muscles of the ureters, described by Sir C. Bell, who supposed that during the contraction of the bladder they served to retain the oblique direction of the ureters, and so prevent the reflux of the urine into them.

The Submucous Coat (tela submucosa).—The submucous coat consists of a layer of areolar tissue connecting together the muscular and mucous coats, and intimately united to the latter.

The Mucous Coat (tunica mucosa).—The mucous coat is thin, smooth, and of a pale rose color. It is continuous above through the ureters with the lining membrane of the uriniferous tubes, and below with that of the urethra. Except at the trigone, it is connected very loosely to the muscular coat by a layer of areolar tissue, and is therefore thrown into folds or rugae when the bladder is empty (Fig. 1060). The mucous membrane over the trigone never presents rugae. The epithelium covering it is of the transitional variety, consisting of a superficial layer of polyhedral flattened cells, each with one, two, or three nuclei (Fig. 1057); beneath these is a stratum of large club-shaped cells with the narrow extremity of each cell directed downward and wedged in between smaller spindle-shaped cells, each an oval nucleus (Fig. 1058). There are no true glands in the mucous membrane of the bladder, though certain mucous follicles which exist, especially near the neck of the bladder, have been regarded as such.

Objects Seen on the Inner Surface.—Upon the inner surface of the bladder are seen the mucous membrane, orifices of the ureters, the trigone, and the commencement of the urethra.

The Mucous Membrane.—The mucous membrane of the empty bladder is thrown into folds or rugae, except over the trigone, where it is firmly adherent to the muscular coat and is smooth (Figs. 1059 and 1060). The folds disappear when the bladder is distended.

The Orifices of the Ureters (Figs. 1059 and 1060).—These are situated at the base of the trigone, being distant from each other about two inches when the bladder is moderately distended. Each orifice is about an inch and a half from the base of the prostate and the commencement of the urethra in the moderately distended bladder.

The Vesical Trigone or the Trigonum Vesicae (Fig. 1000) is a triangular smooth surface, with the apex directed forward, situated at the base of the bladder, immediately behind the urethral orifice. It is paler in color than the rest of the interior, and never presents any rugae, even in the collapsed condition of the organ, owing to the intimate adhesion of its mucous membrane to the subjacent tissue. It is bounded at each posterior angle by the orifice of a ureter, and in front by the orifice of the urethra. Projecting from the lower and anterior part of the bladder, and reaching to the orifice of the urethra, is a slight elevation of mucous membrane, particularly prominent in old persons, called the uvula vesicae. It is formed by a thickening of the submucous tissue.
Stretching from one ureteral opening to the other is a smooth, slightly curved ridge, the convexity of which is toward the urethra. It is produced by transverse muscle-fibres beneath the mucous membrane. The outer prolongations of this ridge beyond the ureteral orifices are called the ureteral folds (*plicae uretericae*). They are created by the ureters as they traverse the bladder wall. About the ureteral orifice are slight radial folds of mucous membrane, which are continuous with the longitudinal folds of the prostatic urethra. "In the empty bladder the ureteral orifice and the openings of the two ureters lie at the angles of an approximately equilateral triangle, whose sides are about one inch in length. When the bladder is distended the distance between the openings may be increased to one and a half inches or more."\(^1\)

---

The muscles of the ureters were referred to on p. 1447.

The internal urethral orifice (orificium urethrae internum) is sickle-shaped and is surrounded by a circular prominence (annulus urethralis), which is most distinct in the male.

Vessels and Nerves.—The arteries (Fig. 427) supplying the bladder are the superior, middle, and inferior vesical in the male, with additional branches from the uterine and vaginal in the female. They are all derived from the anterior trunk of the internal iliac. The obturator and sciatic arteries also supply small visceral branches to the bladder. The veins form a complicated plexus around the neck, sides, and base of the bladder (Fig. 474). The veins communicate below with the plexus about the prostate and terminate in the internal iliac vein.

The lymphatics form two plexuses, one in the muscular and another in the submucous coat. They accompany the blood-vessels. The mucous membrane of the bladder contains no lymphatics whatever (Sappey). The muscular tissue contains a few lymphatics. The subperitoneal tissues contain the usual number. The collecting trunks from the anterior surface terminate in the external iliac glands. The trunks from the posterior surface terminate in the internal iliac glands, the hypogastric glands and the glands in front of the sacral promontory.

The nerves are derived from the pelvic plexus of the sympathetic and from the third and fourth sacral nerves; the former supplying the upper part of the organ, the latter its base and neck. According to F. Darwin, the sympathetic fibres have ganglia connected with them, which send branches to the vessels and to the muscular coat.

Surface Form.—The surface form of the bladder varies with its degree of distention and under other circumstances. In the young child it is represented by a conical figure, the apex of which, even when the viscus is empty, is situated in the hypogastric region, about an inch above the level of the symphysis pubis. In the adult, when the bladder is empty, its apex does not reach above the level of the upper border of the symphysis pubis, and the whole organ is situated in the pelvis; the neck, in the male, corresponding to a line drawn horizontally backward through the symphysis a little below its middle. As the bladder becomes distended, it gradually rises out of the pelvis into the abdomen, and forms a swelling in the hypogastric region, which is perceptible to the hand as well as to percussion. In extreme distention it reaches into the umbilical region. Under these circumstances the lower part of its anterior surface, for a distance of about two inches above the symphysis pubis, is closely applied to the abdominal wall, without the intervention of peritoneum, so that it can be tapped by an opening in the middle line just above the symphysis pubis, without any fear of wounding the serous membrane. When the rectum is distended, the prostatic portion of the urethra is elongated and the bladder lifted out of the pelvis and the peritoneum pushed upward. Advantage is taken of this by some surgeons in performing the operation of suprapubic cystotomy. The rectum is distended by an India-rubber bag which is introduced into this cavity empty, and is then filled with ten or twelve ounces of water. If now the bladder is injected with about half a pint of some antiseptic fluid, it will appear above the pubes plainly perceptible to the sight and touch. The peritoneum will be pushed out of the way, and an incision three inches long may be made in the linea alba, from the symphysis pubis upward, without any great risk of wounding the peritoneum. Other surgeons object to the employment of this bag, as its use is not unattended with risk, and because it causes pressure on the prostatic veins and hence produces congestion of the vessels over the bladder and a good deal of venous hemorrhage.

When distended, the bladder can be felt in the male, from the rectum, behind the prostate, and fluctuation can be perceived by a bimanual examination, one finger being introduced into the rectum and the distended bladder being tapped on the front of the abdomen with the finger of the other hand. This portion of the bladder—that is, the portion felt in the rectum by the finger—is uncovered by peritoneum.

Surgical Anatomy.—A certain defect of development in which the bladder is implicated is known under the name of extroversion of the bladder. In this condition the lower part of the abdominal wall and the anterior wall of the bladder are wanting, so that the posterior surface of the bladder presents on the abdominal surface, and is pushed forward by the pressure of the viscera within the abdomen, forming a red, vascular protrusion, on which the openings of the ureters are visible. The penis, except the glans, is rudimentary and is cleft on its dorsal surface, exposing the floor of the urethra—a condition known as epispadias. The pelvic bones are also arrested in development (see page 222).

The bladder may be ruptured by violence applied to the abdominal wall when the viscus is
distended without any injury to the bony pelvis, or it may be torn in case of fracture of the pelvis. The rupture may be either intraperitoneal or extraperitoneal—that is, may implicate the superior surface of the bladder in the former case, or one of the other surfaces in the latter. Rupture of the antero-inferior surface alone is, however, very rare. Until recently intraperitoneal rupture was uniformly fatal, but now abdominal section and suturing the rent with Lambert sutures often saves the patient. The sutures are inserted only through the peritoneal and muscular coats in such a way as to bring the serous surfaces at the margins of the wound into apposition, and one is also inserted just beyond each end of the wound. The bladder should be tested as to whether it is water-tight before closing the external incision.

The muscular coat of the bladder undergoes hypertrophy in cases in which there is any persistent obstruction to the flow of urine. Under these circumstances the bundles of which the muscular coat consists become much increased in size, and, interfacing in all directions, give rise to what is known as the fasciculated bladder. Between these bundles of muscular fibres the mucous membrane may bulge out, forming sacculi, constituting the sacculated bladder, and in these little pouches phosphatic concretions may collect, forming encysted calculi. The mucous membrane is very loose and lax, except over the trigone, to allow of the distention of the viscus.

Various forms of tumours have been found springing from the wall of the bladder. The innocent tumours are the papilloma and the mucous polypus, arising from the mucous membrane; the fibrous tumor, from the submucous tissue; and the myoma, originating in the muscular tissue; and, very rarely, dermoid tumors, the exact origin of which it is difficult to explain.

Of the malignant tumors, epitheliomata are the most common, but sarcomata are occasionally found in the bladders of children.

**Puncture of the bladder** is performed above the pubes without wounding the peritoneum. Puncture by the rectum is not now performed, as a permanent fistula may be left from abscess forming between the rectum and the bladder; or pelvic cellulitis may be set up; moreover, it is exceedingly inconvenient to keep a cannula in the rectum. In some cases in performing this operation the recto-vesical pouch of peritoneum has been wounded, inducing fatal peritonitis. The operation, therefore, has been abandoned. Suprapubic cystotomy is considered above under the heading of Surface Form. This operation may be employed to permit of the removal of a calculus and is then called suprapubic lithotomy.

**THE MALE URETHRA (URETHRA VIRILIS)** (Figs. 1061, 1062, 1063, 1064, 1069).

The urethra in the male extends from the neck of the bladder at the **internal orifice of the urethra** (orificium urethrae internum) to the **meatus urinarius**, the external orifice of the urethra (orificium urethrae externum), at the end of the penis. The internal orifice has been described (p. 1449). The urethra presents a double curve in the flaccid state of the penis (Fig. 1069), but in the erect state of this organ it forms only a single curve, the concavity of which is directed upward. Its length varies from eight to nine inches; and it is divided into three portions, the **prostatic, membranous,** and **spongy,** the structure and relations of which are essentially different. Except during the passage of the urine or semen, the urethra is a mere cleft or slit, transverse, T-shaped or crescentic (Fig. 1063), with its upper and under surfaces in contact. At the meatus urinarius the slit is vertical, and in the prostatic portion somewhat arched (Fig. 1063).

**The First or Prostatic Portion** (pars prostatica) (Figs. 1051, 1061, 1062, 1070, and 1071).—The first or prostatic portion is the widest and most dilatable part of the canal. It is between the internal orifice of the urethra and the superior layer of the triangular ligament and is within the pelvic cavity. It passes between the two lateral lobes of the prostate gland, from the base to the apex of the gland, lying nearer its anterior than its posterior surface. The gland seems to completely surround this portion of the urethra (Fig. 1068), but the glandular matter of the gland does not (Fig. 1066). The gland is like a buckle open in front, and the open part of the buckle is closed by the prostatic muscle. The prostatic urethra is about an inch and a quarter in length; the form of the canal is spindle-shaped, being wider in the middle than at either extremity, and narrowest below, where it joins the membranous portion. Except during the passage of fluid, the canal is in a collapsed state, the anterior wall resting upon the posterior wall (Fig. 1063), and the mucous membrane exhibiting longitudinal folds. When distended, the largest portion of the prostatic urethra has a diameter of about one-third of an inch.
A transverse section of the canal as it lies in the prostate is horseshoe-shaped, the convexity being directed forward (Figs. 1063 and 1066). The direction of the canal is nearly vertical, there being a slight curve, which is concave forward (Figs. 1051 and 1052).

Upon the posterior wall or floor of the canal is a narrow longitudinal ridge, the crest of the urethra (crista urethralis), formed by an elevation of the mucous membrane and its subjacent tissue (Fig. 1061). This crest begins at the uvula vesicae, and passes through the prostatic portion and into the membranous portion of the urethra (Fig. 1071), and usually bifurcates at its distal end; it contains, according to Kobelt, muscular and erectile tissues. On this longitudinal ridge is an enlargement, the verumontanum or caput gallinaginis (colliculus seminalis) (Figs. 1061 and 1071).

When distended, it may serve to prevent the passage of the semen backward into the bladder. On each side of the verumontanum is a slightly depressed fossa, the floor of which is perforated by numerous apertures, the orifices of the prostatic ducts (Figs. 1061 and 1071), from the lateral lobes of the glands; the ducts of the middle lobe open behind the verumontanum. At the forepart of the verumontanum, in the middle line, is a depression, the prostatic sinus, prostatic utricle, prostatic vesicle, uterus masculinus or sinus peculiaris (utriculus prostaticus) (Figs. 1052 and 1071); and upon or within its margins are the slit-like openings of the ejaculatory ducts (ductus ejaculatorii) (Fig. 1071).

The sinus peculiaris forms a cul-de-sac about a quarter of an inch in length, which runs upward and backward in the substance of the prostate behind the transverse band of prostatic tissue which joins the lateral lobes behind the posterior wall of the urethra; its prominent anterior wall partly forms the verumontanum. Its walls are composed of fibrous tissue, muscular fibres, and mucous membrane, and numerous small glands open on its inner surface. It has been called by Weber, who discovered it, the uterus masculinus, from its being developed from the united lower ends of the atrophied Müllerian ducts, and therefore being homologous with the uterus and vagina in the female.

The Second, Muscular or Membranous Portion (pars membranacea) (Figs. 1061, 1062, and 1071) extends downward and forward between the apex of the prostate and the bulb of the corpus spongiosum. It is the narrowest part of the canal (excepting the meatus), and measures three-quarters of an inch along its upper, and half an inch along its lower, surface, in consequence of the bulb projecting backward beneath it. Its anterior concave surface is placed about an inch below and behind the pubic arch, from which it is separated by the dorsal vessels and nerves of the penis, and some muscular fibres. Its posterior convex surface is separated from the rectum by a triangular space, which constitutes the perineum. The membranous portion of the urethra lies chiefly between the inferior and superior layers of
the triangular ligament (Fig. 308). The termination of this part of the urethra is overlapped by the bulb, and is in front of the triangular ligament (Fig. 308). As it pierces the inferior layer, the fibres around the opening are prolonged over the tube and fix the two structures firmly to each other. The membranous urethra is surrounded by cavernous tissue and by the Compressor urethrae muscle (m. sphincter urethrae membranaceae) (Fig. 309). On the floor of the membranous urethra is the anterior extremity of the crista urethralis. Behind this part of the urethra, on each side of the middle line, are Cowper's glands (Figs. 307 and 1071). The canal enters the bulb a little in front of the posterior extremity, and the anterior wall or roof of the membranous urethra is a little longer than the posterior wall or floor. The backward projection of the bulb hangs over most of the floor of the membranous urethra (Figs. 307, 308, 1061, 1071, and 1073). When the urethra is empty the mucous membrane of the second part is thrown into longitudinal folds, which are obliterated by distention.

![Fig. 1062.—Proximal portions of urethra with surrounding parts. (After Testut.]

The Third, Penile, Pendulous, Cavernous or Spongy Portion (pars cavernosa) (Figs. 1051, 1061, 1062, and 1064) is the longest part of the urethra, and is contained in the corpus spongiosum. It is about six inches in length, and extends from the termination of the membranous portion to the meatus urinarius. It is surrounded throughout its entire course by the erectile tissue of the corpus spongiosum and glans penis. Its proximal end is fixed in position and unchangeable in direction. Its distal end is movable and changeable in direction. Commencing just below the triangular ligament it is first directed forward through the bulb; it then passes downward and forward, the turn beginning at the seat of attachment of the suspensory ligament of the penis (Fig. 1051). The direction of the third portion of the urethra is changed by alterations in the position of the penis. When the canal is closed the anterior and posterior walls are in contact (roof and floor), except in the glans penis, where the lateral walls come together. "Thus the first part of the canal when empty is represented in cross-section by a transverse slit, and the terminal part by a vertical slit"\(^1\) (Fig. 1063). The calibre of the spongy urethra varies in different portions of the tube. It is of larger diameter in the bulb (bulbous portion of urethra) and in the glans than between these two points. In the

---

\(^1\) Professor A. Francis Dixon, in Professor D. J. Cunningham's 'Text-book of Anatomy.'
body of the penis the canal is of uniform size, and is about one-quarter of an inch in diameter. The fossa navicularis (fossa navicularis urethrae [Morgagni]) is an oblong dilatation of the terminal portion of the penile urethra (Figs. 1051, 1061, and 1075). In the front of the fossa navicularis there is a transverse fold of mucous membrane, the valve of Guerin (valvulae fossae navicularis). It is part of a distinct depression or pocket. The fossa navicularis opens anteriorly by the meatus urinarius.

The meatus urinarius or external orifice of the urethra (orificium urethrae externum) (Figs. 1061 and 1074) is the most contracted part of the urethra; it is a vertical slit (Fig. 1063), about three lines in length, bounded on each side by a small lip or labium.

The inner surface of the lining membrane of the urethra, especially on the floor of the spongy portion, presents the orifices of numerous mucous glands (Fig. 1064) situated in the submucous tissue, and named the glands of Littre (glandulae urethrales). A number of little recesses or follicles, called lacunae (lacunae urethrales), open into the penile urethra. Some of the glands of Littre open into the lacunae; some do not. They vary in size, and their orifices are directed forward, so that they may easily intercept the point of a catheter in its passage along the canal. One of these lacunae, larger than the rest, is situated in the upper surface of the fossa navicularis, about half an inch from the orifice; it is called the lacuna magna (Fig. 1075). Into the bulbous portion are found opening the ducts of Cowper's glands.

Structure.—The urethra is composed of a continuous mucous membrane, supported by a submucous tissue which connects it with the various structures through which it passes.

The Mucous Coat.—The mucous coat forms part of the genito-urinary mucous membrane. It is continuous with the mucous membrane of the bladder, ureters, and kidneys; externally with the integument covering the glans penis; and is prolonged into the ducts of the glands which open into the urethra—viz., Cowper's glands and prostate gland—into the vasa differentia and the seminal vesicles through the ejaculatory ducts. The mucous membrane is arranged in longitudinal
folds when the tube is empty. Small papillae are found upon it near the orifice, and its epithelial lining is of the columnar variety, excepting near the meatus, where it is squamous.

The Glands and Crypts of the Urethral Mucous Membrane (Fig. 1063).—There is a pocket, the lacuna magna (Fig. 1060), opening to the front in the upper wall of the fossa navicularis. The fossa is bounded by the valve of Guerin (valvulae fossa navicularis). The lacunae of Morgagni are in the spongy urethra back of the valve of Guerin. The lacunae look forward. The largest of them is on the roof of the fossa navicularis, one and one-half inches from the orifice (see above). Some of the lacunae receive the secretion from the glands of Littré; others do not, because some of the glands open on the free surface. The larger lacunae are one-third of an inch deep and are placed in a longitudinal row upon the anterior wall. The smaller lacunae are in longitudinal rows at the sides of the tube. The glands of Morgagni are present throughout the urethra, except in its most anterior part. In the prostatic urethra they are arranged in rows. In the membranous urethra they are scattered irregularly. In the spongy portion they are most numerous on the anterior wall and are more plentiful on the sides than on the floor. Besides the lacunae and racemose glands, there are the opening of the prostatic glands, the ejaculatory ducts, Cowper's glands, and the opening of the sinus peculiaris.

The Submucous Tissue.—The submucous tissue consists of a vascular erectile layer. It contains the glands of Littré, especially in the posterior part. These glands are lined with cylindrical epithelium and enter the submucous coat.

The Muscular Layer.—The muscular layer is continuous with the muscle of the prostate and bladder. It is composed of non-striated muscle arranged in an outer layer of circular fibres (stratum circulare) and an inner layer of longitudinal fibres (stratum longitudinale). It is placed external to the submucous coat. In the penile urethra there is only a thin layer of longitudinal fibres. In the membranous urethra and the prostatic urethra there are two layers of muscle, an inner thin layer of longitudinal fibres and a thicker layer of circular fibres. The longitudinal fibres, when contracted, shorten the urethra and increase its diameter. The circular fibres are in a state of tonic contraction and close the urethra. In fact, they constitute the real sphincter (Zeissl, Zuckerkrandl). The so-called sphincter of the urethra, the Accelerator urinae, is a voluntary muscle and is not the real sphincter. Outside of the muscular layer of the urethra is the tissue of the corpus spongiosum.

Surgical Anatomy.—The urethra may be ruptured by the patient falling astride of any hard substance and striking his perineum, so that the urethra is crushed against the pubic arch. Bleeding will at once take place from the urethra, and this, together with the bruising in the perineum and the history of the accident, will at once point to the nature of the injury.

Rupture of the urethra leads to extravasation of urine. In rupture back of the superior layer of the triangular ligament the urine usually follows the rectum and reaches the margin of the anus. Rupture between the two layers of the triangular ligament liberates urine between the two layers, where it remains until a path of exit is made by suppuration or the surgeon's knife. In rupture in front of the anterior layer of the ligament the urine passes into the scrotum and may mount up to the abdomen between the symphysis and the pubic spine, between which points the deep layer of the superficial fascia is not attached. It cannot pass to the thigh nor cross the mid-line, because the fascia is attached to the fascia lata and at the mid-line.

The surgical anatomy of the urethra is of considerable importance in connection with the passage of instruments into the bladder. Otis was the first to point out that the urethra is capable of great dilatation, so that, excepting through the external meatus, an instrument corresponding to 18 English gauge (29 French) can usually be passed without damage. The orifice of the urethra is not so dilutable, and therefore may require slitting, although the introduction of the Oberlander dilator, which is expanded after introduction, renders slitting of the meatus seldom necessary in cases of chronic gonorrhoea. A recognition of this dilatability caused Bigelow to very considerably modify the operation of lithotrity and introduce that of litholapaxy. In passing a fine catheter, the point of the instrument after it has passed the lacuna magna should be kept as far as possible along the upper wall of the canal, as the point is otherwise very liable to enter one of the lacunae. Stricture of the urethra is a disease of very common
occurrence, and is generally situated in the spongy portion of the urethra, most commonly in the bulbous portion, just in front of the membranous urethra, but in a very considerable number of cases in the penile or ante-serotinal part of the canal. Even in a normal urethra, and very markedly in an inflamed urethra, a bougie encounters resistance behind the bulb. This is usually supposed to be due to spasm of the Compressor urethrae muscle.

In *irrigation of the urethra by gravity* fluid tends to block at the same point, especially if it is thrown in suddenly or forcibly. If a reservoir is raised seven and one-half feet from the floor, and if a patient sits on a chair or lies upon a bed, fluid can be readily made to pass by hydraulic pressure from the meatus to the bladder. Spasm may temporarily prevent the inflow, but the weight of the column of fluid soon tires out the muscle and causes it to relax. Relaxation is favored by having the patient take slow, deep breaths and make efforts at urination (Valentine).

*Chronic gonorrhoea* is frequently kept up by persistent inflammation of the ducts and follicles in the mucous membrane. This condition is known as *chronic glandular urethritis* or *paraurthritis*. In these crypts and glands gonococci may remain when gonorrhoea appears to have passed away, and from time to time reinfecion of the urethra may arise from such a source.

*Median urethrotomy* or *perineal section* is opening of the membranous urethra. Through such an opening the bladder can be drained and explored, and the operation is sometimes called *median cystotomy*.

In *lateral lithotomy* the knife enters the membranous urethra and strikes the groove of the staff. Its edge is then turned toward the left ischial tuberosity and is carried along the groove into the bladder, dividing the membranous urethra, the prostatic urethra, the posterior layer of the triangular ligament, the Compressor urethrae muscle, anterior fibres of the Levator ani muscle and the left lobe of the prostate gland.

THE FEMALE URINARY BLADDER.

The female bladder is situated at the anterior part of the pelvis. It is in relation, *in front*, with the symphysis pubis; *behind*, with the uro-vesical pouch of peritoneum, which separates it from the body of the uterus; its *base* lies in contact with the connective tissue in front of the cervix and upper part of the vagina. *Laterally*, is the recto-vesical fascia. The bladder is said by some anatomists to be larger in the female than in the male. At any rate, it does not rise above the symphysis pubis till more distended than in the male, but this is perhaps owing to the more capacious pelvis rather than to its being of actually larger size. It is described in the section on the Bladder (p. 1441).

THE FEMALE URETHRA (URETHRA MULIEBRI).  

The female urethra is a narrow membranous canal, about an inch and a half in length, extending from the internal urethral orifice (orificium urethrae internum) at the neck of the bladder to the vestibule of the vagina, where it ends, being called at its termination the external orifice of the urethra or the meatus urinarius (orificium urethrae externum). The meatus is usually a vertical slit. The urethra is placed behind the symphysis pubis, embedded in the anterior wall of the vagina; and its direction is obliquely downward and forward, its course being slightly curved, the concavity directed forward and upward. Its diameter when undilated is about a quarter of an inch. The urethra perforates both layers of the triangular ligament, and its external orifice is situated directly in front of the vaginal opening and about an inch behind the glans clitoridis. Except above, the posterior wall of the urethra is firmly connected to the anterior wall of the vagina.

Structure.—The urethra consists of three coats: *muscular*, *erectile*, and *mucous*.

The *Muscular Coat* (tunica muscularis).—The muscular coat is continuous with that of the bladder; it extends the whole length of the tube, and consists of an internal layer of *non-striated longitudinal fibres* (stratum longitudinale) and an external layer of *non-striated circular fibres* (stratum circulare). Superficial to the circular fibres "lies a layer of cross-striped muscle-fibres, which form a closed ring near the bladder only."
The Submucous Coat (*tunica submucosa*).—Internal to the muscular coat is the submucous coat, which contains a venous plexus, networks from which pass between the muscular layers and impart to these layers an erectile or spongy nature (*corpus spongiosum urethrae*). In addition to this, between the two layers of the triangular ligament, the female urethra is surrounded by the Compressor urethrae muscle, as in the male.

The Mucous Coat (*tunica mucosa*).—The mucous coat is pale, continuous externally with that of the vulva, and internally with that of the bladder. It is thrown into longitudinal folds, one of which, placed along the floor of the canal, extends from the vesical trigone almost to the external orifice of the urethra. It is called the crest (*crista urethralis*). The outline of the urethra is stellate when collapsed, because of the formation of numerous longitudinal folds. It is lined by laminated epithelium, which becomes transitional near the bladder. Many mucous glands open into the urethra, and there are numerous lacunae. External to the external orifice, on each side, a group of mucous glands opens by a common duct, the ductus para-urethralis.

The urethra, because it is not surrounded by dense resisting structures, as in the male, admits of great dilatation, which enables the surgeon to remove with considerable facility calculi or other foreign bodies from the cavity of the bladder.
THE MALE ORGANS OF GENERATION.

THE PROSTATE GLAND (PROSTATA) (Figs. 1062, 1066, 1067, 1068, 1069, 1070, 1071, 1072).

The prostate gland (προστατήμα, to stand before) is a structure accessory to the true generative organs and furnishes a viscid, opalescent secretion in which spermatozoïds will live (W. G. Richardson). It is a pale, firm, partly glandular and partly muscular body, which is placed immediately below the neck of the bladder and about the commencement of the urethra in the male. The prostate appears to completely surround the first portion of the urethra (Figs. 1068 and 1072), but the glandular matter does not in reality completely surround the tube (Figs. 1066 and 1072). As Spalteholz says, it partly surrounds it as a broad clasp, open in front. This opening in the glandular tissue is closed, and a complete ring is established about the urethra by the prostatic muscle (m. prostaticus) (Figs. 1066 and 1072). This muscle below is composed of striated fibres and is continuous with the Compressor urethrae (m. sphincter urethrae membranacea);

above it is composed of non-striated muscle, and is continuous with the circular muscular fibres of the bladder which surround the internal urethral orifice and
constitute the Sphincter vesicae (Fig. 1067). The general course of the fibres is transverse, with radiations into the gland substance. The apex of the gland for about one-quarter of an inch is completely surrounded by the muscle (Fig. 1067).

Ascending from the apex the fibres cover for a short distance only the front of the gland and are attached at the sides to the fascia (Fig. 1067). Higher up the muscle passes between the sheath and the capsule and ascends to the base of the prostate, uniting the sheath to the capsule along the mid-line in front. The prostate is placed in the pelvic cavity, behind the lower part of the symphysis pubis, and above the
deep layer of the triangular ligament, and rests upon the rectum, through which it may be distinctly felt, especially when enlarged (Fig. 1070).

The ejaculatory ducts (Figs. 1068, 1069, and 1070) enter the prostate at the margin which separates the base from the posterior surface of the gland; they pass downward, inward, and forward through the prostate, and open into the prostatic urethra. The prostate when surrounded by its sheath resembles a chestnut in shape. When dissected out from its sheath and capsule and from the Prostatic muscle, it resembles an "open clasp" or horseshoe. The sheath of the prostate

is derived from the recto-vesical fascia. It is called the prostatic fascia (fascia prostaticae), is distinct and dense, and covers the entire prostate, except at the apex and at the attachment of the base of the prostate to the neck of the bladder. The prostatic fascia is a distinct structure, though it is thin. The veins of the prostatic plexus lie in the layers of the sheath, "and are everywhere separated from the prostatic capsule proper by a layer of this sheath." In an enlarged prostate the sheath is thick and fibrous. It is very difficult to shell out a normal prostate from its sheath, but it is easy to shell out an enlarged prostate. Within the prostatic sheath (which, be it remembered, carries the veins) is the true or proper capsule

of the prostate. The true capsule is a continuous investment from the entrance of the urethra above to the triangular ligament below. It is thin, but firm and fibrous. It is not everywhere absolutely distinct from the sheath, but may be fused
with it here and there, and many bands of fibres run from the sheath to the capsule. The capsule is continuous with the stroma of the gland and cannot be stripped off as can the kidney capsule. Any attempt to strip off the capsule tears away fragments of gland. The capsule is composed of fibrous tissue and unstriated muscle-fibres. From its deep surface the capsule is continuous with the stroma of the prostate (W. G. Richardson). Sir Henry Thompson, half a century ago, pointed out the distinction between true capsule and sheath, and suggested these names. The prostate is divided for study into a base, apex, posterior surface, anterior surface, and lateral surfaces.

The Base (basis prostatae).—The base is directed upward, and is situated immediately below the base of the bladder. It is in contact with and supports the base of the bladder. The external longitudinal muscular layer of the bladder is attached to the posterior portion of the base of the prostate, and some of the fibres reach and adhere to the true capsule. The anterior portion of the base is called the isthmus (isthmus prostatae) (Fig. 1068).

The Apex (apex prostatae).—The apex is directed downward and rests upon the deep layer of the triangular ligament. The apex is fixed, except for the slight mobility of the triangular ligament; the rest of the gland is somewhat movable.

Surfaces. — The Posterior Surface (facies posterior).—The posterior surface is flattened, marked by a slight longitudinal furrow, and rests on the second part of the rectum, and is distant about one inch and a half from the anus. At the upper and posterior border of the gland are the seminal vesicles. Their direction is downward and inward; in fact, almost transverse.

The Anterior Surface (facies anterior).—The anterior surface is convex, and placed about three-fourths of an inch behind the pubic symphysis, from which it is separated by a plexus of veins and a quantity of loose fat. It is connected to the pubic bone on either side by the pubo-prostatic ligament. It is shorter than the posterior surface.

The Lateral Surfaces. — The lateral surfaces are prominent, and are covered by the anterior portions of the Levatores ani muscles, which are, however, separated from the gland by a plexus of veins.

The prostate measures about an inch and a half transversely at the base, an inch in its antero-posterior diameter, and an inch and a quarter in its vertical diameter. Its weight is about four and a half drachms. It is held in position by the anterior ligaments of the bladder (ligamenta puboprostatica); by the deep layer of the triangular ligament, which invests the commencement of the membranous portion of the urethra and prostate gland; and by the anterior portions of the Levatores ani muscles, which pass backward from the os pubis and embrace the sides of the prostate. These portions of the Levatores ani, from the support they afford to the prostate, are named the Levator prostatae.

The prostate consists of two lateral lobes and a middle lobe.

The Lateral Lobes (lobus dexter et sinister).—The two lateral lobes are of equal size, separated by a deep notch above, and by a furrow upon the anterior and posterior surfaces of the gland, which indicates the bilobed condition of the organ in some animals. At the upper and posterior portion of the prostate the two lobes are united by two bands of gland-tissue. One of these bands is in front of the ejaculatory ducts, the other is below them. "The upper limit of the gland is thus in the form of a horseshoe, open in front." Below the level of the prostatic ducts the prostate and urethra are in relation, but are not closely connected. Above this level the connection is intimate (J. W. Thomson Walker).

The So-called Middle Lobe (lobus medius).—The middle lobe is not in reality a lobe, and the name is usually employed to describe an enlargement of the region of the prostate on the posterior portion of the urethra in front of the ejaculatory ducts. The so-called third or middle lobe is an abnormal condition. It is due to enlargement of the transverse band of prostatic tissue which joins the lateral lobes beneath the

---

1 W. G. Richardson on the Development and Anatomy of the Prostate Gland.
base of the bladder, behind the posterior wall of the urethra and in front of the ejaculatory ducts. This mass of tissue is beneath the uvula vesicae. Walker points out that frequently nodules of enlarged prostate protrude into the bladder, being covered only by bladder mucous membrane. This is accomplished by the enlarging prostate forcing its way through the lumen of the vesical sphincter and dilating it, and separating and passing between the strands of the internal longitudinal muscle of the bladder. "The so-called middle lobe is formed by the protrusion of a nodule between the two bands of muscle which pass into the trigone from the ureters, and unite on the posterior wall of the prostatic urethra."

The urethra passes forward between the lateral lobes of the prostate. The prostate is perforated by the ejaculatory ducts. The urethra usually lies on the level of the junction of the anterior and middle thirds of a lateral lobe. The ejaculatory ducts pass obliquely downward and forward through the posterior part of the prostate, and open into the prostatic portion of the urethra.

**Structure** (Fig. 1072).—As previously stated (p. 1459), the prostate is surrounded by a sheath from the recto-vesical fascia, and possesses also a true capsule.

The glands of the prostate are of the branched tubular variety and number forty or fifty. Many of the ducts join and form from fifteen to twenty-five smaller ducts, which empty into the prostatic urethra, to the sides of the verumontanum (Fig. 1071). The ducts and glands are lined with cubical epithelium. The *prostatic secretion* or *prostatic fluid* (*sueus prostaticus*) is a viscid, opalescent, serous secretion, alkaline in reaction, containing a ferment, but no mucus. The substance of the prostate is of a pale, reddish-gray color, of great density and not easily torn. It consists of glandular substance and muscular tissue.

The muscular tissue, according to Köllicker, constitutes the proper stroma of the prostate, the connective tissue being very scanty, and simply forming thin trabeculae between the muscular fibres, in which the vessels and nerves of the gland run. The true capsule is continuous with the stroma. The stroma lies between the glandular substance and strands of stroma pass in convergent lines toward the prostatic urethra, especially toward the dorsum of the urethra. These strands or septa divide the prostate into small irregular subdivisions called *lobules*. Next to the urethra, the stroma forms a thick layer. As age advances the interstitial tissue of the prostate increases and the glandular substance shrinks.

**Vessels and Nerves.**—The arteries supplying the prostate are derived from the *internal pudic*, *inferior vesical*, and *middle haemorrhoidal*. Branches of the vessels enter the gland in the septa between the lobules and send off minute branches to the lobules (Walker). The veins form a plexus around the sides and base of the gland between layers of the fascial sheath; they receive in front the *dorsal vein of the penis*, and terminate in the *internal iliac vein*. The lymphatics of the prostate begin as networks about the acini of the gland, pass to beneath the capsule, and form another network, and from this peripheral network collecting trunks arise. Several trunks pass from the posterior portion of the gland. One trunk passes to the *external iliac glands*, one to the *internal iliac glands*, and several end in the *lateral sacral glands*, and the glands of the sacral promontory. An anterior trunk is joined by lymphatics from the membranous urethra and prostatic urethra and passes to a gland on the *internal pudic artery*. The nerves are derived from the hypogastric plexus.

**Surgical Anatomy.**—The relation of the prostate to the rectum should be noted: by means of the finger introduced into the gut the surgeon detects enlargement or other disease of the prostate; he can feel the apex of the gland, which is the guide to *Cock's operation* for stricture; he is enabled also by the same means to direct the point of a catheter when its introduction is attended with difficulty either from injury or disease of the membranous or prostatic portions of the urethra. When the finger is introduced into the bowel the surgeon may, in some cases, especially in boys,

---

2 Pollier and Charpy. Human Anatomy.
learn the position, as well as the size and weight, of a calculus in the bladder. In the operation for the removal of a calculus, if, as is not unfrequently the case, the stoeie should be lodged behind an enlarged prostate, it may be displaced from its position by pressing upward the base of the bladder from the rectum. The prostate gland is occasionally the seat of suppuration, either due to injury, gonorrhoea, or tuberculous disease. The gland is enveloped in a dense unyielding capsule, which determines the course of an abscess, and also explains the great pain which is present in acute inflammation. The abscess most frequently bursts into the urethra, the direction in which there is least resistance, but may occasionally burst into the rectum, or more rarely in the perineum. In advanced life the prostate often becomes considerably enlarged, and may project into the bladder so as to impede the passage of the urine. According to Dr. Messer’s researches, conducted at Greenwich Hospital, it would seem that such obstructions exist in 20 per cent. of all men over sixty years of age. The prostate may be enlarged by the growth of innocent tumors, adenomata, fibromata, myomata, and myofibromata. The entire gland may be hypertrophied. A tumor may be encapsulated, but often is surrounded by an area of hyperplasia of prostatic tissues, and usually the area of hyperplasia is much more extensive than the tumor. A tumor may be beneath the mucous membrane, deep in the gland, or beneath the sheath. The growth called the third lobe is submucous. In some cases the enlargement affects principally the lateral lobes, which may undergo considerable enlargement without causing much inconvenience. In other cases it would seem that the nodule forms the so-called middle lobe, and even a small enlargement of this character may act injuriously, by forming a sort of valve over the urethral orifice, preventing the passage of the urine, and the more the patient strains, the more completely will it block the opening into the urethra. In consequence of the enlargement of the prostate a pouch is formed at the base of the bladder behind the projection, in which urine collects and cannot entirely be expelled. The urine becomes decomposed and ammoniacal, and leads to cystitis. If the prostate enlarges the urethra is lengthened, often dilated, altered in shape, or distorted.

The relation of the enlarged prostate to the neck of the bladder is greatly altered from the relation of the normal prostate. Normally, it is extravesical; when enlarged it may encase the “neck of the bladder in a cuff-like manner, extending several inches upward on its wall,” and often it protrudes “into the vesical cavity, carrying on its surface the mucosa vesicae.” In many cases of prostatic enlargement the gland should be removed (prostatectomy). One method is enucleation through a suprapubic incision; another method is enucleation through a perineal incision; another method is carried out by both incisions (the combined method).

The Bottini operation is prostatectomy, effected by a special instrument for the purpose of cauterizing the gland and thus causing shrinking.

In elderly individuals the gland tubules may form round, indurated, and sometimes calcified masses, about 1 mm. in diameter, and called prostatic stones.

COWPER’S GLANDS (GLANDULAE BULBO-URETHRALES) (Figs. 1071, 1078).

Cowper’s glands are two small, rounded, and somewhat lobulated bodies of a yellow color, about the size of peas, placed behind the forepart of the membranous portion of the urethra, between the two layers of the triangular ligament. They lie close above the bulb, and are enclosed by the transverse fibres of the Compressor urethrae muscle. Their existence is said to be constant; they gradually diminish in size as age advances.

Structure.—Each gland consists of several lobules held together by a fibrous investment. Each lobule consists of a number of acini lined by columnar epithelial cells, opening into one duct, which, joining with the ducts of other lobules outside the gland, form a single excretory duct (ductus excretorius). The excretory duct of each gland, nearly an inch in length, passes obliquely forward beneath the mucous membrane, and opens by a minute orifice on the floor of the bulbous portion of the urethra.

THE PENIS (Figs. 1073, 1074, 1075, 1076, 1077, 1078).

The penis is a long body of prismatic shape placed below and in front of the symphysis pubis. It surrounds the greatest length of the urethra. It consists of a root, body, and extremity or glans penis. The root and the posterior portion

1 John B. Murphy, in the Journal of the American Medical Association, May 28, 1904.
of the body lie beneath the scrotum and the integument of the perineum (Fig. 1069), and are firmly fixed to the triangular ligament, the pubic bones, and the symphysis; hence this portion of the organ is called the fixed portion (pars fixa) (Fig. 309). The balance of the organ is free and movable (Fig. 1069), and is called the mobile portion (pars mobilia). When the penis is relaxed there is an angle between the fixed and mobile portions; when the penis is erect, the angle disappears.

The Root (radix penis).—The root is firmly connected to the rami of the os pubis and ischium by two strong tapering, fibrous processes, the crura (Figs. 1073, 1077, and 1078), and to the front of the symphysis pubis by the suspensory ligament (Fig. 1076), a strong band of fibrous tissue which passes downward from the front of the symphysis pubis to the root of the penis.

The extremity, acorn, or glans penis (Figs. 1074 and 1075) presents the form of an obtuse cone, flattened from above downward. At its summit is a vertical fissure, the external orifice of the urethra or the meatus urinarius (orificium urethrae externum). The base of the glans forms a rounded projecting border, the corona glandis, and behind the corona is a deep constriction, the cervix or neck (collum glandis). Upon both the corona and neck numerous small sebaceous glands are found, the glandulae Tysonii odoriferae. They secrete a sebaceous matter of very peculiar odor, which probably contains casein and becomes easily decomposed.

---

1 Stieda (Comptes-rendus du XII. Congrès International de Médecine, Moscow, 1897) asserts that Tyson’s glands are never found on the corona glandis, and that what have hitherto been mistaken for glands are really large papillae.—En of 15th English edition.
The Body of the Penis (corpus penis).—The body of the penis is the part between the root and extremity. In the flaccid condition of the organ it is cylindrical, but when erect it has a triangular prismatic form with rounded angles, the broadest side being turned upward, and called the dorsum penis. The lower surface of the body of the penis is called the urethral surface (facies urethralis). The body is covered by integument, and contains in its interior a large portion of the urethra. The integument covering the penis is remarkable for its thinness, its dark color, its looseness of connection with the deeper parts of the organ, and for the absence of adipose tissue. At the root of the penis the integument is continuous with that upon the pubes and scrotum, and at the neck of the glans it leaves the surface and becomes folded upon itself to form the prepuce (praeputium) (Fig. 1074). The internal layer of the prepuce is attached behind to the cervix or neck (Fig. 1074), and approaches in character to a mucous membrane; from the cervix it is reflected over the glans penis, and at the meatus urinarius is continuous with the mucous lining of the urethra.

The integument covering the glans penis contains no sebaceous glands, but projecting from its free surface are a number of small, highly sensitive papillae.

At the back part of the meatus urinarius a fold of mucous membrane passes backward to the bottom of a depressed raphé, where it is continuous with the prepuce; this fold is termed the fraenum (frenulum praeputii). The skin of the penis covers the mobile parts of the organ. It is thin, extremely elastic, and contains very few hairs. Beneath the skin of the penis is the dartos layer (Figs. 1076 and 1083), continuous with the scrotal dartos, containing chiefly non-striated muscular fibres arranged longitudinally. It passes forward to the orifice of the prepuce, and then turns backward, growing thinner and thinner, and finally disappearing at the cervix. Beneath the dartos and extending forward to the orifice of the prepuce is a sheath of areolar tissue. It is a lax sheath rich in elastic tissue and containing almost no fat. The superficial vessels and nerves are in the areolar sheath. Beneath the areolar sheath of the penis, from the corona to the root, is the fascia of the penis (fascia penis) (Fig. 1083). It covers the organ from the root to the corona, and also covers the dorsal artery, veins, and nerves. It is continuous behind with the superficial perineal fascia and suspensory ligament. It is composed chiefly of elastic tissue.

Structure of the Penis.—The penis is composed of a mass of erectile tissue enclosed in three cylindrical fibrous compartments. Of these, two, the corpora...
cavernosa, are placed side by side along the upper part of the organ; the third, or corpus spongiosum, encloses the urethra and is placed below.

The Two Corpora Cavernosa (corpora cavernosa penis) (Figs. 1077 and 1078).—The two corpora cavernosa form the chief part of the body of the penis. They consist of two fibrous cylindrical tubes, placed side by side, and intimately connected along the median line for their anterior three-fourths, whilst at their back part they separate from each other to form the crura penis, which are two strong tapering fibrous processes or roots firmly connected to the rami of the os pubis and ischium (Figs. 1073, 1077, and 1078). Each crus commences by a
blunt-pointed process in front of the tuberosity of the ischium, and before its junction with its fellow to form the body of the penis it presents a slight enlargement, named by Kobelt the **bulb of the corpus cavernosum**. Just beyond this point they become constricted, and retain an equal diameter to their anterior extremity, where they form a single rounded end which is received into a fossa in the base of the glans penis (Figs. 1075 and 1077). A median groove on the upper surface lodges the dorsal arteries, nerves, and veins of the penis (Figs. 1081, 1082, and 1083), and the groove on the under surface receives the corpus spongiosum (Fig. 1077). The root of the penis is connected to the symphysis pubis by the suspensory ligament.

**Structure** (Fig. 1083).—Each corpus cavernosum is composed of erectile tissue. The erectile tissue is surrounded by a strong fibrous envelope, the **tunica albuginea**, **corpora cavernosa**, consisting of two sets of fibres—the one, longitudinal in direction, being common to the two corpora cavernosa, and investing them in a common covering; the other, internal, circular in direction, and being proper to each corpus cavernosum. The internal circular fibres of the two corpora cavernosa form, by their junction in the mesial plane, an incomplete partition or septum, the **septum penis**, between the two bodies.

![Fig. 1079.—The dartos. (Poirier and Charpy.)](image)

The **septum** between the two corpora cavernosa is thick and complete behind, but in front it is incomplete, and consists of a number of vertical bands, which are arranged like the teeth of a comb, whence the name which it has received, **septum pectiniforme**. These bands extend between the dorsal and the urethral surface of the corpora cavernosa. The fibrous-investment of the corpora cavernosa is extremely dense, of considerable thickness, and consists of bundles of shining white fibres, with an admixture of well-developed elastic fibres, so that it is possessed of great elasticity.

From the internal surface of the fibrous envelope, as well as from the sides of the septum, are given off a number of bands or cords which cross the interior of each crus in all directions, subdividing it into a number of separate compart-
ments, and giving the entire structure a spongy appearance. These bands and cords are called *trabeculae corporum cavernosum*, and consist of white fibrous tissue, elastic fibres, and plain muscular fibres. In them are continued numerous arteries and nerves.

The component fibres of which the trabeculae are composed are larger and stronger around the circumference than at the centre of the corpora cavernosa; they are also thicker behind than in front. The interspaces, on the contrary, are larger at the centre than at the circumference, their long diameter being directed transversely; they are largest anteriorly. They are called *cavernous spaces* and are occupied by venous blood, and are lined by a layer of flattened cells similar to the endothelial lining of veins (Fig. 1080).

The whole of the structure of the corpora cavernosa contained within the fibrous sheath consists, therefore, of a sponge-like tissue the areolar spaces of which freely communicate with each other and are filled with venous blood. The spaces may therefore be regarded as large cavernous veins.

The arteries bringing the blood to these spaces are the *arteries of the corpora cavernosa* and branches from the *dorsal artery of the penis*, which perforate the fibrous capsule, along the upper surface, especially near the forepart of the organ.

These arteries on entering the cavernous structure divide into branches which are supported and enclosed by the trabeculae. Some of these terminate in a capillary network, the branches of which open directly into the cavernous spaces (Fig. 1080); others assume a tendril-like appearance, and form convoluted and somewhat dilated vessels, which were named by Müller *helicine arteries* (*arteriae helicinae*). They project into the spaces, and from them are given off small capillary branches to supply the trabecular structure. They are bound down in the spaces by fine fibrous processes, and are more abundant in the back part of the corpora cavernosa.

The blood from the cavernous spaces is returned by a series of vessels, some of which emerge in considerable numbers from the base of the glans penis and converge on the dorsum of the organ to form the *deep dorsal vein*; others pass out on the upper surface of the corpora cavernosa and join the dorsal vein; some emerge from the under surface of the corpora cavernosa, and, receiving branches from the corpus spongiosum, wind around the sides of the penis to terminate in the dorsal vein; but the greater number pass out at the root of the penis and join the *prostatic plexus*.

The **Corpus Spongiosum** (*corpus cavernosum urethrae*) (Figs. 1075, 1077, and 1078).—The corpus spongiosum encloses the urethra, and is situated in the groove on the under surface of the corpora cavernosa penis. It commences posteriorly below the superficial layer of the triangular ligament of the urethra, between the diverging crura of the corpora cavernosa, where it forms a rounded enlargement, the *bulb of the urethra*, and terminates anteriorly in another expansion, the *glans penis* (Figs. 1074, 1075, 1077, and 1078), which overlaps the anterior rounded extremity of the corpora cavernosa. The central portion, or body of the corpus spongiosum, is cylindrical, and tapers slightly from behind forward.

The **Bulb of the Urethra** (*bulbus urethrae*) (Figs. 1073, 1077, and 1078) varies in size in different subjects; it receives a fibrous investment from the superficial layer of the triangular ligament, and is surrounded by the Accelerator urinae muscle. The urethra enters the bulb nearer its upper than its lower surface, being surrounded by a layer of erectile tissue, a thin prolongation of which is continued backward around the membranous and prostatic portions of the canal to the neck of the bladder, lying between the two layers of muscular tissue. The portion of the bulb below the urethra presents a partial division into two *lobes* (*hemisphaeria bulbi urethrae*), being marked externally by a linear raphé, whilst internally there projects, for a short distance, a thin *fibrous median septum* (*septum bulbi urethrae*), which is more distinct in early life.
Structure.—The corpus spongiosum consists of a strong fibrous envelope enclosing a trabecular structure, which contains in its meshes erectile tissue. The fibrous envelope is thinner, whiter in color, and more elastic than that of the corpora cavernosa of the penis. The trabeculae are more delicate, more nearly uniform in size, and the meshes between them smaller than in the corpora cavernosa, their long diameter, for the most part, corresponding with that of the penis. The external envelope or outer coat of the corpus spongiosum is formed partly of unstriped muscular fibre, and a layer of the same tissue immediately surrounds the canal of the urethra.

Ligaments of the Penis.—The suspensory ligament (ligamentum suspensorium penis) (Fig. 1076) is firm and fibrous. It passes from the front of the symphysis pubis to the tunica albuginea of the corpora cavernosa. The ligamentum fundiforme penis (Fig. 1073), formerly called the suspensory ligament, arises from the linea alba, sheath of the rectus, superficial fascia, and symphysis pubis, and surrounds the penis in a loop, being attached more distalward than is the suspensory ligament, and usually passes into the scrotum. It is composed of elastic tissue.

Vessels and Nerves of the Penis.—The arteries (Fig. 1081) of the penis come from branches of the internal pudic artery. The deep arteries of the penis give the chief supply to the erectile tissue of the corpora cavernosa, and the dorsal artery also sends branches to it; the artery of the bulb (p. 693) supplies the erectile tissue of the corpus spongiosum. The chief blood-supply of the glans is from the dorsal artery (p. 694). In the trabeculae the arteries are very small and often twisted. The twisted vessels are called helicine arteries. The small arteries open directly into the venous spaces. The veins of the penis empty directly into
THE PROSTATE PLEXUS OR INTO THE DEEP DORSAL VEIN, WHICH EMBUTES INTO THE PROSTATIC PLEXUS. ON EACH SIDE OF THE DEEP DORSAL VEIN IS A DORSAL ARTERY AND EXTERNAL TO EACH DORSAL ARTERY IS A DORSAL NERVE (FIG. 1083). THE SUPERFICIAL DORSAL VEIN (FIGS. 1082 AND 1083), RECEIVING SMALL VEINS FROM THE PREPUCE, PASSES BACK BENEATH THE SKIN, REACHES THE SYMPHYSIS AND DIVIDES INTO TWO BRANCHES, EACH OF WHICH PASSES TO THE CORRESPONDING SUPERFICIAL EXTERNAL PUBIC VEIN.

THE LYMPHATICS OF THIS REGION HAVE BEEN STUDIED CAREFULLY BY Poirier, Cunéo, and Delamare,¹ WHICH BOOK I HAVE FREELY USED.

THE NERVES ARE DERIVED FROM THE INTERNAL PUBIC NERVE AND THE PELVIC Plexus. ON THE GLANS AND BULB SOME FILAMENTS OF THE CUTANEOUS NERVES HAVE PACINIAN BODIES CONNECTED WITH THEM, AND, ACCORDING TO Krause, MANY OF THEM TERMINATE IN A PECULIAR FORM OF END-BULB.

² Ibid.
THE TESTICLES (TESTES) AND THEIR COVERINGS (Figs. 1086, 1087).

The testicles are two glandular organs, which secrete the semen; they are situated in the scrotum, being suspended by the spermatic cords. At an early period of foetal life the testes are contained in the abdominal cavity, behind the peritoneum, but they subsequently descend into the scrotum.

DESCENT OF THE TESTIS (DESCENDUS TESTIS).

Each testis at an early period of foetal life is placed at the back part of the abdominal cavity, behind the peritoneum, in front and a little below the kidney. The anterior surface and sides are invested by peritoneum. At about the third month of intra-uterine life a peculiar structure, the gubernaculum testis, makes its appearance. This structure is at first a slender band which extends from the situation of the internal ring to the epididymis and body of the testicle, and is then continued upward in front of the kidney toward the Diaphragm. As development advances the peritoneum covering the testicle encloses it and forms a mesentery, the mesorchium, which also encloses the gubernaculum and forms two folds—one above the testicle, and the other below it. The one above the testicle is the plica vascularis, and contains ultimately the spermatic vessels; the one below, the plica gubernatrix, contains the lower part of the gubernaculum, which has now grown into a thick cord; it terminates below at the internal ring in a tube of peritoneum, the processus vaginalis, which now lies in the inguinal canal. The lower part of the gubernaculum by the fifth month has become a thick cord, whilst the upper part has disappeared. The lower part can now be seen to consist of a central core of unstriped muscle-fibre, and outside this of a firm layer of striped elements, connected, behind the peritoneum, with the abdominal wall. Later on, about the sixth month, the lower end of the gubernaculum can be traced into the inguinal canal, extending to the pubes, and, at a later period, to the bottom of the scrotum. The fold of peritoneum constituting the processus vaginalis projects itself downward into the inguinal canal, forming a gradually elongating depression or cul-de-sac, which eventually reaches the bottom of the scrotum. This cul-de-sac is now invaginated by the testicle, as the body of the fectus grows, for the gubernaculum does not grow commensurately with the growth of other parts, and therefore the testicle, being attached by the gubernaculum to the bottom of the
scrotum, is prevented from rising as the body grows, and is drawn first into the inguinal canal, and eventually into the scrotum. By the eighth month the testicle has reached the scrotum, preceded by the lengthened pouch of peritoneum, the processus vaginalis, which communicates by its upper extremity with the peritoneal cavity. Just before birth the upper part of the pouch usually becomes closed, and this obliteration extends gradually downward to within a short distance of the testis. The process of peritoneum surrounding the testis, which is now entirely cut off from the general peritoneal cavity, constitutes the tunica vaginalis.\(^1\)

Mr. Jacobson\(^2\) says that the attachments of the gubernaculum above are to the vas, the epididymis, and afterward to the testicle. The lower attachments of the gubernaculum, some of which are temporary, are the abdominal wall, pubes and root of the scrotum, Scarpa’s triangle, perineum and scrotum. The remains of the scrotal fibres constitute a so-called ligament of the scrotum or the mesorchium, which causes adhesion between the testicle and skin (Fig. 1086).

In the female, a small cord, corresponding to the gubernaculum in the male, descends to the inguinal region and ultimately forms the round ligament of the uterus. A pouch of peritoneum accompanies it along the inguinal canal, analogous to the processus vaginalis in the male; it is called the canal of Nuck.

**Surgical Anatomy.**—Abnormalities in the formation and in the descent of the testicle may occur. The testicle may fail to be developed, or it may be fully developed and the vasa deferentia may be undeveloped in whole or in part; or, again, both testicle and vasa deferentia may be fully developed, but the duct may not become connected to the gland. The testicle may fail in its descent (*cryptorchismus*) or it may descend into some abnormal position (*ectopia testis*). Thus it may be retained in the position where it was primarily developed, below the kidney; or it may descend to the internal abdominal ring, but fail to pass through this opening; it may be retained in the inguinal canal, which is perhaps the most common position; or it may pass through the external abdominal ring and remain just outside it, failing to pass to the bottom of the scrotum. On the other hand, it may get into some abnormal position; it may pass the scrotum and reach the perineum, or it may fail to enter the inguinal canal, and may find its way through the femoral ring into the crural canal, and present itself on the thigh at the saphenous opening. Ectopia testis is due to the absence, overdevelopment or malposition of some portion of the gubernaculum. There is still a third class of cases of abnormality in the position of the testicle, where the organ has descended in due course into the scrotum, but is misplaced. The most common form of this is where the testicle is *inverted*; that is to say, the organ is rotated, so that the epididymis is connected to the front of the scrotum, and the body, surrounded by the tunica vaginalis, is directed backward. In these cases the vasa deferentia is to be felt in the front of the cord. The condition is of importance in connection with hydrocele and hematocele, and the position of the testicle should always be carefully ascertained before performing any operation for these affections. Again, more rarely, the testicle may be *reversed*. This is a condition in which the top of the testicle, indicated by the globus major of the epididymis, is at the bottom of the scrotum, and the vasa deferentia comes off from the summit of the organ.

**The Coverings of the Testicle** (Fig. 1088).

The coverings of the testicle are the following:

**The Testicular Bag or Scrotum** (Figs. 1086 and 1087).—The testicular bag or scrotum is a cutaneous pouch which contains the testes and part of the spermatic cords. It is divided on its surface into two lateral portions by a median line or

---

1. The obliteration of the process of peritoneum which accompanies the cord, and is hence called the juxticular process, is often incomplete. See section on Inguinal Hernia.
2. Diseases of the Male Organs of Generation.
The coverings of the testicle

Raphé (raphe scroti), which is continued forward to the under surface of the penis and backward along the middle line of the perineum to the anus. Of these two lateral portions, the left is usually longer than the right, and corresponds with the usual greater length of the spermatic cord on the left side. Its external aspect varies under different circumstances: thus under the influence of warmth and in old and debilitated persons it becomes elongated and flaccid, but under the influence of cold and in the young and robust it is short, corrugated, and closely applied to the testes. The wrinkles in the scrotum are called rugae.

The scrotum consists of two layers, the **integument** and the **dartos**.

---

**Fig. 1086.**—The scrotum. On the left side the cavity of the tunica vaginalis has been opened; on the right side only the layers superficial to the cremaster have been removed. (Testut.)

**The Integument.**—The integument is very thin, of a brownish color, and generally thrown into folds or rugae. It is provided with sebaceous follicles, the secretion of which has a peculiar odor, and is beset with thinly-scattered, crisp hairs, the roots of which are seen through the skin.

**The Dartos** (tunica dartos) (Figs. 1079 and 1086).—The dartos is a thin layer of loose tissue, endowed with contractility; it forms the proper tunic of the scrotum, is continuous around the base of the scrotum, with the two layers of the superficial fascia of the groin and perineum, and sends inward a distinct septum, the **septum of the scrotum** (septum scroti) (Fig. 1086), which divides it into two cavities for the two testes, the septum extending between the raphé and the under surface of the penis as far as its root.

The dartos is closely united to the skin externally, but connected with the
subjacent parts by delicate areolar tissue, upon which it glides with the greatest facility. The dartos is very vascular, and consists of a loose areolar tissue containing unstriped muscular fibre, but no fat. Its contractibility is slow, and excited by cold and mechanical stimuli, but not by electricity.

The Intercolumnar or Spermatic Fascia (Fig. 1086).—The intercolumnar fascia is a thin membrane derived from the margin of the pillars of the external abdominal ring, during the descent of the testis in the foetus, which is prolonged downward around the surface of the cord and testis. It is separated from the dartos by loose areolar tissue, which allows of considerable movement of the latter upon it, but is intimately connected with the succeeding layers.

The Cremasteric Fascia (fascia cremasterica) (Figs. 1086 and 1087).—The cremasteric fascia consists of scattered bundles of muscular fibres, the Cremaster muscle (m. cremaster) (Figs. 1086 and 1087) connected together into a continuous covering by intermediate areolar tissue. The muscular fibres are continuous with the lower border of the Internal oblique muscle.
The Infundibuliform Fascia (tunica vaginalis communis) [testis et funiculi spermatici] (Figs. 1086 and 1087).—The infundibuliform fascia is a thin membranous layer, which loosely invests the surface of the cord. It is a continuation downward of the fascia transversalis. Beneath it is a quantity of loose connective tissue which connects this layer of fascia with the spermatic cord and posterior parts of the testicle. This connective tissue is continuous above with the subserous areolar tissue of the abdomen. These two layers, the infundibuliform fascia and the tissue beneath
The male organs of generation

It, are known collectively as the fascia propria. The infundibuliform fascia completely encloses the testicle and epididymis and is fused with the parietal lamina of the tunica vaginalis propria testis.

The Tunica Vaginalis (tunica vaginalis propria testis).—The tunica vaginalis is described with the testis (p. 1480).

Vessels and Nerves.—The arteries supplying the coverings of the testis are: the superficial and deep external pudic, from the femoral; the superficial perineal branch of the internal pudic; and the cremasteric branch from the deep epigastric. The veins follow the course of the corresponding arteries. The lymphatics terminate in the inguinal glands. The nerves are: the ilio-inguinal branch of the lumbar plexus, the two superficial perineal branches of the internal pudic nerve, the inferior pudendal branch of the small sciatic nerve, and the genital branch of the genito-femoral nerve.

THE SPERMATIC CORD (Funiculus Spermaticus)
(Figs. 1086, 1087, 1090, 1091).

The spermatic cord extends from the internal abdominal ring, where the structures of which it is composed converge, to the back part of the testicle. In the abdominal wall the cord passes obliquely along the inguinal canal, lying at first beneath the Internal oblique muscle and upon the fascia transversalis; but nearer the pubes it rests upon Poupart’s ligament, having the aponeurosis of the External oblique in front of it and the conjoined tendon behind it. It then escapes at the external ring, and descends nearly vertically into the scrotum. The left cord is usually rather longer than the right, consequently the left testis generally hangs somewhat lower than its fellow.

Structure.—The spermatic cord contains the spermatic duct, the deferential artery and veins, the spermatic artery, the pampiniform plexus of veins, the spermatic plexus, and the deferential plexus of the sympathetic nerve, lymphatics, and the cord-like remnant of the funicular process of peritoneum called the ligament...
of Cloquet (Fig. 1090). All the above structures are held together by connective tissue. These structures are enshrouded by the infundibuliform process of the transversalis fascia (Fig. 1096 and p. 1074). This fascia is thin above and thicker below, and encloses the testicle and epididymis, as well as the cord, being firmly adherent to the parietal layer of the vaginal tunic of the testicle and with the posterior portion of the testicle and epididymis. Upon this fascia are the fibres of the Cremaster muscle, which spring from the internal oblique, and in this fascia are the cremasteric artery, the genital branch of the genito-femoral nerve, and external spermatic veins. This fascia is surrounded by the intercolumnar or spermatic fascia, which is distinct above, but not below.

**Vessels and Nerves of the Spermatic Cord.**—The arteries (Figs. 1089 and 1096) of the cord are: the spermatic, from the aorta; the artery of the vas deferens, from the superior vesical; the cremasteric, from the deep epigastrie.

The spermatic artery (a. spermatica interna) arises from the abdominal aorta below the renal artery, descends by the Psoas muscle, crosses the ureter and external iliac vessels, meets the vas deferens at the internal abdominal ring, escapes from the abdomen at the internal or deep abdominal ring, and lying in front of the vas deferens accompanies the other constituents of the spermatic cord along the inguinal canal and through the external abdominal ring into the scrotum. It then descends to the testicle, and, becoming tortuous, divides into several branches, two or three of which, the epididymal branches, accompany the vas deferens and supply the epididymis, anastomosing with the artery of the vas deferens and the cremasteric artery; others, the glandular branches, pierce the back of the tunica albuginea and supply the substance of the testis.

The artery of the vas deferens, a branch of the superior vesical, is a long slender vessel which accompanies the vas deferens, ramifying upon the coats of that duct, and anastomosing with the spermatic artery and the cremasteric artery near the testis.
The cremasteric artery (*a. spermatica externa*) is a branch of the deep epigastric artery. It accompanies the spermatic cord and supplies the Cremaster muscle and other coverings of the cord, anastomosing with the spermatic and deferential arteries.

The spermatic veins (Figs. 1089, 1090, 1091, and 1093) emerge from the back of the testis and receive tributaries from the epididymis; they unite and form a convoluted plexus, the pampiniform plexus (*plexus.pampiniformis*), which forms the chief mass of the cord; the vessels composing this plexus are very numerous, and ascend along the cord in front of the vas deferens; below the external or superficeal abdominal ring they unite to form three or four veins, which pass along the inguinal canal, and, entering the abdomen through the internal or deep abdominal ring, coalesce to form two veins. These again unite to form a single vein, which opens on the right side into the postcava at an acute angle, and on the left side into the renal vein at a right angle.

The lymphatic vessels of the scrotum terminate in the superficial inguinal glands. The lymphatics of the testicle join the lymphatics of the epididymis and of the visceral layer of the vaginal tunic of the testicle, and ascend in the spermatic cord. They reach the lumbar region along the spermatic blood-vessels and terminate in the juxta-aorta glands, and sometimes in the glands in front of the aorta. The lymphatics of the seminal duct pass to the *external iliac glands*.

The nerves are the spermatic plexus from the sympathetic, joined by filaments from the pelvic plexus which accompany the artery of the vas deferens.

The Ligament of the Scrotum.—See Fig. 1085 and p. 1472.

Surgical Anatomy.—The scrotum forms an admirable covering for the protection of the testicle. This body, lying suspended and loose in the cavity of the scrotum, and surrounded by
a serous membrane, is capable of great mobility, and can therefore easily slip about within the scrotum, and thus avoid injuries from blows or squeezes. The skin of the scrotum is very elastic and capable of great distention, and on account of the looseness and amount of subcutaneous tissue the scrotum becomes greatly enlarged in cases of edema, to which this part is especially liable on account of its dependent position. The scrotum is frequently the seat of epithelioma; this is no doubt due to the rugae on its surface, which favor the lodgement of dirt, and this, causing irritation, is the exciting cause of the disease. Cancer was especially common in chimney-sweeps from the lodgement of soot. The scrotum is also the part most frequently affected by elephantiasis.

On account of the looseness of the subcutaneous tissue considerable extravasations of blood may take place from very slight injuries. It is therefore generally recommended never to apply leeches to the scrotum, since they may lead to considerable ecchymosis, but rather to puncture one or more of the superficial veins of the scrotum in cases where local bloodletting from this part is judged to be desirable. The muscular fibre in the dartos causes contraction and considerable diminution in the size of a wound of the scrotum, as after the operation of castration, and is of assistance in keeping the edges together and covering the exposed parts.

The testicles are suspended in the scrotum by the spermatic cords. As the left spermatic cord is rather longer than the right one, the left testicle hangs somewhat lower than its fellow. Each gland is of an oval form, compressed laterally, and having an oblique position in the scrotum, the upper extremity (extremitas superior) being directed forward and a little outward, the lower extremity (extremitas inferior), backward and a little inward; the anterior convex border (margo anterior).
looks forward and downward; the posterior or straight border (margo posterior), to which the cord is attached, backward and upward.

The anterior border and lateral surfaces (facies lateralis et facies mediialis), as well as both extremities of the organ, are convex, free, smooth, and invested by the visceral layer of the tunica vaginalis. The posterior border, to which the cord is attached, receives only a partial investment from that membrane. Lying upon the outer edge of this posterior border is a long, narrow, flattened body, named, from its relation to the testis, the epididymis (ἄντειος, testis) (Figs. 1094 and 1095). The curve of the epididymis is convex outward and backward. It consists of a central portion or body (corpus epididymidis); an upper enlarged extremity, the head or globus major (caput epididymidis); and a lower pointed extremity, the tail or globus minor (cauda epididymidis). The globus major is directed inward and is intimately connected with the upper end of the testicle by means of its efferent ducts, and the globus minor is connected with its lower end by cellular tissue and a reflection of the tunica vaginalis. The globus minor bends suddenly and passes into the seminal duct, the direction of which is upward and backward. The outer surface and upper and lower ends of the epididymis are free and covered by serous membrane; the body is also completely invested by it, excepting along its posterior border, and between the body and the testicle is a pouch or cul-de-sac, named the digital fossa (sinus epididymidis). Above this fossa is a fold of the tunica vaginalis, which is called the ligamentum epididymidis superior, and below it is another fold, the ligamentum epididymidis inferior. The epididymis is connected to the back of the testis by a fold of the serous membrane. Attached to the upper end of the testis, close to the globus major, is a small body. It is oblong in shape and has a broad base. Attached to the globus major of the epididymis is another small body, which is pear-shaped and has a stalk. These bodies are believed to be the remains of the upper extremity of the Müllerian duct, and are termed the hydatids of Morgagni; some observers, however, regard the stalked hydatid as being a rudiment of the pronephros. The body with a broad base is the non-pedunculated hydatid (appendix testis [Morgagnii]) (Figs. 1086 and 1094);

the pear-shaped body is the pedunculated hydatid (appendix epididymidis). When the testicle is removed from the body, the position of the vas deferens, on the
posterior surface of the testicle and inner side of the epididymis, marks the side to which the gland has belonged.

**Size and Weight.**—The average dimensions of this gland are from one and a half to two inches in length, one inch in breadth, and an inch and a quarter in the antero-posterior diameter, and the weight varies from six to eight drachms, the left testicle being a little the larger.

**The Tunics of the Testicle.**—The testis is invested by three tunics—the tunica vaginalis, tunica albuginea, and tunica vasculosa. The Proper Sheath of the Testicle or the Tunica Vaginalis (tunica vaginalis propria testis) (Figs. 1084, 1086, 1087, 1088, and 1096) is the serous covering of the testicle and epididymis. It is a pouch of serous membrane, derived from the peritoneum (processus vaginalis peritonei) during the descent of the testis in the foetus from the abdomen into the scrotum. After its descent that portion of the pouch which extends from the internal ring to near the upper part of the gland, the **funicular process**, becomes obliterated, the lower portion remaining as a shut sac, which invests the outer surface of the testis, and is reflected on to the internal surface of the scrotum; hence it may be described as consisting of a visceral and parietal portion.

The **Visceral Portion** (lamina visceralis) of the tunica vaginalis propria covers the outer surface of the testis, as well as the epididymis, connecting the latter to the testis by means of a distinct fold. From the posterior border of the gland it is reflected on to the internal surface of the infundibuliform process of the transversalis fascia, and between the tunica and the fascia is a layer of unstriated muscle fibres, the **Internal cremaster muscle** (Fig. 1088).

The **Parietal Portion** (lamina parietalis) of the tunica vaginalis propria is the reflected portion. It is far more extensive than the visceral portion, extending upward for some distance in front and on the inner side of the cord, and reaching below the testis. The inner surface of the tunica vaginalis is free, smooth, and covered by a layer of endothelial cells. The interval between the visceral and parietal layers of this membrane constitutes the **cavity of the tunica vaginalis** and contains a small amount of serous fluid.

The obliterated portion of the pouch may generally be seen as a fibro-cellular thread, the **ligament of Cloquet** (rudimentum processus vaginalis) (Fig. 1090), lying in the loose areolar tissue around the spermatic cord; sometimes this may be traced as a distinct band from the upper end of the inguinal canal, where it is connected with the peritoneum, down to the tunica vaginalis; sometimes it gradually becomes lost on the spermatic cord. Occasionally no trace of it can be detected. In some cases it happens that the pouch of peritoneum does not become obliterated, but the sac of the peritoneum communicates with the tunica vaginalis. This may give rise to one of the varieties of oblique inguinal hernia; or in other cases the
pouch may contract, but not become entirely obliterated; it then forms a minute canal leading from the peritoneum to the tunica vaginalis.\footnote{1}

The **Tunica Albuginea** (Figs. 1088, 1095, and 1096).—The tunica albuginea is the fibrous covering of the testis. It is a dense fibrous membrane, of a bluish-white color, composed of bundles of white fibrous tissue, which interlace in every direction. Its outer surface is covered by the tunica vaginalis, except at the points of attachment of the epididymis to the testicle, and along its posterior border, where the spermatic vessels enter the gland. This membrane surrounds the glandular structure of the testicle, and at its posterior border forms a projection, triangular in shape and cellular in structure, which is reflected into the interior of the gland, forming an incomplete vertical septum, called the **mediastinum testis**.

The **Mediastinum Testis** (*corpus Highmori*) (Figs. 1088, 1095, and 1096) extends from the upper, nearly to the lower, extremity of the gland, and is wider above than below. From the front and sides of this septum numerous slender fibrous cords and imperfect septa, called the **trabeculae** (*septula testis*) (Fig. 1096), are given off, which radiate toward the surface of the organ, and are attached to the inner surface of the tunica albuginea. This scaffolding of connective tissue divides the **parenchyma** (*parenchyma testis*) of the organ into a number of incomplete spaces, which are somewhat cone-shaped, being broad at their bases at the surface of the gland, and becoming narrower as they converge to the mediastinum. The mediastinum supports the blood-vessels, lymphatics, and ducts of the testis in their passage to and from the substance of the gland, and contains numerous fine canals, into which open the very small tubules of the proper substance of the testicle.

The **Tunica Vasculosa** (Fig. 1088).—The tunica vasculosa is the vascular layer of the testis, and consists of a plexus of blood-vessels held together by a delicate areolar tissue. It covers the inner surface of the tunica albuginea and the different septa in the interior of the gland, and therefore forms an internal investment to all the spaces of which the gland is composed.

**Structure of the Testicle and Epididymis** (Fig. 1096).—The glandular structure of the testis consists of numerous **lobules** (*lobuli testis*). Their number, in a single testis, is estimated by Berres at 250, and by Krause at 400. They differ in size according to their position, those in the middle of the gland being larger and longer. The lobules are conical in shape, the base of each being directed toward the circumference of the organ, the apex toward the mediastinum. Each lobule is contained in one of the intervals between the fibrous cords and vascular processes which extend between the mediastinum testis and the tunica albuginea, and consists of from one to three or more minute convoluted tubes, which anastomose with each other, the **tubuli seminiferi contorti**. The contorted tubes unite at the apex of the lobules and form the **straight tubes** (*tubuli seminiferi recti*). The straight tubes pass into the mediastinum testis and form the network known as the **rete testis** of Haller (Fig. 1096). The rete testis is lined with flattened epithelium. The tubes are lined with columnar ciliated epithelium. The **efferent ducts** (*duetuli efferentes testis*) (Fig. 1096), about twelve to fifteen in number, arise from the rete. The contorted tubes may be separately unravelled by careful dissection under water, and may be seen to commence either by free caecal ends or by anastomotic loops. The total number of tubes is considered by Munro to be about 300 and the length of each about sixteen feet; by Lauth their number is estimated at 840, and their average length two feet and a quarter. The diameter varies from \( \frac{1}{5} \) to \( \frac{1}{6} \) of an inch. The tubuli are pale in color in early life, but in old age they acquire a deep-yellow tinge from containing much fatty matter. Each tube consists of a basement layer, formed

\footnote{1 It is recorded that in the post-mortem examination of Sir Astley Cooper a minute funicular canal was found on each side of the body. Sir Astley Cooper states that when a student he suffered from inguinal hernia; probably this was of the congenital variety, and the canal found after death was the remains of the one down which the hernia travelled (Lancet, 1824, vol. ii. p. 116).—Ed. of 15th English edition.
of epithelioid cells united edge to edge, outside of which are other layers of flattened cells arranged in interrupted laminae, which give to the tube an appearance of striation in cross-section. The cells of the outer layers gradually pass into the interstitial tissue. Within the basement-membrane are epithelial cells arranged in several irregular layers, which are not always clearly separated, but which may be arranged in three different groups. Among these cells may be seen the spermatozoids in different stages of development. 1. Lining the basement-membrane and forming the outer zone is a layer of cubical cells, with small nuclei; these are known as the lining cells or spermatogonia. The nucleus of some of them may be seen to be in the process of indirect division (karyokinetics), and in consequence of this daughter cells are formed, which constitute the second zone.

2. Within this first layer is to be seen a number of larger cells with clear nuclei, arranged in two or three layers; these are the intermediate cells or spermatocytes. Most of these cells are in a condition of karyokinetic division, and the cells which result from this division form those of the next layer, the spermatoblasts or spermatids. 3. The third layer of cells therefore consists of the spermatoblasts or spermatids, and each of these, without further subdivision, becomes a spermatozoid. They are ill-defined granular masses of protoplasm, of an elongated form, with a nucleus which becomes the head of the future spermatozoid. In addition to these three layers of cells others are seen, which are termed the supporting cells, or cells of Sertoli. They are elongated and columnar, and project inward from the basement-membrane toward the lumen of the tube. They give off numerous lateral branches, which form a reticulum for the support of the three groups of cells just described. As development of the spermatozoids proceeds the latter group themselves around the inner extremities of the supporting cells. The nuclear part of the spermatozoid, which is partly embedded in the supporting cell, is differentiated to form the head of the spermatozoid, while the cell protoplasm becomes lengthened out to form the middle piece and tail, the latter projecting into the lumen of the tube. Ultimately the heads are separated and the spermatozoids are set free.

**Spermatogenesis.**—The stages in the development of the spermatozoids are as follows: The spermatogonia become enlarged to form the spermatocytes, and each spermatocyte subdivides into two cells, and each of these again divides into two spermatids or young spermatozoids, so that the spermatocyte gives origin to four spermatozoids.

The process of spermatogenesis bears a close relation to that of maturation of the ovum. The spermatocyte is equivalent to the immature ovum. It undergoes subdivision, and ultimately gives origin to four spermatozoids, each of which contains, therefore, only one-fourth of the chromatin elements of the nucleus of the spermatocyte. In the process of maturation of the ovum its nucleus divides, one-half being extended as the first polar body. The remaining half of the nucleus again subdivides, one-half being extended as the second polar body. The portion of the nucleus which is retained to form the female pronucleus of the now matured ovum contains, therefore, only one-fourth of the chromatin elements of the original nucleus, and thus the spermatozoid and the matured ovum, so far as their nuclear elements are concerned, may be regarded as of the same morphological value.

The tubules are enclosed in a delicate plexus of capillary vessels, and are held together by an intertubular connective tissue, which presents large interstitial spaces lined by endothelium, which are believed to be the rootlets of lymphatic vessels of the testis.

The Aberrant Ducts of the Epididymis (ductuli aberrantes) are tortuous and end in blind extremities. The superior aberrant duct (ductus aberrans superior) is in the globus major and joins the rete testis. The inferior aberrant duct (ductus aberrans inferior) (Fig. 1096) is in the tail of the epididymis, and takes origin from the
duct of the epididymis or the seminal duct. It is a persistent canal of the Wolffian body. It extends up the cord for two or three inches and terminates by a blind extremity, which is occasionally bifurcated. It may be as much as fourteen inches in length. Its structure is similar to that of the seminal duct.

The Seminal Duct or Vas Deferens (ductus deferens) (Figs. 1089, 1090, 1091, 1096, 1097, and 1135).—The seminal duct or vas deferens, the excretory duct of the testis, is the continuation of the epididymis. Commencing at the lower part of the globus minor, it ascends along the posterior border of the testis and inner side of the epididymis, and along the back part of the spermatic cord, through the inguinal canal to the internal or deep abdominal ring. From the ring it curves around the outer side of the internal epigastric artery and vein, crosses the external iliac vessels, and descends into the pelvis at the side of the bladder; it arches backward and downward to its base, crossing over the obliterated hypogastric artery and to the inner side of the ureter. At the base of the bladder it lies between that viscus and the rectum, running along the inner border of the seminal vesicle. Behind the bladder it becomes enlarged and sacculated, forming the ampulla (ampulla ductus deferentis) (Fig. 1097), and then, becoming narrowed at the base of the prostate, unites with the duct of the seminal vesicle to form the ejaculatory duct (Fig. 1098). From the internal abdominal ring to the middle of the ampulla the seminal duct is beneath the peritoneum. The vas deferens offers a hard and cord-like sensation to the fingers; it is about two feet in length, of cylindrical form, and about a line and a quarter in diameter. Its walls are dense, measuring one-third of a line, and its canal is extremely small, measuring about half a line.

Structure.—The vas deferens consists of three coats: 1. An external or areolar coat (tunica adventitia). 2. A muscular coat (tunica muscularis), which in the greater part of the tube consists of two layers of unstriped muscular fibre: an inner layer of thin longitudinal fibres (stratum internum) existing only at the beginning, a thick layer of circular fibres (stratum medium), and a thick external layer of longitudinal fibres (stratum externum). 3. An internal or mucous coat (tunica mucosa), which is pale, and arranged in longitudinal folds; its epithelial cells are of the columnar variety.

Organ of Giraldes (paradidymis).—This term is applied to a small body of rounded shape in the lower end of the spermatic cord, in front of the blood-vessels. It consists of a small collection of minute vesicles and a small collection of convoluted tubules. These tubes are lined with columnar ciliated epithelium, and probably represents the remains of a part of the Wolffian body.

Surgical Anatomy.—Abnormalities in the descent and position of the testicle have been discussed (p. 1472). The testicle may require removal for malignant disease, tuberculous disease, cystic disease, in cases of large hernia testis, and in some instances of incompletely descended or misplaced testicles. The operation of double castration has also been, during the last few years, performed for enlargement of the prostate gland; for it has been found that removal of the testicles is followed by very rapid and often considerable diminution in the size of the prostate. The operation is, however, one of severity, and is frequently followed by death in these cases, performed, as it necessarily is, in old men. Reginald Harrison has proposed to substitute for it excision of a portion of each vas deferens (vasectomy). The operation of castration is a comparatively simple one. An incision is made into the cavity of the tunica vaginalis from the external ring to the bottom of the scrotum. The coverings are shelled off the organ, and the mesorchium, stretching between the back of the testicle and the scrotum, divided. The cord is then isolated, and an aneurism needle, armed with a double ligature, passed under it, as high as is thought necessary, and the cord tied in two places, and divided between the ligatures. Sometimes, in cases of malignant disease, it is desirable to open the inguinal canal and tie the cord as near the internal abdominal ring as possible.

A collection of serous fluid in the sac of the vaginal tunic of the testicle is known as an ordinary or testicular hydrocele. In congenital hydrocele a communication remains between the tunica vaginalis testis and the peritoneal cavity. This communication should have closed during development. In infantile hydrocele the tunica vaginalis and part of the funicular process are distended with fluid, but the funicular process is closed above and the cavity of the hydrocele
THE TESTICLES

The Semen and the Spermatozoids.—Semen consists of spermatozoids with liquids and solids. Part of the semen comes from the testicles, most of it from accessory glands—that is, from the glands of the seminal ducts, the seminal vesicles, the prostate gland, and Cowper’s glands. Semen is a viscid, whitish fluid, of alkaline reaction and characteristic odor. It contains water and about 18 per cent. of solid matter. In this solid matter are fat, cholesterin, lecithin, proteids, nuclein, xanthin, chlorides, sulphates, and phosphates of sodium and potassium. Böttcher’s crystals, which can be obtained from semen, are composed of phosphate of spermine. Spermine is a nitrogenous substance. The fluid portion of semen carries and probably nourishes the living cells known as spermatozoids.

The spermatozoids (Fig. 1097) are minute, thread-like bodies, which constitute the essential elements of the semen. Each consists of a head, a middle piece or body, and an elongated filament or tail. The head, on surface view, appears oval in shape, but if seen in profile it is narrow and pointed at its free end. It represents the modified nucleus of the spermatid, and consists chiefly of chromatin, and so stains readily with nuclear reagents; it is covered by a thin cap of protoplasm. The body is a short cylindrical or conical piece, intervening between the head and tail, and is therefore sometimes spoken of as the intermediate segment. The tail is about four times the combined lengths of the head and body; its terminal part is extremely fine, and is named the end-piece. Contained within the body and tail is an axial filament, surrounded, except in the end-piece, by a thin layer of protoplasm; this axial filament terminates just below the head in a rounded knob or button. In virtue of their tails, which act as propellers, the spermatozoids, in the fresh condition, are capable of free movement, and if placed in favorable surroundings (e. g., in the female passages) may retain their vitality for some days or even weeks.
THE SEMINAL VESICLES (VESICULAE SEMINALES) (Figs. 1098, 1099).

The seminal vesicles are two lobulated membranous pouches placed between the base of the bladder and the rectum, serving as reservoirs for the semen, and secreting a fluid to be added to the secretion of the testicles. Each sac is somewhat pyramidal in form, the broad end being directed backward and the narrow end forward toward the prostate. It measures about two and a half inches in length, about five lines in breadth, and two or three lines in thickness. They vary, however, in size, not only in different individuals, but also in the same individual on the two sides. The upper surface is in contact with the base of the bladder, extending from near the termination of the ureters to the base of the prostate gland. The under surface rests upon the rectum, from which it is separated by the recto-vesical fascia. Their posterior extremities diverge from each other. Their anterior extremities are pointed, and converge toward the base of the prostate gland, where each joins with the corresponding seminal duct to form the ejaculatory duct. Along the inner margin of each vesicle runs the enlarged and convoluted vas deferens. The inner border of the vesicle and the corresponding seminal duct form the lateral boundaries of a triangular space, limited behind by the recto-vesical peritoneal fold; the portion of the bladder included in this space rests on the rectum.

Each vesicle consists of a single tube, coiled upon itself and giving off several irregular caecal diverticula (Fig. 1098), the separate coils, as well as the diverticula, being connected together by fibrous tissue. When uncoiled this tube is about the diameter of a quill, and varies in length from four to six inches; it terminates posteriorly in a cul-de-sac; its anterior extremity becomes constricted into a narrow straight duct, the excretory duct (ductus excretorius) (Fig. 1099), which joins with the corresponding seminal duct, and forms the ejaculatory duct.
The Ejaculatory Ducts (*ductus ejaculatorii*) (Fig. 1099).—The ejaculatory ducts are two in number, one on each side. Each duct is formed by the junction of the duct of the seminal vesicle with the seminal duct. Each duct is about three-quarters of an inch in length; it commences at the base of the prostate, and runs forward and downward between the middle and lateral lobes of that gland, and along the side of the sinus pocularis, to terminate by a separate slit-like orifice close to or just within the margins of the sinus. The ducts diminish in size and also converge toward their termination.

Structure.—The seminal vesicles are composed of three coats: an *external* or areolar (*tunica adventitia*); a *middle* or muscular coat (*tunica muscularis*), which is thinner than in the seminal duct, and is arranged in two layers, an outer, longitudinal, and inner, circular; an *internal* or mucous coat (*tunica mucosa*), which is pale, of a whitish-brown color, and presents a delicate reticular structure, like that seen in the gall-bladder, but the meshes are finer. The epithelium is columnar.

The coats of the ejaculatory ducts are extremely thin. They are: an *outer fibrous layer*, which is almost entirely lost after the entrance of the duct into the prostate; a *layer of muscular fibres*, consisting of an outer thin circular and an inner longitudinal layer; and the *mucous membrane*.

Vessels and Nerves.—The *arteries* supplying the seminal vesicles are derived from the *middle and inferior vesical* and *middle haemorrhoidal*. The *veins* and *lymphatics* accompany the arteries. The lymphatics anastomose on the surface of the vesicle. The trunks from this network anastomose with the lymphatics of the bladder and prostate, and pass to the *external* and *internal iliac glands*. The *nerves* are derived from the *pelvic plexus*.

Surgical Anatomy.—The seminal vesicles are often the seat of an extension of the disease in cases of *tuberculosis* of the testicle, and should always be examined through the rectum before coming to a decision with regard to castration in this affection. The vesicles have been deliberately *extirpated* for local tuberculosis. In gonorrhoea the seminal vesicles may become acutely inflamed (*acute seminal vesiculitis*). *Chronic seminal vesiculitis* may follow the acute form or may arise insidiously during gonorrhoea.
THE FEMALE ORGANS OF GENERATION.

EXTERNAL ORGANS (PARTES GENITALES EXTERNAL MULIEBRES).

The external organs of generation in the female are: the mons Veneris, the labia majora and minora, the vestibule, the clitoris, the vaginal bulb, and the glands of Bartholin. The term vulva (pudendum muliebre), as generally applied, includes all of these parts. In examining the structures entering into the formation of the vulva we find the homologues of most of the structures which make up the male genitals.

THE LARGE LIPS OR LABIA MAJORA (LABIA MAJORA PUDENDI)

(Figs. 1101, 1102, 1103).

The labia majora are two prominent longitudinal cutaneous folds, narrow behind but fuller and larger toward the mons Veneris, and enclosing the pudendal slit (rami pudendi) or common urino-genital opening. Each labium majus (labium 94 (1480)
majus pudendi) has two surfaces, an outer, which is covered by pigmented skin with numerous sebaceous glands and strong, crisp hairs, and an inner, which is smooth and moist, and is continuous with the genito-urinary mucous tract. In the subcutaneous areolo-fatty tissue of each labium majus the round ligament of the uterus ends. The labia are joined with each other anteriorly by the mons Veneris or anterior comissure (commissura labiorum anterior). Posteriorly they appear to become lost in the neighboring integument, although sometimes connected by a slight transverse fold in front of the anus, the posterior comissure (commissura labiorum posterior) or posterior boundary of the vulvar orifice. The interval between the posterior comissure and the anus, about an inch in length, constitutes the obstetric perinaeum.

Blood-vessels, Nerves, and Lymphatics.—The arteries of the labia majora are derived from the superficial external pudic arteries and from perineal branches of the internal pudic arteries. Homologous with the scrotum, the nerve-supply is derived from branches of the ilio-inguinal, internal pudic, and perineal branches of the small sciatic. The lymphatics drain into the superficial inguinal and internal iliac lymph-nodes.

THE SMALL LIPS, NYMPHAE OR LABIA MINORA (LABIA MINORA PUDENDI) (Figs. 1101, 1102, 1103).

The labia minora, or nymphae, are two smaller, narrower longitudinal folds, with a delicate covering of modified skin, and usually hidden from view unless the labia majora are separated. They end posteriorly by gradually joining the labia
THE CLITORIS (Figs. 1102, 1103, 1105).

The clitoris is an erectile structure which is the morphologic homologue of the penis; unlike the penis, however, it is not traversed by the urethra. It is situated beneath the anterior commissure (or mons Veneris) partially hidden between the anterior extremities of the labia minora. It is composed of a body and two crura; the extremity of the body is surmounted by a small glans.

The body of the clitoris, composed of erectile tissue, is about an inch and a quarter in length, bent upon itself so that the angle opens downward. It tapers toward the glans, is enclosed by a dense fibrous coat, and is divided by an incomplete

---

**Fig. 1104.**—Female pelvic organs in situ, seen from above. (Bardeleben.)

**Fig. 1105.**—Varieties of hymen. (Testut, after Rose.)
septum corporum cavernosum into two semi-cylindrical corpora cavernosa clitoridis, homologous with the corpora cavernosa of the male. A suspensory ligament passes from the pubic symphysis to the fibrous coat of the body of the clitoris. Each corpus cavernosum diverges from its fellow to form the crus clitoridis. Each crus is attached to the pubic arch (pubis and ischium) and covered by the Ischiocavernosus muscle (m. erector clitoridis).

To each crus of the clitoris goes a branch from the internal pudic artery, which branch is known as the deep artery of the clitoris. The dorsal arteries of the clitoris (arteriae dorsalis clitoridis) from the internal pudic send branches to the glans. The nerves of the clitoris consist of the dorsal nerves of the clitoris from the internal pudic nerve and sympathetic fibres from the hypogastric plexus.

---

**Fig. 1106.**—The female external organs of generation dissected. (Spaltehola.)

The glans clitoridis is a minute mass of erectile tissue, surmounting the tapering apex of the body of the clitoris. It is covered by a very sensitive epithelium, and its erectile tissue, like that of the glans penis, is continuous with the erectile tissue of the bulbus vestibuli, the homologue of the corpus spongiosum of the male. The preputium clitoridis and the frenulum clitoridis have already been described (p. 1491) as divisions of the labia minora.

Arteries and Nerves of the Clitoris.—The body and the crura of the clitoris derive their blood-supply from the deep artery of the clitoris (arteria profunda clitoridis) from the internal pudic artery. Another branch of this artery, the dorsal artery of
the clitoris (arteria dorsalis clitoridis) supplies the glans. The nerve-supply is derived from the dorsal nerve of the clitoris, from the internal pudic, and from the hypogastric sympathetic plexus.

THE VAGINAL BULB (BULBUS VESTIBULI) (Fig. 1106).

The bulbus vestibuli may be regarded as the homologue of the bulb portions of the corpus spongiosum of the male. The principal morphological difference lies in the fact that the two halves are fused in the male, but remain separated in the female. The bulbus vestibuli consists of a mass of minute convoluted bloodvessels, of such plexiform arrangement as to be often called erectile tissue, arranged in two halves on either side of the vaginal and urethral orifices. Each half is thicker or more massive posteriorly, while anteriorly it is attenuated and joins its fellow of the opposite side to form the pars intermedia, continuous with the erectile tissue of the glans clitoridis. Each half of the bulbus vestibuli rests against the lateral wall of the vagina and lies superficial to the triangular ligament. Externally and inferiorly it is covered by the Bulbo-cavernous muscle.

Arteries and Nerves of the Bulbus Vestibuli.—The blood is supplied by the artery to the bulb (arteria bulbì vestibuli), a branch of the internal pudic artery. The nerve-supply is by branches of the hypogastric sympathetic plexus.

GLANDS OF BARTHOLIN (GLANDULA VESTIBULARIS MAJOR [BARTHOLINI]) (Fig. 1106).

On each side of the posterior part of the commencement of the vagina is a round or oblong body, of a reddish-yellow color, and of the size of a horse-bean, analogous to Cowper's gland in the male. It is called the gland of Bartholin, the gland of Duverney, the vulvo-vaginal gland or the suburethral gland. Bartholin's gland lies partly in the inferior or anterior leaf of the triangular ligament. The posterior portion of the bulbus vestibuli and the Bulbo-cavernous muscle partly cover it. Each gland opens by means of a long single duct immediately external to the hymen, in the angle or groove between it and the nympha (Fig. 1105).

INTERNAL ORGANS (PARTES GENITALES INTERNAE MULIEBRES).

The internal organs of generation are—the vagina, the uterus and its appendages, the Fallopian tubes, the ovaries and their ligaments.

THE VAGINA (Figs. 1100, 1103, 1109).

The vagina extends from the vulva to the uterus. It is situated in the cavity of the pelvis, behind the bladder and in front of the rectum. Its direction is curved upward and backward, at first in the line of the pelvic outlet, and afterward in that of the axis of the cavity of the pelvis. Its walls are ordinarily in contact, and its usual shape on transverse section is that of an H, the transverse limb being slightly curved forward or backward, whilst the lateral limbs are somewhat convex toward the median line. Its length is about two and a half inches along its anterior wall (partes anterior), and three and a half inches along its posterior wall (paries posterior). It is constricted at its commencement, and becomes dilated medially, and narrowed near its uterine extremity; it surrounds the vaginal portion of the cervix uteri, a short distance from the os, its attachment extending higher up on the posterior than on the anterior wall of the uterus (Fig. 1112).
The vaginal axis forms with the uterine axis an obtuse angle opening forward, and, as a rule, a little greater than a right angle (Fig. 1110). The fact that the attachment of the vagina to the cervix is above the external os causes the formation of a recess between the cervix and vaginal wall, known as the vaginal fornix \((fornix vaginae)\). This recess is deeper posteriorly than it is laterally or in front. The anterior portion of the fornix is called the anterior fornix (Fig. 1103). The posterior portion is called the posterior fornix (Fig. 1103). The right and left portions are called the right and left lateral fornices. The vagina opens into the uro-genital cleft, between the labia minora and back of the urethra and clitoris. It opens by the vaginal orifice \((orificium vaginae)\) (Fig. 1102). In the virgin the opening is partly closed by the hymen (p. 1492). After rupture of the hymen atrophied fragments of the torn membrane remain around the vaginal orifice, and are known as the carunculae myrtiformes \((carunculae hymenales)\).

**Relations** (Figs. 1100 and 1103).—The upper part of the anterior wall of the vagina is in relation with the base of the bladder, being separated from that viscus by lax connective tissue. Lower down the middle line of the anterior wall and closely joined to it is the urethra. The upper part of the posterior wall, near the middle line, is covered for a quarter of an inch or more with peritoneum, which forms the anterior wall of the depths of the recto-vaginal pouch of peritoneum or pouch of Douglas \((excavatio rectouterina [Douglas])\) (Fig. 1112), between the uterus and vagina and the rectum. The portion of the posterior wall below the level of the pouch of Douglas is placed close to the rectum, a layer of pelvic fascia intervening. As the vaginal orifice is neared, the rectum and vagina separate, and interposed between them is a mass of fibro-fatty tissue called the perinaeum or perineal body. Its sides are enclosed between the Levatores ani muscles. The ureter toward its termination (Fig. 1113) lies near the lateral wall of the vagina, passing at this point in a direction downward, inward, and slightly forward to reach the bladder. The vagina near its termination passes through the triangular ligament, and upon its sides are the bulbs of the vestibule, the glands of Bartholin, and the Bulbo-cavernous muscle.

**Structure.**—The vagina consists of an internal mucous lining, of a muscular coat, and between the two of a layer of erectile tissue.

**The Mucous Membrane** \((tunica mucosa)\) (Fig. 1109).—The mucous membrane is continuous above with that lining the uterus. Its inner surface presents, along the anterior and posterior walls, a longitudinal ridge or raphé, called the rugous columns of the vagina \((columna rugarum anterior et posterior)\). The anterior column extends downward as far as the external orifice of the urethra, forming the carina urethralis vaginae. Numerous transverse ridges or rugae \((rugae vaginales)\) extend outward from the raphé on either side. These rugae are divided by furrows of variable depth, giving to the mucous membrane the appearance of being studded over with conical projections or papillae; they are most numerous near the orifice of the vagina, especially in females before parturition. The epithelium covering the mucous membrane is of the squamous variety. The submucous tissue is very loose and contains numerous large veins, which by their anastomoses form a plexus, together with smooth muscular fibres from the muscular coat; it is regarded by Gussenbauer as an erectile tissue (see p. 1497). It contains a number of mucous crypts, but no true glands.

**The Muscular Coat** \((tunica muscularis)\).—The muscular coat consists of two layers: an external longitudinal, which is far the stronger, and an internal circular layer. The longitudinal fibres are continuous with the superficial muscular fibres of the uterus. The strongest fasciculi are those attached to the recto-vesical fascia on each side. The two layers are not distinctly separable from each other, but
are connected by oblique decussating fasciculi which pass from the one layer to the other. Above the triangular ligament the fibres are non-striated; in the region of the ligament they show striations. In addition to this the vagina at its lower end is surrounded by a band of striped muscular fibres, the sphincter vaginae (p. 463). External to the muscular coat is a layer of connective tissue containing a large plexus of blood-vessels.

The Erectile Tissue.—The erectile tissue consists of a layer of loose connective tissue situated between the mucous membrane and the muscular coat; embedded in it is a plexus of large veins, and numerous bundles of unstriped muscular fibres derived from the circular muscular layer. The arrangement of the veins is similar to that found in other erectile tissues.

Blood-vessels, Nerves, and Lymphatics.—The arteries of the vagina are branches of the vesico-vaginal artery; the vaginal branch of the uterine artery (p. 688), and branches of the internal pudic and middle haemorrhoidal. The veins form an abundant plexus around the wall of the vagina and pass to the internal iliac veins. The lymphatics (Fig. 1107) arise from two communicating networks, one of which is below the mucous membrane, the other in the muscular wall. There is a third network around the vaginal wall, from which the collectors arise. The trunks from the upper third of the vagina pass to the external iliac glands; those from the middle third pass to the internal iliac glands; those from the lower third terminate in the glands at the promontory of the sacrum or in the lateral sacral glands. The nerves come from the third and fourth sacral nerves and from the utero-vaginal and vesical plexuses of the sympathetic.

1 The Lymphatics. By Poirier, Cunéo, and Delamare. Translated and edited by Cecil H. Leaf.
THE WOMB OR UTERUS (Figs. 1100, 1103, 1104, 1108, 1113).

The uterus is the organ of gestation, receiving the fecundated ovum in its cavity, retaining and supporting it during the development of the foetus, and becoming the principal agent in its expulsion at the time of parturition. It is a hollow muscular organ. The non-pregnant uterus is contained in the cavity of the pelvis between the bladder and rectum (Figs. 1103 and 1104). It is rarely placed exactly in the mid-line, but inclines to one side or the other, more often to the left than to the right. The walls of the organ are extremely thick. The uterus is movable as a whole, and the body of the uterus is movable upon the neck. Its position varies with the condition of adjacent parts, especially the bladder and rectum. The cervix is more firmly fixed than the body and fundus, and hence the latter vary more in position than the former. Normally, in an erect individual, with the bladder and rectum empty, the external os is at the level of the upper surface of the pubic symphysis (Fig. 1100) and in frontal plane passing through the ischiatic spines. The long axis of the uterus is directed forward and upward (Fig. 1100), and is angled where the body and cervix join. Hence, normally, with the bladder empty, the uterus is antverted and anteflexed. When the bladder fills the anteverision and anteflexion are almost abolished. If the bladder is overdistended and the rectum is empty, the uterus is pushed strongly backward, so that its long axis corresponds to the long axis of the vagina; in other words, it is retroverted.

In the virgin state it is pear-shaped, flattened from before backward, and is retained in its position by the round and broad ligaments on each side, and projects into the upper end of the vagina below (Figs. 1108 and 1109). Its upper end, or base, is directed upward and forward; its lower end, or apex, downward and backward, in the line of the axis of the inlet of the pelvis. It therefore forms an angle with the vagina, since the direction of the vagina corresponds to the axis of the cavity and outlet of the pelvis. The non-pregnant adult uterus measures about three inches in length, two inches in breadth at its upper part, and nearly an inch in thickness, and it weighs from an ounce to an ounce and a half.

It consists of two parts (Fig. 1108): (1) An upper and larger portion, consisting of the body and fundus. This portion is flattened from before backward. (2) A lower, smaller, and cylindrical portion, the cervix.

![Diagram of the uterus](image-url)
The Fundus (fundus uteri) (Fig. 1108).—The fundus is the upper broad extremity of the uterus. If a line is drawn from the uterine opening of one Fallopian tube to the other, the portion above the line is the fundus. The fundus is directly continuous with the body.

The Body of the Uterus (corpus uteri) (Fig. 1108).—The body of the uterus is below and continuous with the fundus. In outline, when seen from in front or behind, it resembles a triangle, the base being above and the point being absent.

The anterior surface (facies vesicalis) passes on each side into the posterior surface (facies intestinalis) by the lateral border (margo lateralis).

The body gradually narrows from the fundus to the neck. Its anterior surface is so slightly rounded as to appear flattened. It is covered by peritoneum (Fig. 1108), which becomes separated from it at its union with the cervix, in order to form the utero-vesical pouch, which lies between the uterus and bladder (Fig. 1112). Its posterior surface is more rounded than the anterior, being convex transversely. It is
covered by peritoneum throughout (Fig. 1113), and separated from the rectum by some convolutions of the small intestine (Fig. 1102). The peritoneum which covers the posterior surface forms most of the anterior wall of Douglas' cul-de-sac (Figs. 866, 1112, and 1113, and p. 1258). Its lateral margins (Figs. 1108 and 1113) are concave, and each gives attachment to the Fallopian tube above, the round ligament below, and in front of this the ligament of the ovary; behind both of these structures, and from the side of the womb the broad ligament passes. The division between the body and the cervices is indicated externally by a slight constriction, and by the reflection of the peritoneum from the anterior surface of the uterus on to the bladder, and internally by a narrowing of the canal called the internal os (Fig. 1111).

**The Neck or Cervix Uteri** (Figs. 1108 and 1111).—The neck or cervix uteri is the lower constricted segment of the uterus; around its circumference is attached the upper end of the vagina (Figs. 1103, 1108, 1109, and 1112), which extends upward a greater distance behind than in front. The neck is spindle-shaped in those who have had no children, cylindrical in those who have had children.

**The Supravaginal Portion** (portio supravaginalis [cervicis]) (Figs. 1108 and 1112).—The supravaginal portion is not covered by peritoneum in front; a pad of cellular tissue is interposed between it and the bladder. Behind, the peritoneum is extended over it.

**The Vaginal Portion** (portio vaginalis [cervicis]) (Figs. 1103, 1108, 1109, and 1112).—The vaginal portion is the lower end projecting into the vagina. It is round or
elliptical, the long axis of the elliptical figure being transversely placed. On its surface is a small aperture, the external mouth of the womb, or os uteri, or external os (orificium externum uteri) (Figs. 1108, 1109, 1111, and 1112), generally circular in shape, but sometimes oval or almost linear. If a woman has borne children the opening is transverse and the margins are irregular. The margin of the opening is, in the absence of past parturition or disease, quite smooth. This aperture divides the vaginal portion of the cervix into two lips, an upper or posterior lip (labium posterius) and a lower or anterior lip (labium anterius). On each side of the cervix and upper portion of the vagina there is a space containing bloodvessels and filled with loose cellular tissue. This loose tissue passes upward between the layers of the broad ligament and is called parametrium. On each side of the cervix and three-quarters of an inch away is the terminal portion of the corresponding ureter.

**Folds and Ligaments.**—The ligaments of the uterus are eight in number. Some are simple folds of peritoneum; others contain connective tissue and muscle. The ligaments are as follows: one anterior, one posterior, two lateral or broad, two sacro-uterine—all these being formed of peritoneum—and, lastly, two round ligaments.
The **Anterior Ligament** or the **Utero-vesical Fold** or **Vesico-uterine Ligament** is reflected on to the bladder from the front of the uterus, at the junction of the cervix and body. It forms the **uterine pouch** *(excavatio vesicouterina)* (Figs. 1112 and 1113).

The **Posterior Ligament** or the **Recto-vaginal Fold** passes from the posterior wall of the uterus over the upper fourth of the vagina, and thence on to the rectum and sacrum. It thus forms a pouch, called the **recto-vaginal pouch** or **Douglas' pouch** (Figs. 866, 1112, and 1113), the boundaries of which are, in front, the posterior wall of the uterus, the supravaginal portion of the cervix, and the upper fourth of the vagina; behind, the rectum and sacrum; above, the small intestine; and, laterally, the folds of Douglas or recto-uterine folds, which contain the sacro-uterine ligaments.

The **Lateral or Broad Ligament** *(ligamentum latum uteri)* (Figs. 1104, 1114, and 1121) is a peritoneal fold which passes from each side of the uterus to the lateral wall of the pelvis as high as the external iliac vein. From this region comes the peritoneal fold called the **suspensory ligament of the ovary** (Fig. 1114). The two broad ligaments form a septum across the pelvis, which divides that cavity into two portions. In the anterior part are contained the bladder, urethra, and vagina; in the posterior part, the rectum. In the uterus normally placed the anterior surface of the broad ligament faces forward and downward, and the posterior surface faces upward and backward. The ligament is more nearly vertical at its pelvic insertion. The two layers of the broad ligament are mostly near to each other, to the side and below they separate and pass into the peritoneum of the lateral pelvic wall, the bladder and the rectum. Between the two layers of each broad ligament are contained—(1) the Fallopian tube superiorly; (2) the round ligament; (3) the ovary and its ligament; (4) the parovarium or organ of Rosenmüller, and the paro-ophoron; (5) loose connective tissue, which is called **parametrium**; (6) unstriped muscular fibre; and (7) blood-vessels and nerves. The Fallopian tube is in the free edge of the broad ligament, and is contained in a special fold, which is attached to the part of the ligament near the ovary, and is known by the name of the **mesosalpinx** (Figs. 1110, 1114, and 1121). If the mesosalpinx is spread out, it is seen to be roughly triangular; the base of the triangle is outward, the apex at the upper and outer angle of the uterus; the upper boundary is the Fallopian tube, and the lower boundary is the ovary and its ligament. Between the two layers of the mesosalpinx are the parovarium and the paro-ophoron. Between the fimbriated extremity of the tube and the lower attachment of the broad ligament is a concave rounded margin, called the **infundibulo-pelvic ligament** (Fig. 1120).
The ovary lies in a depression of the broad ligament called the ovarian bursa (bursa ovarii) (Figs. 1114 and 1121), and is joined to the ligament by a short fold, the mesovarium (Fig. 1121).

The mesovarium passes upward from the posterior surface of the broad ligament (Fig. 1114). Beneath the mesovarium is a larger and thicker portion of the broad ligament, called the mesometrium (Fig. 1114).

The Sacro-uterine or Utero-sacral Ligaments (plicae rectouterinae) are contained in the peritoneal folds of Douglas. They pass from the second and third bones of the sacrum, downward and forward on the lateral aspects of the rectum to be attached one on each side of the uterus at the junction of the supravaginal cervix and the body, this point corresponding internally to the position of the os internum. They contain fibrous tissue and unstriated muscle-fibre. Muscular fibres from the uterine wall to the rectal wall constitute the Recto-uterinus muscle (musculus rectouterinus). This muscle is part of the sacro-uterine ligaments.

A Round Ligament (ligamentum teres uteri) (Figs. 1104, 1113, 1116, and 1121) is attached on each side of the uterus. The two ligaments are rounded cords between four and five inches in length, each situated between the layers of the broad ligament in front of and below the Fallopian tube. Commencing at the superior angle of the uterus, this ligament passes forward, upward, and outward through the internal abdominal ring, along the inguinal canal, to the labium majus, in which it becomes lost. The round ligament consists principally of muscular tissue prolonged from the uterus; also of some fibrous and areolar tissue, besides blood-vessels and nerves, enclosed in a duplication of peritoneum, which in the foetus is prolonged in the form of a tubular process for a short distance into the inguinal canal. This process is called the canal of Nuck. It is generally obliterated in the adult, but sometimes remains pervious even in advanced life. It is analogous to the peritoneal pouch which precedes the descent of the testis.

The Cavity of the Uterus (cavum uteri) (Fig. 1111).—The cavity of the uterus is small in comparison with the size of the organ, because of the great thickness of the wall. That portion of the cavity which corresponds to the body is triangular, flattened from before backward, so that its anterior and posterior walls are closely approximated, and having its base directed upward toward the fundus. At each superior angle is a funnel-shaped cavity, which constitutes the remains of one division of the body of the uterus into two cornua, and at the bottom of each cavity is the minute orifice of the Fallopian tube. At the inferior angle of the uterine cavity is a small constricted opening, smaller and more nearly circular than the external os uteri, the internal orifice of the uterus or internal os uteri (orificium internum uteri) (Fig. 1111), which leads into the cavity of the cervix.

The Cavity of the Cervix or Cervical Canal (canalis cervicis uteri) (Fig. 1111).
—The cavity of the cervix or cervical canal extends from the internal os uteri to the external os uteri. It is somewhat fusiform, flattened from before backward, broader at the middle than at either extremity, and communicates below with the vagina. The wall of the canal presents, anteriorly and posteriorly, a longitudinal column, from which proceed a number of small oblique columns, giving the appearance of branches from the stem of a tree; and hence the name uterine arbor vitae (plicae palmatae) applied to it. These folds usually become very indistinct after the first labor.

Structure.—The uterus is composed of three coats: an external or serous coat, a middle or muscular coat, and an internal or mucous coat.

The Serous Coat or Perimetrium (tunica serosa) (Figs. 1103, 1108, 1112, and 1113).—The serous coat is derived from the peritoneum; it invests the fundus and the whole of the posterior surface of the uterus; but covers the anterior surface only as far as the junction of the body and cervix. In the lower fourth of the posterior surface the peritoneum, though covering the uterus, is not closely connected with
it, being separated from it by a layer of loose cellular tissue and some large veins. At the lateral margins of the uterus the serous coat passes on to the broad ligaments. The serous coat adheres closely to the uterus, and it is very difficult to separate it from the muscle.

The Muscular Coat (tunica muscularis) (Fig. 1111).—The muscular coat forms the chief bulk of the substance of the uterus. In the unimpregnated state it is dense, firm, of a grayish color, and cuts almost like cartilage. It is thick opposite the middle of the body and fundus, and thin at the orifices of the Fallopian tubes. It consists of bundles of unstripped muscular fibres, disposed in layers, intermixed with areolar tissue, blood-vessels, lymphatic vessels, and nerves. The muscular tissue is disposed in three layers—external, middle, and internal.

The external layer is placed beneath the peritoneum, disposed as a thin plane on the anterior and posterior surfaces. It consists of fibres which pass transversely across the fundus, and, converging at each superior angle of the uterus, are continued on the Fallopian tube, the round ligament, the ligament of the ovary; some passing at each side into the broad ligament, and others running backward from the cervix into the sacro-uterine ligaments. The fibres of the external portion of the outer layer (stratum subserosum) are longitudinal. The fibres of the inner portion of the outer layer (stratum supravascularare) are partly circular and partly longitudinal.

The middle layer of fibres (stratum vascularare), which is thickest, presents bundles of circular fibres closely connected with blood-vessels. In this layer are most of the blood-vessels. The circular fibres about the internal os form a distinct sphincter. Those which surround the orifices of the Fallopian tubes are arranged in the form of two hollow cones, the apices of which surround the orifices of the Fallopian tubes, their bases intermingling with one another on the middle of the body of the uterus.

The internal or deep layer (stratum mucosum) consists of longitudinal fibres. Some consider the deeper portion of the muscular tissue of the uterus to be the muscularis mucosas. But the deep portion of the muscular substance is continuous with the more superficial portion, and there is no submucous coat between the muscle and the mucous membrane. The deeper layer of muscular fibres of the uterus contains connective tissue and elastic fibres. The muscular tissue of the cervix contains more connective and elastic tissue than does the body of the uterus; hence, the cervix is harder and stiffer than the body.

The Mucous Membrane (tunica mucosa) (Fig. 1111).—The mucous membrane is thin, smooth, and closely adherent to the subjacent muscular tissue. It is continuous, through the fimbriated extremity of the Fallopian tubes, with the peritoneum, and through the os uteri with the lining of the vagina.

In the body of the uterus it is smooth, soft, of a pale-red color lined with columnar ciliated epithelium, and presents, when viewed with a lens, the orifices of numerous tubular follicles arranged perpendicularly to the surface. It is unprovided with any submucosa, but is intimately connected with the innermost layer of the muscular coat. In structure its corium differs from ordinary mucous membrane, consisting of an embryonic nucleated and highly cellular form of connective tissue, in which run numerous large lymphatics. In it are the tube-like uterine glands (glandulæ uterinae), which are of small size in the unimpregnated uterus, but shortly after impregnation become enlarged and elongated, presenting a contorted or waved appearance toward their closed extremities, which reach into the muscularis, and may be single or bifid. The uterine glands consist of a delicate membrane, lined with epithelium, which becomes ciliated toward the orifices.

In the cervix the mucous membrane is sharply differentiated from that of the uterine cavity. It is thrown into numerous oblique ridges, which diverge from an anterior and posterior longitudinal raphé, presenting an appearance which has
received the name of arbor vitae. In the upper two-thirds of the canal the mucous membrane is provided with numerous deep glandular follicles (glandulae cervicales uteri), which secrete a clear viscid alkaline mucus; and in addition, extending through the whole length of the canal, are a variable number of little cysts, presumably follicles, which have become occluded and distended with retained secretion. They are called the ovules of Naboth. The mucous membrane covering the lower half of the cervical canal presents numerous papillae. The epithelium of the upper two-thirds is cylindrical and ciliated, but below this it loses its cilia, and gradually changes to squamous epithelium close to the external os.

The Uterus at Different Ages.—The uterus of the foetus is in the abdominal cavity projecting above the brim of the pelvis. The cervix is considerably larger than the body. At birth the cervix is larger relatively than in the adult; there is no distinct internal os distinguishing the cavity of the body of the uterus from the cavity of the cervix, and “the arbor vitae extends throughout the whole length of the uterus.”

The growth of the uterus is slow until puberty is almost reached, when for a time the growth is rapid. The growth of the uterine body causes the mucous membrane of this part to lose its folds, hence the arbor vitae disappears from the body. In a woman who has had children the uterine cavity is larger than in a woman who has never borne a child. In advanced years the uterine wall becomes paler and hard and rigid from atrophic fibrous changes. A more distinct constriction separates the body and cervix. The internal os frequently and the external os occasionally are obliterated in old age.

Abnormalities.—Very rarely the uterine cavity is divided into two by a septum. Occasionally the condition known as bicornate uterus exists. In this condition each lateral angle is prolonged into a horn or cornu. The uterus is formed by the union of the two ducts of Müller, and failure of fusion of these ducts makes a double uterus or a bicornate uterus.

Changes at a Menstrual Period.—For several days before the menstrual flow begins the mucous membrane increases in thickness and vascularity and its surface is cast into folds. After these preparatory changes the superficial portions of the mucous membrane break down and are cast off, and bleeding begins. At the termination of menstruation the mucous membrane rapidly regenerates. At each menstrual period from 100 to 200 grammes of blood are discharged. The meaning of menstruation is uncertain. Pflüger believes the wall of the uterus is made raw, so that if an impregnated ovum arrives it will adhere. Reichert believes that menstruation means that no impregnated ovum has arrived in the womb, and hence no bed is needed for one.

Changes Induced by Pregnancy.—The muscular fibres hypertrophy enormously and become vastly longer and broader. There is a great increase in connective tissue, and new connective-tissue fibres pass between bundles of muscle. The peritoneal coat undergoes hyperplasia. It remains closely adherent to the uterus, except over the lower segment, from which region it can be easily stripped. The blood-vessels become large and tortuous. The nerves are increased in length and new filaments form. The lymphatics undergo hypertrophy and hyperplasia (Prof. Barton Cooke Hirst). The uterus becomes spherical, and after the fourth month ovoidal. Early in pregnancy the increase in weight causes the uterus to descend in the pelvis. After the third month it rises progressively, and during the ninth month the fundus reaches the epigastrium. “Before term (four weeks in primiparae, ten days or one week in multiparae) the fundus sinks again, as the presenting part and lower uterine segment become engaged in the pelvic cavity. This phenomenon is explained by contraction of the overstretched abdominal walls.”

The womb is acutely anteflexed during the first three months.
of pregnancy. After this period, as the womb rises, the anteflexion is diminished, but some degree remains, because the abdominal walls are too lax to hold the organ straight. The uterus passes somewhat to the right side and undergoes a rotation on its longitudinal axis, so that the anterior surface looks front and to the right. These changes in position are caused by fecal distention of the sigmoid. The intestines are above and back of the uterus. During the first four months the cervix softens and enlarges somewhat. The length of the cervical canal is not altered during pregnancy, and the canal does not dilate until labor begins. During pregnancy the cervical glands secrete thick mucus, which coagulates and occludes the cervical canal; the round ligaments become stronger, and the layers of the broad ligament are separated toward their inner portions by the enlarging womb.
After parturition the uterus nearly regains its former size, usually weighing something over one and a half ounces; but its cavity is larger than in the virgin state, the external orifice is more marked, its edges present a fissured surface, its vessels are very tortuous, and its muscular layers are more defined.

Vessels and Nerves (Fig. 1116).—The arteries of the uterus are the uterine, from the internal iliac, and the ovarian, from the aorta. They are remarkable for their tortuous course in the substance of the organ and for their frequent anastomoses. The uterine artery reaches the lower part of the uterus at the side and is, pro-

![Diagram of the uterus and its vessels](image)

Fig. 1118.—The lymphatics of the internal organs of generation in the female. (Poirier and Charpy.)

longed as a large artery to the body and fundus, which ascends between the layers of the broad ligament. The uterine artery gives off a smaller branch, the cervical, which descends to supply the cervix and sends cervico-vaginal branches to the vagina. The azygos arteries of the vagina come from the cervico-vaginal reinforced by branches of the vaginal arteries (Fig. 1121). A median longitudinal vessel is formed in front and behind, which descends in the vaginal wall. The termination of the ovarian artery meets the termination of the uterine artery, and forms an anastomotic trunk from which branches are given off to supply the uterus. Dr. Robinson, instead of describing the uterine and ovarian
arteries as two vessels, describes them as parts of one vessel, the *arteria uterina ovarica* (p. 689). The *veins* are of large size, and correspond with the arteries. In the impregnated uterus these vessels form the *uterine sinuses*, consisting of the lining membrane of the veins adhering to the walls of the canals channelled through the substance of the uterus. They terminate in the *uterine plexuses*, which empty into the *internal iliac veins*. The *lymphatics* (Figs. 1117 and 1118) originate from three networks, a muscular network, a peritoneal network, and a network in the stroma. The trunks from these networks Anastomose, and thus form another network beneath the peritoneum, and from the fourth network the collectors arise. The network of the cervix is continuous with that of the body. The collecting trunks from the cervical region number from five to eight. Some terminate in the *external iliac glands*, some in the *internal iliac glands*, some in the *lateral sacral glands*, or the glands of the promontory. The collecting trunks from the body terminate chiefly in the *juxta-aortic* or *pre-aortic glands*, but some terminate in the *external iliac glands*, and some in the *inguinal glands*. The *nerves* come chiefly from the *utero-vaginal plexus*, which continues into the *hypogastric plexus* and receives filaments from the *third* and *fourth sacral nerves*. The uterus also receives direct fibres from the *hypogastric plexus* and from the *vesical plexus*.

![Fig. 1119.—Relations between uterus, ureter, and uterine artery. (Schematic.)](image)

**Surgical Anatomy.** *Pelvic cellulitis* (*parametritis*) is inflammation of the pelvic cellular tissue. It is due to sepsis, and its usual antecedent is uterine sepsis. A laceration of the cervix may admit bacteria. An abscess may form. If it points in the vagina it should be incised through the vaginal wall. The uterus may require removal (*hysterectomy*) in cases of *malignant disease* or for *fibroid tumors*. *Carcinoma* is the most common form of malignant disease of the uterus, though *cases of sarcoma* do occur. Carcinoma may show itself either as a columnar carcinoma or as a squamous carcinoma; the former commencing either in the cervix or body of the uterus, the latter always commencing in the epithelial cells of the mucous membrane covering of the vaginal surface of the cervix. The columnar form may be treated in the early stage, before fixation has taken place, by removal of the uterus, either through the vagina or by means of abdominal section. The former operation is attended by the smaller death-rate. Vaginal hysterectomy may be performed in any case in which the uterus or the uterus and tumor are not too large to be withdrawn through the vagina. It is difficult in this operation to deal with adhesions and other complications in the upper part of the pelvis, and for this reason many surgeons prefer the abdominal operation. *Vaginal hysterectomy* is performed by placing the patient in the lithotomy position and introducing a large duckbill speculum into the vagina. The cervix is then seized with a vulsellum and pulled down as far as possible and the mucous membrane of the vagina incised around the cervix as near to it as the disease will allow, especially in front, where the ureters are in danger of being wounded. A pair of dressing forceps are then pushed through into Douglas's

pouch and opened sufficiently to allow of the introduction of the two forefingers, by means of which the opening is dilated laterally as far as the sacro-uterine ligaments. A somewhat similar proceeding is adopted in front, but here the bladder has to be separated from the anterior wall of the uterus for about an inch before the vesico-uterine fold of peritoneum can be reached. This is done by carefully burrowing upward with a director and stripping the tissues off the anterior uterine wall. When the vesico-uterine pouch has been opened and the opening dilated laterally, the uterus remains attached only by the broad ligaments, in which are contained the vessels that supply the uterus. Before division of the ligaments, these vessels have to be dealt with. The forefinger of the left hand is introduced into Douglas's pouch and an aneurism needle, armed with a long silk ligature, is inserted into the vesico-uterine pouch, and is pushed through the broad ligament of one side about an inch above its lower level and at some distance from the uterus. One end of the ligature is now pulled through the anterior opening, and in this way we have the lowest inch of the broad ligament, in which is contained the uterine artery, enclosed in a ligature. This is tied tightly, and the operation is repeated on the other side. The broad ligament is then divided on either side, between the ligature and the uterus, to the extent to which it has been constricted. By traction on the volsellum which grasps the cervix, the uterus can be pulled considerably farther down in the vagina, and a second inch of the broad ligament is treated in a similar way. This second ligature will embrace the pampiniform plexus of veins and, when the broad ligament has been divided on either side, it will be found that a third ligature can be made to pass over the Fallopian tube and top of the broad ligament, after the uterus has been dragged down as far as possible. After the third ligature has been tied and the structures between it and the uterus divided, this organ will be freed from all its connections and can be removed from the vagina. This canal is then sponged out and lightly dressed with gauze, no sutures being used. The gauze may be removed at the end of the second day. In squamous epitheliam, amputation of the cervix is done by some in those cases where the disease is recognized before it has invaded the walls of the vagina or the neighboring broad ligaments. The operation consists in removing a wedge-shaped piece of the uterus, including the cervix, through the vagina and attaching the cut surfaces of the stump to the anterior and posterior vaginal walls, so as to prevent retraction. In view, however, of the continuity of the lymphatic network of the cervix with the lymphatics of the body, the operation is insufficient and should be condemned. Complete abdominal hysterectomy is rarely necessary, except for malignant disease. In this operation the entire uterus is removed. The preliminary introduction of bougies into the ureters as practised by Kelly and Clark enables the surgeon to readily recognize the situations of these tubes. After the abdomen has been opened the uterine vessels are secured and the broad ligaments divided in a similar manner to that employed in vaginal hysterectomy, except that the proceeding is commenced from above. When the first two ligatures have been tied and the broad ligament divided, it will be found that the uterus can be raised out of the pelvis. A transverse incision is now made through the peritoneum, where it is reflected from the anterior surface of the uterus on to the back of the bladder and the serous membrane peeled from the surface of the uterus until the vagina is reached. The anterior wall of this canal is cut across. The uterus is now turned forward and the peritoneum at the bottom of Douglas's pouch incised transversely, and the posterior wall of the vagina cut across until it meets the incision on the anterior wall. The uterus is now almost free, and is held only by the lower part of the broad ligament on either side, containing the uterine artery. A third ligature is made to encircle this, and, after having been tied, the structures are divided between the ligature and the uterus. The organ can now be removed. The vagina is plugged with gauze, and the external wound closed in the usual way. The vagina acts as a drain, and therefore the opening into it is usually left unsutured. In some cases of uterine fibroid the abdomen is opened and the tumor is removed, but the uterus is not taken away. This operation is called myomectomy. This operation is suited only to solitary subperitoneal or interstitial tumors (Penrose).

The common operation for uterine fibroids is supravaginal amputation. The uterus is cut away and the cervical flaps are sutured. Before the technique of hysterectomy was perfected and before myomectomy was devised the favorite operation for uterine fibroids was salpingo-oophorectomy, and by it a large majority of cases operated upon were cured. When it succeeds a premature menopause is induced and the tumor shrinks. The operation is useless if a woman is past the menopause, and is apt to fail if the tumor is very soft or very large.

THE ADNEXA OR APPENDAGES OF THE UTERUS.

The appendages of the uterus are the Fallopian tubes, the ovaries and ovarian ligaments, and the round ligaments. They are placed in the following order: in front is the round ligament; the Fallopian tube occupies the upper margin of the broad ligament; the ovary and its ligament are behind and below both.
THE FALLOPIAN TUBE (TUBA UTERINA [FALLOPII])
(Figs. 1108, 1113, 1114, 1120, 1121).

The Fallopian tubes or oviducts convey the ova from the ovaries to the cavity of the uterus. They are two in number, one on each side, situated in the upper margin of the broad ligament, extending from each superior angle of the uterus to the sides of the pelvis. Each tube is about four inches and a quarter in length, and is placed in a fold of peritoneum, which is part of the broad ligament and is called the mesosalpinx (Fig. 1114). Each tube is described as consisting of four portions: (1) the isthmus (isthmus tubae uterinae) (Fig. 1120), or inner constricted third; (2) the ampulla (ampulla tubae uterinae) (Fig. 1120), or outer dilated portion, which curves over the ovary; and (3) the infundibulum (infundibulum tubae uterinae), the funnel-like expansion of the tube, at the bottom of which is the abdominal orifice or pavilion (ostium abdominale tubae uterinae) (Fig. 1120). The abdominal orifice has a small diameter (2 mm. when relaxed to its full extent). The margin of the infundibulum is rendered irregular by the presence of numerous small processes, the fimbriae (fimbriae tubae). This end of the tube is called the fimbriated extremity (Fig. 1120), because of these processes. The surfaces of the fimbriae looking into the cavity of the infundibulum are covered with mucous membrane continuous with the tubal mucous membrane. The outer surfaces are covered with peritoneum. One of the fimbriae is attached to the ovary and is called the ovarian fimbria (fimbria ovarica) (Fig. 1120). (4) The uterine portion of the tube (pars uterina) (Fig. 1111) is in the uterine wall. The opening into the uterus (ostium uterinum tubae) is even smaller than the abdominal opening, and will admit only a small bristle. The general direction of the Fallopian tube is outward, backward, and downward. In connection with the fimbriae of the Fallopian tube or with the broad ligament close to them there is frequently one or more small vesicles floating on a long stalk of peritoneum. These are termed the hydatids of Morgagni (appendices vesiculosi). They are representative of small portions of the upper extremity of the Wolffian duct.

Course Pursued by the Fallopian Tube (Figs. 1104 and 1120).—The tube on each side begins at the upper and outer angle of the uterus and passes outward in a horizontal direction toward the uterine extremity of the ovary. It then bends almost to a right angle and ascends close to the pelvic wall and in front of the anterior margin to the tubal extremity of the ovary. At this point it turns sharply downward and a little backward, and the inner surface of the infundibulum comes to lie upon the free margin and the posterior portion of the inner surface of the ovary. “The fimbria ovarica thus ascends in a recurrent direction to the extrem- itas tubaria.”

Structure.—The Fallopian tube consists of three coats—serous, muscular, and mucous.

The external or serous coat (tunica serosa) (Fig. 1115) is peritoneal. Beneath this lies the tunica adventitia, composed of lax connective tissue.

The middle or muscular coat (tunica muscularis) consists of an external longitudinal layer (stratum longitudinal), and an internal circular layer (stratum circulare) of muscular fibres continuous with those of the uterus.

The internal or mucous coat (tunica mucosa) is continuous with the mucous lining of the uterus and, at the free extremity of the tube, with the peritoneum. It is thrown into longitudinal folds (plicae tubariae), which in the outer, larger part of the tube or ampulla (plicae ampullares) are much more extensive than in the narrow canal of the isthmus (plicae isthmicae). The lining epithelium is columnar and ciliated. This form of epithelium is also found on the inner surface of the tube.

fimbriae, while on the outer or serous surfaces, of these processes the epithelium gradually merges into the endothelium of the peritoneum.

**Vessels and Nerves.**—The chief artery of the tube is the tubal branch of the uterine artery (ramus tubarius) (Fig. 1116). It also receives branches from the ovarian (Fig. 1116). Some of the tubal veins empty into the uterine veins, some into the ovarian veins. The lymphatics (Figs. 1117 and 1118) coming from the tube unite with the trunks coming from the uterus and ovary and terminate in the juxta-aortic glands. The nerves come from the same plexuses that send branches to the uterus and ovary.

**The Epo-ophoron, Parovarium or Organ of Rosenmüller** (Figs. 1110, 1111, and 1120) is placed in the mesosalpinx, between the ovary and tube. It consists of a number of epithelial-lined closed tubes. This structure can be readily seen if the mesosalpinx is stretched and held in front of the light. One of these tubes runs parallel to the Fallopian tube and is called Gärtners duct (ductus epoophori longitudinalis). A number of tubes (ductuli transversi) ascend from near the ovary and
each empties into Gärtners's duct at a right angle. Gärtners's duct is a portion of the Wolffian duct, which has persisted and is represented in the male by the canal of the epididymis. The tubules which join the duct "are derived from the mesonephros and represent the vasa efferentia and coni vasculosi of the testis, and probably also the ductuli aberrantes of the canal of the epididymis." (Cunningham.)

The Paro-ophoron is within the mesosalpinx, but is nearer to the uterus than is the epo-ophoron. It consists of several small tubules, which can be seen in an adult only by the aid of a pocket lens. They are visible to the naked eye in a child at birth. It represents the organ of Giraldes in the male and is derived from the mesonephros.

THE OVARY (OVARIA) (Figs. 1104, 1108, 1110, 1111, 1113, 1114, 1115, 1120, 1121).

The ovaries, the testes muliebres of Galen, are two in number and are analogous to the testes in the male. They are oval-shaped bodies of an elongated form, flattened from above downward, situated one on each side of the uterus, in the posterior layer of the broad ligament behind and below the Fallopian tube. Each ovary is connected by its anterior straight margin to the broad ligament; by its lower extremity to the uterus by a proper ligament, the ligament of the ovary (ligamentum ovarii proprium) (Fig. 1120); and by its upper end to the fimbriated extremity of the Fallopian tube by the ovarian fimbria (fimbria ovarica) (Fig. 1120), its mesal and lateral surfaces and posterior convex border are free (Fig. 1121). The ovaries are of a grayish-pink color, and present either a smooth or a puckered, uneven surface. They are each about an inch and a half in length, three-quarters of an inch in width, and about a third of an inch thick, and weigh from one to two drachms.

The exact position of the ovary has been the subject of considerable difference of opinion, and writers are in conflict as to what is to be regarded as the normal position. The fact appears to be that the ovary is differently placed in different individuals. The two ovaries are seldom placed in absolutely identical positions. Hasse has described the ovary as being situated with its long axis transverse, or almost transverse, to the pelvic cavity. Schultze, on the other hand, believes that its long axis is antero-posterior. Kölliker asserts that the truth lies between these views, and that the ovary is placed obliquely in the pelvis, its long axis lying parallel to the external iliac vessels, with its surface directed inward and outward, and its convex free border upward. His has made some important observations on this subject, and his views are largely accepted. He teaches that the uterus rarely lies symmetrically in the middle of the pelvic cavity, but is generally inclined to one or other side, most frequently to the left, in the proportion of three to two. The position of the two ovaries varies according to the inclination of the uterus. When the uterus is inclined to the left, the ovary of this side lies with its long axis vertical and with one side closely applied to the outer wall of the pelvis, while the ovary of the opposite side, being dragged upon by the inclination of the uterus, lies obliquely, its outer extremity being retained in close apposition to the side of the pelvis by the infundibulo-pelvic ligament. When, on the other hand, the uterus is inclined to the right, the position of the two ovaries is exactly reversed, the right being vertical and the left oblique. In whichever position the ovary is placed, the Fallopian tube forms a loop around it, the uterine half ascending obliquely over it, and the outer half, including the dilated extremity, descending and bulging freely behind it. From this extremity the fimbriae pass upward on to the ovary and closely embrace it.

Waldeyer1 states, as the result of the examination of fifty female subjects,

ranging from early childhood to advanced age, that the ovary "lies on the lateral pelvic wall and vertically when the woman takes the erect posture." Its tubal extremity is near the external iliac vein; its uterine end is directed downward, while the Fallopian tube overlies it so as to cover it on its medial face entirely or nearly so. Its convex margin looks downward and backward toward the pelvic cavity and rectum, while its straight margin or hilum lies laterally on the pelvic wall attached to the mesosalpinx. He also finds that it lies in a distinct but shallow groove (fossa ovarii) limited above by the hypogastric artery and below by the ureter, in such a manner that the ureter lies along the convex margin of the ovary, and the hypogastric artery passes near the hilum or straight margin.

The ovary possesses two poles or extremities: (1) An outer, superior or tubal extremity (extremitas tubaria ovarii). (2) An inner, inferior or uterine extremity (extremitas uterina ovarii). The ovary has two surfaces, an inner surface (facies medialis), which is also upper; an outer surface (facies lateralis), which is also lower. The posterior or free border (margo liber) is markedly convex. The anterior border (margo mesovaricus) is almost straight and is narrow. The anterior border is not free, but is joined to the posterior layer of the broad ligament by a peritoneal fold known as the mesovarium. There is a groove in the anterior border called the hilum (hilus ovarii), through which vessels and nerves to pass, and emerge from the ovary.

Supports and Connections of the Ovary.

From its upper extremity a peritoneal fold is continuous with the peritoneum over the iliac vessels and Psoas muscle. It is called the ovario-pelvic fold or the suspensory ligament (ligamentum suspensorium ovarii) (Fig. 1104). It is in reality a portion of the broad ligament, and within it are the ovarian vessels and nerves. The vessels (Fig. 1121) and nerves go to the anterior border of the ovary and are surrounded by a peritoneal sheath derived from the posterior layer of the broad ligament; it is thus evident that the anterior border of the ovary is connected to the posterior portion of the broad ligament by a very short mesentery, the mesovarium1 (Fig. 1114). The ligament of the ovary or ovarian ligament (Figs. 1104 and 1120) is a round, cord-like structure, composed chiefly of non-striated muscle-fibres, which passes between the two folds of the broad ligament from the lower extremity of the ovary to the lateral angle of the uterus. The ovarian fimbria (Fig. 1120), as previously stated, passes to the upper extremity of the ovary from the extremity of the Fallopian tube.

The Descent of the Ovary.

In the female there is a gubernaculum which affects a considerable change in the position of the ovary, though not so extensive a change as is effected upon the male testicle. The gubernaculum in the female, as it lies on either side in contact with the fundus of the uterus formed by the union of the Müllerian ducts, contracts adhesions to this organ and thus the ovary is prevented from descending below this level. The remains of the gubernaculum—that is to say, the part between the attachment of the cord to the uterus to its termination in the labium majus—ultimately forms the round ligament of the uterus. A pouch of peritoneum accompanies it along the inguinal canal, analogous to the funicular process in the male; it is called the canal of Nuck. In rare cases the gubernaculum fails to contract adhesions to the uterus, and then the ovary descends through the inguinal canal into the labium majus, extending down the canal of Nuck. Under these conditions, the position of the ovary resembles the position of the testicle in the male.

The Ovary at Different Ages.—The ovary of childhood is smooth and even. The rupture of Graafian follicles, repeated many times, causes the surface

---

1 Prof. Cunningham's Text-book of Anatomy.
THE FEMALE ORGANS OF GENERATION

of the ovary to become pitted, puckered, fibrous, and uneven in old age. The surface of the ovary is grayish-red in color. The corpus luteum of a non-pregnant woman slowly degenerates and disappears. The corpus luteum of an impregnated woman enlarges during pregnancy.

**Structure** (Figs. 1114, 1115, 1122, and 1123).—The ovary consists of a number of Graafian follicles or vesicles embedded in the meshes of a stroma or framework, and invested by a serous covering derived from the peritoneum.

**Serous Covering.**—Though the investing membrane of the ovary is continuous with the peritoneum near the hilum of the ovary (the point of junction being indicated by a narrow white line), it differs essentially from the peritoneum, inasmuch as it is an epithelial structure and consists of a single layer of columnar epithelial cells, instead of the flattened endothelial cells of other parts of the membrane; this has been termed the **germinal epithelium of Waldeyer**, and gives to the surface of the ovary a dull-gray aspect instead of the shining smoothness of serous membranes generally.

**Stroma.**—The stroma is a peculiar soft tissue, abundantly supplied with blood-vessels, consisting for the most part of spindle-shaped cells, with a small amount of ordinary connective tissue. These cells have been regarded by some anatomists as unstriped muscle-cells, which, indeed, they most resemble (His); by others as connective-tissue cells (Waldeyer, Henle, and Kölliker). On the surface of the organ this tissue is much condensed, and forms a layer composed of short connective-tissue fibres, with fusiform cells between them. This was formerly regarded as a distinct fibrous covering, and was termed the **tunica albuginea**, but is nothing more than a condensed layer of the stroma of the ovary.

**Graafian Follicles or Vesicles** (folliculi oophori vesiculor [Graafi]) (Figs. 1122 and 1123).—Upon making a section of an ovary numerous round transparent vesicles of various sizes are to be seen; they are the **Graafian vesicles or ovisacs** containing the ova. Immediately beneath the superficial covering is a layer of stroma, in which are a large number of minute vesicles of uniform size, about \( \frac{1}{16} \) of an inch in diameter. These are the Graafian vesicles in their earliest condition, and the layer where they are found has been termed the **cortical layer**. They are especially numerous in the ovary of the young child. After puberty and during the whole of the child-bearing period large and mature, or almost mature, Graafian vesicles are also found in the cortical layer in small numbers, and also **corpora lutea**, the remains of vesicles which have burst and are undergoing atrophy and absorption. Beneath this superficial stratum other large and mature Graafian vesicles are found embedded in the ovarian stroma. These increase in size as they recede from the surface toward a highly vascular stroma in the centre of the organ, termed the **medullary substance** (zona vasculosa [Waldeyeri]). This stroma forms

![Diagram](image-url)
the tissue of the hilum by which the ovary is attached, and through which the blood-vessels enter; it does not contain any Graafian vesicles.

The larger Graafian follicles consist of an external fibro-vascular coat connected with the surrounding stroma of the ovary by a network of blood-vessels; and an internal coat, named the ovicapsule, which is lined by a layer of nucleated cells, called the membrana granulosa. The fluid contained in the interior of the vesicles is transparent and albuminous, and in it is suspended the ovum. In that part of the mature Graafian vesicle which is nearest the surface of the ovary the cells of the membrana granulosa are collected into a mass which projects into the cavity of the vesicle. This is termed the discus proligerus, and in this the ovum is embedded.

The ova are formed from the germinal epithelium on the surface of the ovary. This becomes thickened, and in it are seen some cells which are larger and more rounded than the rest; these are termed the primordial ova. The germinal epithelium grows downward in the form of tubes or columns, termed the egg tubes of Pflüger, into the ovarian stroma, which grows outward between the tubes, and ultimately cuts them off from the germinal epithelium. These tubes are further subdivided into rounded nests or groups, each containing a primordial ovum which undergoes further development and growth, while the surrounding cells of the nest form the epithelium of the Graafian follicle.

The development and maturation of the Graafian vesicles and ova continue uninterruptedly from puberty to the end of the fruitful period of woman’s life, while their formation commences before birth. Before puberty the ovaries are small, the Graafian vesicles contained in them are disposed in a comparatively thick layer in the cortical substance; here they present the appearance of a large number of minute closed vesicles, constituting the early condition of the Graafian vesicle; many, however, never attain full development, but shrink and disappear. At puberty the ovaries enlarge and become more vascular, the Graafian vesicles are developed in greater abundance, and their ova are capable of fecundation.

Discharge of the Ovum.—The Graafian vesicles, after gradually approaching the surface of the ovary, burst; the ovum and fluid contents of the vesicles are liberated, and escape on the exterior of the ovary, passing thence into the Fallopian tube. This is effected either by application of the tube to the ovary, or by a curling upward of the fimbriated extremity, so that the ovum is caught as it falls.

In the foetus the ovaries are situated, like the testes, in the lumbar region, near the kidneys. They may be distinguished from those bodies at an early period by their elongated and flattened form, and by their position, which is at first oblique and then nearly transverse. They gradually descend into the pelvis.

The Round Ligament (p. 1503).

Vessels and Nerves.—The arteries of the ovaries (Figs. 1116 and 1121) are the ovarian from the aorta, corresponding to the spermatic arteries in the male. The ovarian artery on each side enters the pelvis in the fold of broad ligament known as the suspensory ligament of the ovary and enters the attached border, or hilum, of the ovary. The ovarian vessels anastomose about the hilum with branches of the uterine artery. The veins follow the course of the arteries; they form a plexus near the ovary, the pampiniform plexus, corresponding to a like structure near the male testicle. The lymphatics (Figs. 1117 and 1118) terminate in the glands to the corresponding side of the aorta, and they anastomose in their course with trunks from the uterine fundus and Fallopian tube. The nerves come from the ovarian plexus, which is a continuation of the renal plexus along the ovarian artery, and from the aortic plexus.

Surgical Anatomy of the Appendages.—Extra-uterine pregnancy most commonly occurs in the ampulla of the tube. The product of the conception may escape through the ostium abdominale or the walls of the tube may rupture, a violent hemorrhage resulting.
Pelvic peritonitis is a not uncommon sequence of tubal disease. Salpingitis is inflammation of the mucous coat of the tube—interstitial salpingitis of the middle coat, perosalpingitis of the peritoneal coat.

If inflammation closes the uterine and the abdominal ends of the tube, mucus gathers and distends the tube (hydrosalpinx). If purulent matter gathers, the condition is known as pyosalpinx.

An ovary may fail to descend and remain well above the pelvic brim; it may prolapse into Douglas's pouch; it may enter the sac of a hernia; it may inflame; a tumor or cyst may arise from it. A solid tumor of the ovary may be a fibroma, a sarcoma, or a carcinoma. "Cysts may originate in any part of the tubo-ovarian structure; as the cortical, medullary, or parenchymatous portions of the ovary; in the structure between the tube and ovary known as the Rosenmüller organ or parovarian structures; and in the hydatid of Morgagni."1 Cysts may be simple, proliferating, or dermoid; unicocular or multicocular. Glandular proliferous cysts, papillary proliferous cysts, dermoid cysts, and parovarian cysts may attain a large or even an enormous size. The operation for the removal of an ovarian cyst is one of the most successful of the major procedures of surgery.

THE MAMMARY GLAND (MAMMA) (Figs. 1124, 1125, 1126, 1127).

The breasts, mammary glands or mammae secrete the milk, and are accessory glands of the generative system. They develop fully in the female, but remain permanently rudimentary in the male. There are two of these glands, and they are situated in the superficial fascia of the anterior portion of the thorax. Between the two glands and in front of the sternum is a groove, the bosom.

Description of a Well-developed Breast.—Each gland appears as a hemispherical body projecting from the front of the thorax beneath the skin and lying over a portion of the Pectoralis major muscle and a smaller portion of the Serratus magnus muscle. The hemispherical projection extends usually from the margin of the sternum to the axilla and from the level of the second rib to the level of the sixth rib, or from the third rib to the seventh rib, but this does not represent the real size of the gland. The gland is much larger than this, being rendered so by tails or prolongations of breast tissue, which will be described later (p. 1517).

The Nipple (papilla mammae) (Figs. 1124, 1125, 1126, and 1127).—The nipple projects from a little below and to the median side of the summit of the hemisphere at or above the level of the fifth rib, and is covered with thin skin. The right nipple may not exactly correspond in situation and direction to the left nipple. The nipple varies considerably in height and shape. In the virgin it is usually cylindrical and is directed forward and slightly upward and outward. The apex of the nipple is rendered rough by fissures (Fig. 1124), it exhibits a depression in which are the openings of the milk ducts (Fig. 1126), and its circumference is thrown into concentric ridges (Fig. 1126). The nipple is surrounded by a darker circular wrinkled area, the areola (areola mammae) (Figs. 1124 and 1125), in which are sweat-glands and on which are twelve or fifteen small rounded elevations. These elevations are caused by cutaneous sebaceous glands which in structure represent a transition between sebaceous and mammary glands. They are probably rudimentary portions of the mammary gland and are known as the glands of Montgomery (glandulae areolares) (Fig. 1126). The color of the nipple and areola varies with the complexion of the individual. In brunettes it is darker than in blondes. The usual color of the nipple in a young woman is rosypink, the areola being of a darker shade. During the early months of pregnancy the nipple and areola become dark brown in color, the areola becomes larger in circumference, and the glands of Montgomery increase in size (Fig. 1127). The nipple contains non-striated muscle and mechanical irritation or sexual excitement makes it stiff and erect. The skin covering the breast is clear, soft, and delicate, and subcutaneous veins are often visible. The skin of the nipple and areola is particularly delicate.

Variations in the Mammae.—Before puberty the glands are small, of the infantile type, grow slowly, and differ but slightly from the male organs. The nipple is small and flat and pale. At puberty the increase in the size of the breast is rapid and considerable, due to growth of gland tissue and of subcutaneous fat. During pregnancy the breasts enlarge greatly and remain very large throughout lactation. This enlargement is due to new gland tissue and increased vascularity. Numerous blue veins are visible in the skin, the areola darkens, and the glands of Montgomery enlarge (Fig. 1127). During lactation the associated lymphatic glands may enlarge (A. Marmaduke Shield). After the termination of lactation the breasts diminish in size. They do not become as small as the virgin breast, are apt to lose their hemispherical outlines, and cease to be soft. They droop as flaccid pendulous masses, the subcutaneous fat is largely gone, and the outlines of the lobular breast tissue can be seen and felt. The nipple is long and hangs down like a teat. At the menopause the breast usually shrinks. In some cases, however, it actually increases in size. In such a case, although the gland atrophies, there is an extensive deposit of fat. In old age the glands undergo atrophy and largely disappear, the skin is flabby and thrown into wrinkles, and the breasts contain very little glandular structure, and are hard from the presence of fibrous tissue. The nipples become pigmented and corrugated. Women vary greatly in the development of the breasts. In some women they are large, firm, and well proportioned; in others they are small, flat, or atrophy occurs in the course of certain bodily diseases, as phthisis, and certain mental diseases, as melancholia. If the ovaries are ill-developed the breasts remain flat and small. In newly married women, even though pregnancy does not exist, the breasts often develop decidedly and rapidly. The outline and direction of the breast and also of the nipple may be altered by corsets. The left mamma is usually somewhat larger than the right.

![Dissection of the lower half of the female breast during the period of lactation. (From Luschka.)](image)

One gland or both glands may be entirely absent, the nipple being also absent. One or both glands may be absent, one or both nipples being present. When there is only one nipple, it is apt to be the left. The term polymazia (mammae accessoriae multiebris) means the presence of supernumerary breasts, with or without
nipples. Polytheilia means the presence of supernumerary nipples, the associated glandular structure being rudimentary. There may be one, two, or several supernumerary breasts, and when more than one exists, are usually asymmetrical. If one is functionally active, it enlarges during pregnancy and furnishes milk.

Supernumerary mammae may secrete milk or may be without function. The most common situation is on the part of the chest below and to the inner side of the normally placed gland. They may also exist in the axilla, the abdomen, the groin, the back, and the thigh. Many cases of supposed supernumerary glands have been really instances in which moles, warts, or sebaceous cysts have been mistaken for breast tissue, but some cases are undoubted.

Prolongations of Mammary Tissue.—As previously stated, the outlines of the breasts are not regular, but here and there tails, prolongations, or cusps come off from and are true portions of the gland. Two or even more prolongations pass to the edge of the sternum; others pass toward the axilla, the clavicle, and the origin of the external oblique muscle from the ribs. Underneath the mammary gland prolongations of mammary tissue penetrate the pectoral fascia (Heidenhain). If one of the glandular cusps is of considerable size it is called an outlying lobule.

Structure of Mammary Gland and Nipple (Figs. 1124 and 1125).—The glands of the breast (corpus mammae) rest by a smooth posterior surface upon the loose pectoral fascia, which fastens the breast to the muscle beneath, but so loosely that the breast is movable. The mamma consists of gland-tissue; of fibrous tissue, connecting its lobes, of fatty tissue in the intervals between the lobes, of retinacula, and of skin. The gland-tissue, when freed from fibrous tissue and fat, is of a pale reddish color, firm in texture, in general circular in form, with prolongations here and there, flattened from before backward, thicker in the centre than at the circumference, and presenting several inequalities on its surface, especially in front. On the anterior surface there are many irregular elevated processes with deep spaces between them. From the summits of the elevations connective-tissue strands (retinacula curts) pass to the true skin. The glandular structure consists of numerous lobes (lobi mammae), and these are composed of lobules (lobuli mammae), connected together by areolar tissue, blood-vessels, and ducts. The smallest lobules consist of a cluster of rounded alveoli (Fig. 1124), which open into the smallest branches of the excretory ducts; these ducts, uniting, form larger ducts, which terminate in single canals. Each canal is called a lactiferous, galactophorous or mammillary duct (ductus lactiferus) (Fig. 1124). Each lobe possesses one lactiferous duct. This passes to the apex of the lobe and then into the nipple. The lactiferous ducts are white and cord-like, and contrast with the yellowish-red tissue of the gland itself. The number of excretory ducts varies from fifteen to twenty. They converge toward the areola, beneath which each duct forms a spindle-shaped dilatation, the ampulla (sinus lactiferans) (Fig. 1124). The ampullae serve as reservoirs for the milk. At the base of the nipple the ducts become contracted and pursue a straight course to its summit, perforating it by separate orifices considerably narrower than the ducts themselves. Each orifice (porus lactiferus) is the orifice of a tube which drains an individual lobe. The ducts are composed of areolar tissue, with longitudinal and transverse elastic fibres; muscular fibres are entirely absent; their mucous lining is continuous, at the point of the nipple, with the integument. The epithelium of the mammary gland differs according to the state of activity of the organ. In the gland of a woman who is not pregnant or nursing the alveoli are very small and solid, being filled with a mass of granular polyhedral cells. During pregnancy the alveoli enlarge and the cells undergo rapid multiplication. At the commencement of lactation the cells in the centre of an alveolus undergo fatty degeneration, and are eliminated in the first milk as colostrum-corpuscles. The peripheral cells of the alveolus remain, and form a single layer of granular, short columnar cells lining the limit-
ing membrana propria. The single nucleus of each cell divides and forms two. In the protoplasm, especially, in the end of the cells toward the alveolus,

![Diagram of the mammary gland]

Fig. 1125.—Right breast in sagittal section, inner surface of outer segment. (Testut.)

drops of fat appear, and the nucleus toward this end of the cell also becomes fatty.

![Diagram of nipple and areola]

Fig. 1126.—Nipple and areola of a virgin. (Testut.)

Fig. 1127.—Nipple and areolae of a pregnant woman. (Testut.)

The end of the cell toward the alveolus breaks down, and the liberated material constitutes “the albuminous ingredients of the milk, while the drops of fat become the milk-globules. The portion of the cell which remains forms new
The female organs of generation

Cytoplasm, and the same process is repeated over and over again. The cells also secrete water and the salts which are found in the milk.1

The fibrous tissue (Fig. 1125) invests the entire surface of the breast, and sends down septa between its lobes, connecting them together.

The fatty tissue (Figs. 1124 and 1125) surrounds the surface of the gland and occupies the interval between its lobes. It usually exists in considerable abundance, and determines the form and size of the gland. There is no fat immediately beneath the areola and nipple.

Vessels and Nerves.—The arteries supplying the mammary gland are derived from the perforating branches of the internal mammary, long thoracic branches of the axillary, and branches from the intercostals. The veins describe an anastomotic circle around the base of the nipple, called by Haller the circulus venosus. From this large branches transmit the blood to the circumference of the gland and end in the axillary and internal mammary veins. The lymphatics of the mammary gland (Figs. 1128 and 1129) and mammary region have been previously described (pp. 810 and 811). The nerves are derived from the fourth, fifth, and sixth intercostal nerves, and sympathetic filaments from the dorsal cord pass to the breast along the branches of the intercostal nerves.

Surgical Anatomy.—Occasionally the mammary gland undergoes enormous hypertrophy. This may occur at any age, even in the virgin. The physiological enlargement of puberty may become excessive or the physiological enlargement of pregnancy and lactation may continue and increase after the termination of lactation. The chief elements in the enlargement are fat and connective tissue, and it is doubtful if there is extensive reproduction of glandular tissue.

Abscess of the breast may occur at any age, but is most common by far in nursing women. The portals are opened to infection by a crack in the nipple and bacteria are carried inward by the lymph-vessels. In some cases the pus gathers beneath the skin (supra-mammary abscess), in others in the breast tissue (intra-mammary abscess). In rare cases pus gathers beneath the breast (retro-mammary abscess). In intra-mammary abscess the pus burrows through the

1 Human Physiology. By Joseph Howard Raymond.
fibrous septa or fascia and forms numerous channels, and such a channel is constricted at the point where it passes through fascia or a fibrous septum, as an hour-glass is constricted.

In every patient suffering from abscess the nipple should be examined for a sore or crack, and the area when found should be treated antiseptically. A supra-mammary abscess should be opened by an incision radiating from the nipple.

In intra-mammary abscess follow the advice of Sheild: open the abscess by an incision radiating from the nipple, insert the index finger, and when possible pass it to the bottom of the abscess and carry the tip from the depths of the abscess to as near the surface as possible. At this point make a counter opening. The finger breaks down septa which cause constriction and thus converts the tracking sinuses into one large cavity. Drain by tubes.

A retro-mammary abscess is opened by an incision, following the outline of the breast at the thoraco-mammary junction, the finger being pushed through the incision and up under the gland.

Tuberculosis of the breast may occur, and if it does, cold abscess is apt to form. The best treatment is removal of the gland and the associated lymph glands.

Chronic mastitis is a condition of mammary fibrosis, most common in neurotic single women, and apt to be associated with ovarian or uterine disease.

Malignant dermatitis or Paget's disease of the nipple is a chronic condition consisting of epithelial proliferation, induration, desquamation, and ulceration, and it is apt to be followed by epithelioma.

Chancre of the nipple is occasionally met with.

Secondary and tertiary syphilitic lesions are seen upon the skin of the breast, the nipple, and the areola.

Cysts and tumors are common in the breast.

---

Fig. 1129.—Lymphatics of the breast and axillary glands. (Poirier and Charpy.)

There may be cystic degeneration of the gland in women near the menopause (involution cysts); a lacted cyst; a hydatid cyst; an adenoma may become cystic. The nipple may suffer from epithelioma, myoma, myxoma, angioma, papilloma, or fibroma.

The innocent tumors of the breast are fibro-adenoma, cystic adenoma, myxoma, and angioma. The skin of the breast may suffer from any form of growth or cyst which could arise from the skin of another part. Malignant tumors of the glandular structure are ten times as frequent as innocent tumors. Sarcoma is rare; carcinoma is very common.

Carcinoma of the breast has occupied much of the attention of surgeons during recent years. The old operation was uniformly followed by recurrence. The modern radical operation has been evolved from the studies of Moore, the younger Gross, Heidenhain, Stiles, Banks, Halsted, and others. The modern operation always removes at least the skin and subcutaneous tissue over the hemispherical portion of the breast, the outlying lobules of the breast, the pectoral fascia,

---

1 Diseases of the Breast. By A. Marmaduke Sheild.

96
and the sternal portion of the great Pectoral muscle, the lymphatic tracts from the breast, the lymphatic glands and cellular tissue from the axilla, and from beneath the latissimus dorsi muscle. The pectoral fascia and the sternal portion of the great Pectoral muscle must come away in every case, because breast tissue may pass through the fascia. The entire breast must be removed, because even in a recent case the entire breast is regarded as infected. The clavicular portion of the great Pectoral muscle is anatomically distinct from the sternal portion and its removal is not imperative. Some operators remove the lesser Pectoral muscle. To leave it is of no value to the arm, and it frequently causes an annoying rigid band anterior to the axilla. To take it away gives ready access to the axillary vessels at a desirable point above. The sheath of the axillary vein should be removed with the glands and cellular tissue of the axilla. The glands receiving lymph from the cancerous area must be removed, of course. In view of the fact that in an undetermined percentage of cases a lymph tract passes direct to the subclavian glands, it is evident that these glands may become infected by this route instead of, as is more usual, secondarily to axillary infection; hence it seems wiser in every case to remove the cellular tissue and glands from the subclavian triangle. All of these structures should be removed as one piece, in order to avoid cutting across lymph tracts and flooding the wound with carcinoma cells which might adhere, grow, and reproduce cancer.

Halsted's operation is the method adopted by most surgeons. The wound cannot be completely closed, and the raw spot is covered at once or later with Thiersch skin grafts. (For surgical considerations regarding the lymphatics in mammary carcinoma see page 811.)

The Male Breast (mamma virilis).—The male breast is a small flat structure, consisting chiefly of connective tissue, but containing some branched tubules. Under normal circumstances it remains permanently of the infantile type. It possesses a nipple which is much smaller than that of the female breast, and which usually lies over the fourth intercostal space, but may lie over the fourth or fifth rib. The nipples of the two sides are rarely placed quite symmetrically. Accessory glands and accessory nipples are as common among males as females. The male breast may exhibit some evidence of temporary functional activity at birth and at puberty. Cases have been recorded of actual lactation by the male breast.

Surgical Anatomy.—The male breasts may undergo enormous hypertrophy (gynaecomazia). In these cases the penis is often small and the testicles may be atrophied. The breasts may be absent in the male. Disease of the male breast is not nearly so frequent as disease of the female breast. The organ may be the seat of syphilis, tuberculosis, acute or chronic mastitis, abscess or tumor. A number of cases of cancer of the male breast have been recorded.
THE SURGICAL ANATOMY OF INGUINAL HERNIA AND FEMORAL HERNIA.

Dissection (Fig. 287).—For dissection of the parts concerned in inguinal hernia a male subject, free from fat, should always be selected. The body should be placed in the supine position, the abdomen and pelvis raised by means of blocks placed beneath them, and the lower extremities rotated outward, so as to make the parts as tense as possible. If the abdominal walls are flaccid, the cavity of the abdomen should be inflated through an aperture made at the umbilicus. An incision should be made along the middle line from a little below the umbilicus to the symphysis pubis, and continued along the front of the scrotum, and a second incision from the anterior superior spine of the ilium to just below the umbilicus. These incisions should divide the integument, and the triangular-shaped flap included between them should be reflected downward and outward, when the superficial fascia will be exposed.

The Superficial Fascia of the Abdomen (p. 434).—This, over the greater part of the abdominal wall, consists of a single layer of fascia, which contains a variable amount of fat; but as it approaches the groin it is easily divisible into two layers, between which are found the superficial vessels and nerves and the superficial inguinal lymphatic glands.

The Superficial Layer of the Superficial Fascia or the Fascia of Camper is thick, areolar in texture, containing adipose tissue in its meshes, the quantity of which varies in different subjects. Below, it passes over Poupart's ligament, and is continuous with the outer layer of the superficial fascia of the thigh. In the male this fascia is continued over the penis and over the outer surface of the cord to the scrotum, where it helps to form the dartos. As it passes to the penis, and over the cord to the scrotum it changes its character, becoming thin, destitute of adipose tissue, and of a pale reddish color; and in the scrotum it acquires some involuntary muscular fibres. From the scrotum it may be traced backward, to be continuous with the superficial fascia of the perineum. In the female this fascia is continued into the labia majora.

The hypogastric branch of the ilio-hypogastric nerve perforates the aponeurosis of the External oblique muscle about an inch above and a little to the outer side of the external abdominal ring, and is distributed to the integument of the hypogastric region.

The ilio-inguinal nerve escapes at the external abdominal ring, and is distributed to the integument of the upper and inner part of the thigh, to the scrotum in the male and to the labium in the female.

The superficial epigastric artery arises from the femoral about half an inch below Poupart's ligament, and, passing through the saphenous opening in the fascia lata, ascends on to the abdomen, in the superficial fascia covering the External oblique muscle, nearly as high as the umbilicus. It distributes branches to the superficial inguinal lymphatic glands, the superficial fascia, and the integument, anastomosing with branches of the deep epigastric and internal mammary arteries.

The superficial circumflex iliac artery, the smallest of the cutaneous branches, arises close to the preceding, and, piercing the fascia lata, runs outward, parallel with Poupart's ligament, as far as the crest of the ilium, dividing into branches which supply the superficial inguinal lymphatic glands, the superficial fascia, and
the integument, anastomosing with the deep circumflex iliac and with the gluteal and external circumflex arteries.

Fig. 1130.—Right external abdominal ring and saphenous opening in the male. (Spalteholz.)

Fig. 1131.—Right inguinal canal in the male. Second layer viewed from in front. (Spalteholz.)
The superficial external pudic (superior) artery arises from the inner side of the femoral artery close to the preceding vessels, and, after passing through the saphenous opening, courses inward across the spermatic cord, to be distributed to the integument on the lower part of the abdomen, the penis and scrotum in the male, and the labium in the female, anastomosing with branches of the internal pudic.

The Superficial Veins.—The veins accompanying these superficial vessels are usually much larger than the arteries; they terminate in the internal saphenous vein.

The superficial inguinal lymphatic glands are placed immediately beneath the integument, are of large size, and vary from ten to twenty in number (p. 791).

The Deep Layer of the Superficial Fascia, the Fascia of Scarpa or the Fascia of Cooper (p. 435) is thinner and more membranous in character than the superficial layer. In the middle line it is intimately adherent to the linea alba; above, it is continuous with the superficial fascia over the rest of the trunk; below, it blends with the fascia lata of the thigh a little below Poupart's ligament; below and internally, in the male, it is continued over the penis and over the outer surface of the cord to the scrotum, where it helps to form the dartos. From the scrotum it may be traced backward to be continuous with the base of the triangular ligament of the urethra. In the female it is continuous with the labia majora.

The scrotum is a cutaneous pouch which contains the testes and part of the spermatic cords, and into which an inguinal hernia frequently descends.

The Aponeurosis of the External Oblique Muscle (Fig. 1130).—This is a thin but strong membranous aponeurosis, the fibres of which are directed obliquely downward and inward. That portion of the aponeurosis which extends between
the anterior superior spine of the ilium and the spine of the os pubis is a broad band, folded inward and continuous below with the fascia lata; it is called Poupart's ligament (Figs. 288, 1130, 1133, 1134, 1135, 1141, and 1142). The portion which is reflected from Poupart's ligament at the spine of the os pubis, along the pectineal line, is called Gimbernat's ligament (Fig. 296, 338, 1130, 1141, and 1142). A thin fibrous band extends from the inner end of Poupart's ligament and Gimbernat's ligament upward and inward behind the inner pillar of the external ring to the anterior layer of the rectus sheath. The fibres diverge as they ascend. This band is known as the triangular fascia or Colles's fascia or the triangular ligament of Colles (Figs. 1132 and 1136).

The External or Superficial Abdominal Ring (anulus inguinalis subcutaneus) (Figs. 288 and 1130).—Just above and to the outer side of the crest of the os pubis an interval is seen in the aponeurosis of the External oblique, called the external abdominal ring. This aperture is oblique in direction, somewhat triangular in form, and corresponds with the course of the fibres of the aponeurosis. It usually measures from base to apex about an inch, and transversely about half an inch. It is bounded below by the crest of the os pubis; above, by a series of curved fibres, the intercolumnar fibres, which pass across the upper angle of the ring, so as to increase its strength; and on either side by the margins of the opening in the aponeurosis, which are called the columns or pillars of the ring.

The External Pillar, which at the same time is inferior (crus inferius), from the obliquity of its direction, is the stronger; it is formed by that portion of Poupart's ligament which is inserted into the spine of the os pubis; it is curved, so as to form a kind of groove, upon which the spermatic cord rests.

The Internal or Superior Pillar (crus superius) is a broad, thin, flat band, which is attached to the front of the body of the os pubis, interlacing with its fellow of the opposite side in front of the symphysis pubis, that of the right side being superficial.

The external abdominal ring gives passage to the spermatic cord in the male and round ligament in the female; it is much larger in men than in women, on account of the large size of the spermatic cord, hence the great frequency of inguinal hernia in men.

The Intercolumnar Fibres (fibrae intercruales) (Fig. 1130) are a series of curved tendinous fibres which arch across the lower part of the aponeurosis of the External oblique. They have received their name from stretching across between the two pillars of the external ring; they increase the strength of the lower part of the aponeurosis and prevent the divergence of the pillars from one another. They are thickest below, where they arise from Poupart's ligament, and they are inserted into the linea alba, describing a curve, with the convexity downward. They are much thicker and stronger at the outer angle of the external ring than internally, and are more strongly developed in the male than in the female. These intercolumnar fibres, as they pass across the external abdominal ring, are themselves connected together by delicate fibrous tissue, thus forming a fascia which, as it is attached to the pillars of the ring, covers it in, and is called the intercolumnar fascia. This intercolumnar fascia is continued downward as a tubular prolongation around the outer surface of the cord and testis, and encloses them in a distinct sheet; hence, it is also called the external spermatic fascia. The sac of an inguinal hernia in passing through the external abdominal ring receives an investment from the intercolumnar fascia.

If the finger is introduced a short distance into the external ring and the limb is then extended and rotated outward, the aponeurosis of the External oblique, together with the iliac portion of the fascia lata, will be felt to become tense and the external ring much contracted; if the limb is, on the contrary, flexed upon the pelvis and rotated inward, this aponeurosis will become lax, and the external ring
sufficiently enlarged to admit the finger with comparative ease; hence the patient should always be put in the latter position when the taxis is applied for the reduction of an inguinal hernia, in order that the abdominal walls may be relaxed as much as possible.

The aponeurosis of the External oblique should be removed by dividing it across in the same direction as the external incisions, and reflecting it downward and outward; great care is requisite in separating it from the aponeurosis of the muscle beneath. The lower part of the Internal oblique and the Cremaster are then exposed, together with the inguinal canal, which contains the spermatic cord (Fig. 1133). The mode of insertion of Poupart's and Gimbernat's ligaments into the os pubis should also be examined.

**Poupart's Ligament** (ligamentum inguinale [Pouparti]) (Figs. 288, 1130, 1133, 1134, 1135, 1141, and 1142) or the crural arch is the lower border of the aponeurosis of the External oblique muscle, which extends from the anterior superior spine of the ilium to the spine of the os pubis. From this latter point it is reflected outward to be attached to the pectineal line for about half an inch, forming Gimbernat's ligament. Its general direction is curved downward toward the thigh, where it is continuous with the fascia lata. Its outer half is rounded and oblique in direction; its inner half gradually widens at its attachment to the os pubis, is more horizontal in direction, and lies beneath the spermatic cord.

**Gimbernat's Ligament** (ligamentum lacunare [Gimbernati]) (Figs. 288, 293, 338, 1130, 1141, and 1142) is that portion of the aponeurosis of the External oblique muscle which is reflected upward and outward from the spine of the os pubis to be inserted into the pectineal line. It is about half an inch in length, larger in the male than in the female, almost horizontal in direction in the erect posture, and of a triangular form, with the base directed outward. Its base or outer margin is concave, thin, and sharp, and lies in contact with the femoral sheath, forming the inner boundary of the femoral ring (Fig. 1141). Its apex corresponds to the spine of the os pubis. Its posterior margin is attached to the pectineal line, and is continuous with the pubic portion of the fascia lata. Its anterior margin is continuous with Poupart's ligament.

The **Triangular Fascia of the Abdomen, Colles's Fascia** or the **Triangular Ligament of Colles** (ligamentum inguinale reflexum [Collesi]) (Figs. 1132, 1133, and 1136) is a band of tendinous fibres, of a triangular shape, which is attached by its apex to the inner end of Poupart's ligament and to Gimbernat's ligament. It passes inward beneath the spermatic cord, and expands into a somewhat fan-shaped fascia, lying behind the inner pillar of the external abdominal ring and in front of the conjoined tendon, and interlaces with the ligament of the other side at the linea alba in the anterior layer of the sheath of the Rectus muscle.
The Ligament of Cooper.—See Fig. 296 and p. 439.

The Internal Oblique Muscle (Figs. 1131, 1132, and 1133) has been previously described (p. 439). The part which is now exposed is partly muscular and partly tendinous in structure. Those fibres which arise from Poupart's ligament, few in number and paler in color than the rest, arch downward and inward across the spermatic cord, and, becoming tendinous, are inserted, conjointly with those of the Transversalis, into the crest of the os pubis and pectineal line, forming what is known as the conjoined tendon of the Internal oblique and Transversalis (Figs. 1133 and 1134). This tendon is inserted immediately behind the inguinal canal and external abdominal ring, serving to protect what would otherwise be a weak point in the abdominal wall. The conjoined tendon is sometimes divided into an outer and an inner portion, the former being called the ligament of Hesseltbach (ligamentum interfoveolare) (Fig. 291), and the latter the ligament of Henle (Fig. 291). Sometimes the conjoined tendon is insufficient to resist the pressure from within, and is carried forward in front of the protrusion through the external ring, forming one of the coverings of direct inguinal hernia, or the hernia forces its way through the fibres of the conjoined tendon.

The Cremaster (Figs. 1131 and 1133) is derived from the lower margin of the Internal oblique, of which muscle it is in reality a portion. It is a thin muscular layer composed of a number of fasciculi. It arises by a thick external bundle of fibres from the upper portion of Poupart's ligament, being connected with the Internal oblique muscle and also occasionally with the Transversalis. It arises also by a thin inner bundle of fibres from the anterior layer of the rectus sheath.

The thick bundle of origin is on the lateral surface; the thin bundle is on the medial surface of the spermatic cord. The Cremaster passes along with the spermatic cord, and descends with it through the external ring. Upon the front and sides of the cord both bundles spread out upon the vaginal tunic of the testicle and epididymis, and form a series of loops which differ in thickness and length in different subjects. These loops are united together by areolar tissue, and form a thin covering over the cord and testis, the cremasteric fascia (fascia cremasterica).

It will be observed that the Cremaster is a separated portion of the Internal oblique. This fact affords an easy explanation of the manner in which the testicle and cord are invested by this muscle. At an early period of foetal life the testis is placed at the lower and back part of the abdominal cavity, but during its descent toward the scrotum, which takes place before birth, it passes beneath the arched border of the Internal oblique. In its passage beneath this muscle some fibres are derived from its lower part, which accompany the testicle and cord into the scrotum.

It occasionally happens that the loops of the Cremaster surround the cord, some lying behind as well as in front. It is probable that under these circumstances the testis in its descent passes through, instead of beneath, the fibres of the Internal oblique.

In the descent of an oblique inguinal hernia, which takes the same course as the spermatic cord, the Cremaster muscle forms one of its coverings. This muscle becomes largely developed in cases of hydrocele and large old scrotal herniae. No such muscle exists in the female, but an analogous structure is developed in those cases where an oblique inguinal hernia descends beneath the margin of the Internal oblique.

The Internal oblique should be detached from Poupart's ligament, separated from the Transversalis to the same extent as in the previous incisions, and reflected inward on to the sheath of the Rectus (Fig. 1134). The deep circumflex iliac vessels, which lie between these two muscles, form a valuable guide to their separation.
The Transversalis Muscle (Figs. 1132 and 1134) has been previously described (p. 444). The part which is now exposed is partly muscular and partly tendinous in structure; it arises from the outer third of Poupart's ligament, its fibres curve downward and inward, and are inserted, together with those of the Internal oblique, into the lower part of the linea alba, into the crest of the os pubis and the pectineal line, forming what is known as the conjoined tendon of the Internal oblique and Transversalis (Figs. 1133 and 1134). The falx aponeurotica [inguinalis] is a collection of fibres of tendinous consistence in the inner side of the Transversalis insertion. Between the lower border of this muscle and Poupart's ligament a space is left in which is seen the transversalis fascia.

The Inguinal or Spermatic Canal (canalis inguinalis) (Figs. 1131, 1132, and 1134) contains the spermatic cord in the male and the round ligament in the female. It is an oblique canal, about an inch and a half in length, directed downward and inward and placed parallel with, and a little above, Poupart's ligament. It commences above at the internal or deep abdominal ring, which is the point where the cord enters the inguinal canal, and terminates below at the external or superficial ring. It is bounded, in front, by the integument and superficial fascia, by the aponeurosis of the External oblique throughout its whole length, and by the Internal oblique for its outer third; behind, by the triangular fascia, the conjoined tendon of the Internal oblique and Transversalis, transversalis fascia, and the subperitoneal fat and peritoneum; above, by the arched fibres of the Internal oblique and Transversalis; below, by the union of the transversalis fascia with Poupart's ligament. That form of hernia in which the intestine follows the course of the spermatic cord along the inguinal canal is called oblique inguinal hernia.

On the posterior wall of the inguinal canal is seen the band of fibres known as the ligament of Hesselbach (ligamentum interfoveolare [Hesselbachi]) (Fig. 291). It is placed in front of the deep epigastric artery. The fibres come from the external portion of the lower fibres of the conjoined tendon (Fig. 1133) and pass

---

**Fig. 1134.**—Inguinal hernia. Dissection showing the Transversalis muscle, the transversalis fascia, and the internal abdominal ring.
downward for a distance, some of them then passing outward and upward, some of them downward and inward to the inner surface of Poupart's ligament.

The Transversalis Fascia (Figs. 296, 1134, and 1142) is a thin aponeurotic membrane which lies between the inner surface of the Transversalis muscle and the peritoneum. It forms part of the general layer of fascia which lines the interior of the abdominal and pelvic cavities, and is directly continuous with the iliac and pelvic fasciae.

In the inguinal region the transversalis fascia is thick and dense in structure, and joined by fibres from the aponeurosis of the Transversalis muscle; but it becomes thin and cellular as it ascends to the Diaphragm. Below, it has the following attachments; external to the femoral vessels it is connected to the posterior margin of Poupart’s ligament, and is there continuous with the iliac fascia. Internal to the vessels it is thin, and attached to the os pubis and pectineal line behind the conjoined tendon, with which it is united; and, corresponding to the points where the femoral vessels pass into the thigh, this fascia descends in front of them, forming the anterior wall of the femoral sheath. The spermatic cord in the male and the round ligament in the female pass through this fascia; the point where they pass through is called the internal or deep abdominal ring. This opening is not visible externally, owing to a prolongation of the transversalis fascia on the structures forming the infundibuliform fascia.

The Internal or Deep Abdominal Ring (annulus inguinalis abdominalis) (Figs. 296 and 1134) is situated in the transversalis fascia, midway between the anterior superior spine of the ilium and symphysis pubis, and about half an inch above Poupart’s ligament. It is of an oval form, its long diameter being directed upward and downward; it varies in size in different subjects, and is much larger in the male than in the female. It is bounded above and externally by the arched fibres of the Transversalis muscle, below and internally by the deep epigastric vessels. It transmits the spermatic cord in the male and the round ligament in the female. From its circumference, a thin, funnel-shaped membrane, the infundibuliform fascia, is continued around the cord and testis, enclosing them in a distinct pouch (Fig. 1134). When the sac of an oblique inguinal hernia passes through the internal or deep abdominal ring, the infundibuliform fascia constitutes one of its coverings.

The Subperitoneal Areolar Tissue or the Fascia Propria of Cooper.—Between the transversalis fascia and the peritoneum is a quantity of loose areolar tissue. In some subjects it is of considerable thickness and loaded with adipose tissue. Opposite the internal ring it is continued around the surface of the cord, forming a loose sheath for it.

The Deep Epigastric Artery (Figs. 291 and 1135) arises from the external iliac artery a few lines above Poupart’s ligament. It at first descends to reach this ligament, and then ascends obliquely along the inner margin of the internal or deep abdominal ring, lying between the transversalis fascia and the peritoneum, and passing upward pierces the transversalis fascia and enters the sheath of the Rectus muscle by passing over the semilunar fold of Douglas. Consequently the deep epigastric artery bears a very important relation to the internal abdominal ring as it passes obliquely upward and inward from its origin from the external iliac. In this part of its course it lies along the lower and inner margin of the internal ring and beneath the commencement of the spermatic cord. At its commencement it is crossed by the vas deferens in the male and by the round ligament in the female.

The Peritoneum (Fig. 1135), corresponding to the inner surface of the internal ring, presents a well-marked depression, the depth of which varies in different subjects. A thin fibrous band is continued from it along the front of the cord for a variable distance, and becomes ultimately lost, the ligament of Cloquet. This is the remains of the pouch of peritoneum which, in the foetus, precedes
the cord and testis into the scrotum, the obliteration of which commences soon after birth. In some cases the fibrous band can only be traced a short distance, but occasionally it may be followed, as a fine cord, as far as the upper end of the tunica vaginalis. Sometimes the tube of peritoneum is closed only at intervals and presents a sacculated appearance, or a single pouch may extend along the whole length of the cord, which may be closed above, or the pouch may be directly continuous with the peritoneum by an opening at its upper part.

In the female fetus the peritoneum is also prolonged in the form of a tubular process for a short distance into the inguinal canal. This process is called the canal of Nuck. It is generally obliterated in the adult, but sometimes it remains pervious even in advanced life.

In order to understand the relation of the peritoneum to inguinal hernia, it is necessary to view the anterior abdominal wall from its internal aspect, when it will be seen as shown in Fig. 1135. Between the upper margin of the front of the pelvis and the umbilicus, the peritoneum, when viewed from behind, will be seen to be raised into five vertical folds, with intervening depressions, by more or less prominent bands which converge to the umbilicus. One of these is situated in the median line, and is caused by the urachus, the remnant of the allantois; it extends from the summit of the bladder to the umbilicus. The fold of peritoneum covering it is known as the fold of the urachus or the plica urachi (plica umbilicalis media). On either side of this is a prominent band, caused by the obliterated hypogastric artery, which extends from the side of the bladder obliquely upward and inward to the umbilicus. This is covered by a fold of peritoneum which is known as the
hypogastric fold or the plica hypogastrica \((\text{plica umbilicalis lateralis})\). To either side of these three cords is the deep epigastric artery, which ascends obliquely upward and inward from a point midway between the symphysis pubis and the anterior superior spine of the ilium to the semilunar fold of Douglas, in front of which it disappears. It is covered by a fold of peritoneum which is known as the plica epigastrica. Between these raised folds are depressions of the peritoneum, constituting so-called fossae. The most internal, between the plica urachi and the plica hypogastrica, is known as the internal inguinal fossa \((\text{fovea supravesicalis})\). The middle one is situated between the plica hypogastrica and the plica epigastrica, and is termed the middle inguinal fossa \((\text{fovea inguinalis mesialis})\). The external one is external to the plica epigastrica, and is known as the external inguinal fossa \((\text{fovea inguinalis lateralis})\). Occasionally the deep epigastric artery corresponds in position to the obliterated hypogastric artery, and then there is but one fold on each side of the middle line, and the two external fossae are merged into one. In the usual condition of the parts the floor of the external inguinal fossa corresponds to the internal abdominal ring, and into this fossa an oblique inguinal hernia descends. To the inner side of the plica epigastrica are the two internal fossae, and through either of these a direct hernia may descend, as will be explained in the sequel (p. 1535). The whole of this space, that is to say, the space between the deep epigastric artery, the margin of the Rectus and Poupart’s ligament, is commonly known as Hesselbach’s triangle. These three depressions or fossae are situated above the level of Poupart’s ligament, and in addition to them is another below the ligament, corresponding to the position of the femoral ring, and into which a femoral hernia descends.

**INGUINAL HERNIA.**

Inguinal hernia is that form of protrusion which makes its way through the abdomen in the inguinal region.

There are two principal varieties of inguinal hernia—external or oblique, and internal or direct.

External or oblique inguinal hernia, the more frequent of the two, takes the same course as the spermatic cord. It is called external from the neck of the sac being on the outer or iliac side of the deep epigastric artery.

Internal or direct inguinal hernia does not follow the same course as the cord, but protrudes through the abdominal wall on the inner or pubic side of the deep epigastric artery.

**Oblique Inguinal Hernia.**

In oblique inguinal hernia (Fig. 1135) the intestine or omentum escapes from the abdominal cavity at the internal ring. Before it is a pouch of peritoneum, which forms the hernial sac (Fig. 1137, A). This pouch of peritoneum is invested by the subserous areolar tissue, and is enclosed in the infundibuliform process of the transversalis fascia, which it receives as it enters the inguinal canal. In passing along the inguinal canal the hernia displaces upward the arched fibres of the Transversalis and Internal oblique muscles, and is imperfectly surrounded by the fibres of the Cremaster muscles, the coat being completed by the cremasteric fascia. It then passes along the front of the cord, and escapes from the inguinal canal at the external ring, receiving an investment from the intercolumnar fascia. Lastly, it descends into the scrotum, receiving coverings from the superficial fascia and the integument.

The coverings of this form of hernia, after it has passed through the external ring, are, from without inward, the integument, superficial fascia, intercolumnar...
OBVERSE INGUINAL HERNIA

This form of hernia lies in front of the vessels of the spermatic cord and seldom extends below the testis, on account of the intimate adhesion of the coverings of the cord to the tunica vaginalis (Fig. 1137, A).

The seat of stricture in a strangulated oblique inguinal hernia is either at the external ring, in the inguinal canal, caused by the fibres of the Internal oblique or Transversalis; or at the internal ring, most frequently in the latter situation. If it is situated at the external ring, the division of a few fibres at one point of its circumference is all that is necessary for the replacement of the hernia. If in the inguinal canal or at the internal ring, it may be necessary to divide the

aponeurosis of the External oblique so as to lay open the inguinal canal. In dividing the stricture the direction of the incision should be upward.

When the hernia passes along the inguinal canal and escapes from the external ring into the scrotum, the condition is called complete oblique inguinal or scrotal hernia (Fig. 1137, A). If the hernia does not escape from the external ring, but is retained in the inguinal canal, the condition is called incomplete inguinal hernia or bubonocele. In each of these cases the coverings which invest the intestine or omentum will depend upon the extent to which it descends in the inguinal canal.

There are some other varieties of oblique inguinal hernia depending upon congenital defects in the processus vaginalis. The testicle in its descent from the abdomen into the scrotum is preceded by a pouch of peritoneum, which about
the period of birth becomes shut off from the general peritoneal cavity by a closure of that portion of the pouch which extends from the internal abdominal ring to

![Diagram of hernia types](image)

near the upper part of the testicle, the lower portion of the pouch remaining persistent as the tunica vaginalis. It would appear that this closure commences at
two points—viz., at the internal abdominal ring and at the top of the epididymis—and gradually extends until, in the normal condition, the whole of the intervening portion is converted into a fibrous cord. From failure in the completion of this process variations in the relation of the hernial protrusion to the testicle and tunica vaginalis are produced, which constitute distinct varieties of inguinal hernia, and which have received separate names and are of surgical importance. These are congenital, infantile, encysted, and hernia of the funicular process.

**Congenital Hernia** (Fig. 1137, B).—Where the congenital pouch of peritoneum which precedes the cord and testis in its descent remains patent throughout and is unclosed at any point, the cavity of the tunica vaginalis communicates directly with the cavity of the peritoneum. The intestine descends along this pouch into the cavity of the tunica vaginalis, which constitutes the sac of the hernia, and the gut lies in contact with the testicle.

**Infantile and Encysted Hernia.**—Where the congenital pouch of peritoneum is occluded at the internal ring only, but remains patent throughout the rest of its extent, two varieties of oblique inguinal hernia may be produced, which have received the names of infantile and encysted hernia. In the **infantile form** (Fig. 1137, C) the septum which closed the congenital sac above and the peritoneum in its immediate neighborhood yields and forms a sac, which descends behind the tunica vaginalis, so that in front of the bowel there are three layers of peritoneum, the two layers of the tunica vaginalis and the layer of the proper hernial sac. In the **encysted form** (Fig. 1137, D) yielding occurs in the same position as in the infantile form—namely, at the occluded spot in the pouch—and a sac forms which projects into and not behind the tunica vaginalis, as in the infantile form, and thus it constitutes a sac within a sac, so that in front of the bowel there are two layers of peritoneum—one layer of the tunica vaginalis and one of true hernial sac.

**Hernia into the Funicular Process** (Fig. 1137, E).—Where the congenital pouch of peritoneum is occluded at the lower point only—that is, just above the testicle—the intestine descends into the pouch of peritoneum as far as the testicle, but is prevented from entering the sac of the tunica vaginalis by the septum which has formed between it and the pouch, so that it resembles the congenital form in all respects, except that, instead of enveloping the testicle, that body can be felt below the rupture.

**Direct Inguinal Hernia.**

In direct inguinal hernia the protrusion makes its way through some part of the abdominal wall internal to the epigastric artery.

At the lower part of the abdominal wall is a triangular space, **Hesselbach's triangle**, bounded externally by the deep epigastric artery, internally by the margin of the Rectus muscle, below by Poupart's ligament (Fig. 1135). The conjoined tendon is stretched across the inner two-thirds of this space, the remaining portion of the space having only the subperitoneal areolar tissue and the transversalis fascia between the peritoneum and the aponeurosis of the External oblique muscle.

In some cases the hernial protrusion escapes from the abdomen on the outer side of the conjoined tendon, pushing before it the peritoneum, the subserous areolar tissue, and the transversalis fascia. It then enters the inguinal canal, passing along nearly its whole length, and finally emerges from the external ring, receiving an investment from the intercolumnar fascia. The coverings of this form of hernia are precisely similar to those investing the oblique form, with the insignificant difference that the infundibuliform fascia is replaced by a portion derived from the general layer of the transversalis fascia.

In other cases—and this is the more frequent variety—the hernia is either forced through the fibres of the conjoined tendon or the tendon is gradually distended in
front of it so as to form a complete investment for it. The intestine then enters the lower end of the inguinal canal, escapes at the external ring lying on the inner side of the cord, and receives additional coverings from the superficial fascia and the integument. This form of hernia has the same coverings as the oblique variety, excepting that the conjoined tendon is substituted for the Cremaster, and the infundibuliform fascia is replaced by a portion derived from the general layer of the transversalis fascia.

The difference between the position of the neck of the sac in these two forms of direct inguinal hernia has been referred, with some probability, to a difference in the relative positions of the obliterated hypogastric artery and the deep epigastric artery. When the course of the obliterated hypogastric artery corresponds pretty nearly with that of the deep epigastric the projection of these arteries toward the cavity of the abdomen produces two fossae in the peritoneum. The bottom of the external fossa of the peritoneum corresponds to the position of the internal abdominal ring, and a hernia which distends and pushes out the peritoneum lining this fossa is an oblique hernia. When, on the other hand, the obliterated hypogastric artery lies considerably to the inner side of the deep epigastric artery, corresponding to the outer margin of the conjoined tendon, it divides the triangle of Hesselbach into two parts, so that three depressions will be seen on the inner surface of the lower part of the abdominal wall—viz., an external one on the outer side of the deep epigastric artery; a middle one, between the deep epigastric and the obliterated hypogastric arteries; and an internal one, on the inner side of the obliterated hypogastric artery (pp. 1531 and 1532). In such a case a hernia may distend and push out the peritoneum forming the bottom of either fossa. These fossae are the inguinal fossae. When the hernia distends and pushes out the peritoneum forming the bottom of the external fossa, it is an oblique or external inguinal hernia.

When the hernia distends and pushes out the peritoneum forming the bottom of either the middle or the internal fossa, it is a direct or internal hernia.

The anatomical difference between these two forms of direct or internal inguinal hernia is that, when the hernia protrudes through the middle fossa—that is, the fossa between the deep epigastric and the obliterated hypogastric arteries—it will enter the upper part of the inguinal canal; consequently its coverings will be the same as those of an oblique hernia, with the insignificant difference that the infundibuliform fascia is replaced by a portion derived from the general layer of the transversalis fascia, whereas when the hernia protrudes through the internal fossa it is either forced through the fibres of the conjoined tendon or the tendon is gradually distended in front of it so as to form a complete investment for it. The intestine then enters the lower part of the inguinal canal, and escapes from the external abdominal ring lying on the inner side of the cord.

This form of hernia has the same coverings as the oblique variety, excepting that the conjoined tendon is substituted for the Cremaster, and the infundibuliform fascia is replaced by a portion derived from the general layer of the fascia transversalis.

The seat of stricture in strangulation in both varieties of direct hernia is most frequently at the neck of the sac or at the external ring. In that form of hernia which perforates the conjoined tendon it not infrequently occurs at the edges of the fissure through which the gut passes. In dividing the stricture the incision should in all cases be directed upward.1

If the hernial protrusion passes into the inguinal canal, but does not escape

1 In all cases of inguinal hernia, whether oblique or direct, it is proper to divide the stricture directly upward: the reason of this is obvious, for by cutting in this direction the incision is made parallel to the deep epigastric artery—either external to it in the oblique variety, or internal to it in the direct form of hernia—and thus all chance of wounding the vessel is avoided. If the incision was made outward, the artery might be divided if the hernia was direct; and if made inward, the vessel would stand an equal chance of injury if the case was one of oblique inguinal hernia.—Ed. of 15th English edition.
from the external abdominal ring, it forms what is called **incomplete direct hernia**. This form of hernia is usually of small size, and in corpulent persons is very difficult of detection.

Direct inguinal hernia is of much less frequent occurrence than the oblique, their comparative frequency being, according to Cloquet, as one to five. It occurs far more frequently in men than in women, on account of the larger size of the external ring in the former sex. It differs from the oblique in its smaller size and globular form, dependent most probably on the resistance offered to its progress by the transversalis fascia and conjoined tendon. It differs also in its position, being placed over the os pubis and not in the course of the inguinal canal. The deep epigastric artery runs on the outer or iliac side of the neck of the sac, and the spermatic cord along its external and posterior side, not directly behind it, as in oblique inguinal hernia.

### FEMORAL HERNIA.

The dissection of the parts comprised in the anatomy of femoral hernia should be performed, if possible, upon a female subject free from fat. The subject should lie upon the back; a block is first placed under the pelvis, the thigh everted, and the knees slightly bent and retained in this position. An incision should then be made from the anterior superior spinous process of the ilium along Poupart’s ligament to the symphysis pubis; a second incision should be carried transversely across the thigh about six inches beneath the preceding; and these are to be connected together by a vertical one carried along the inner side of the thigh (Fig. 338). These several incisions should divide merely the integument; this is to be reflected outward, when the superficial fascia will be exposed.

The **Superficial Fascia** forms a continuous layer over the whole of the thigh, consisting of areolar tissue, containing in its meshes much fat, and capable of being separated into two or more layers, between which are found the superficial vessels and nerves. It varies in thickness in different parts of the limb. In the groin it is thick, and the two layers are separated from one another by the superficial inguinal lymphatic glands, the internal saphenous vein, and several smaller vessels. One of these layers, the superficial, is continuous with the superficial fascia of the abdomen.

The superficial layer should be detached by dividing it across in the same direction as the external incisions; its removal will be facilitated by commencing at the lower and inner angle of the space, detaching it at first from the front of the internal saphenous vein, and dissecting it off from the anterior surface of that vessel and its tributaries; it should then be reflected outward in the same manner as the integument. The cutaneous vessels and nerves and superficial inguinal glands are then exposed, lying upon the deep layer of the superficial fascia. These are the internal saphenous vein and the superficial epigastric, superficial circumflex iliac, and superficial external pudic vessels, as well as numerous lymphatics, ascending with the saphenous vein to the inguinal glands.

The **internal or long saphenous vein** (Figs. 1138, 1139, and 1140) ascends along the inner side of the thigh, and, passing through the saphenous opening in the fascia lata, terminates in the femoral vein about an inch and a half below Poupart’s ligament (Fig. 1130). This vein receives at the saphenous opening the superficial epigastric, the superficial circumflex iliac, and the superficial external pudic veins. The **superficial external pudic artery** (superior) **arises** from the inner side of the femoral artery, and, after passing through the saphenous opening, courses inward across the spermatic cord, to be distributed to the integument on the lower part of the abdomen, the penis and scrotum in the male and the labium in the female, Anastomosing with branches of the internal pudic.

The **superficial epigastric artery** arises from the femoral about half an inch below Poupart’s ligament, and, passing through the saphenous opening in the fascia lata, ascends on to the abdomen, in the superficial fascia covering the External oblique muscle, nearly as high as the umbilicus. It distributes branches
to the superficial inguinal lymphatic glands, the superficial fascia, and the integument, anastomosing with branches of the deep epigastric and internal mammary arteries.

The **superficial circumflex iliac artery**, the smallest of the cutaneous branches, arises close to the preceding, and, piercing the fascia lata, runs outward, parallel with Poupart’s ligament, as far as the crest of the ilium, dividing into branches which supply the superficial inguinal lymphatic glands, the superficial fascia, and the integument of the groin, anastomosing with the deep circumflex iliac, and with the gluteal and external circumflex arteries.

**The Superficial Veins** (Fig. 1138).—The veins accompanying these superficial arteries are usually much larger than the arteries; they terminate in the internal or long saphenous vein at the saphenous opening.

**The superficial inguinal lymphatic glands.**—See p. 791.

---

**Fig. 1138.**—Femoral hernia. Superficial dissection.

The **ilio-inguinal nerve** arises from the first lumbar nerve. It escapes at the external abdominal ring, and is distributed to the integument of the upper and inner part of the thigh—to the scrotum in the male and to the labium in the female. The size of this nerve is in inverse proportion to that of the ilio-hypogastric nerve. Occasionally it is very small, and ends by joining the ilio-hypogastric; in such cases a branch of the ilio-hypogastric takes the place of the ilio-inguinal, or the latter nerve may be altogether absent. The **crural branch of the genitofemoral nerve** passes along the inner margin of the Psoas muscle, beneath Poupart’s ligament, into the thigh, entering the sheath of the femoral vessels, and lying
superficial and a little external to the femoral artery. It pierces the anterior layer of the sheath of the vessels, and, becoming superficial by passing through the fascia lata, it supplies the skin of the anterior aspect of the thigh as far as midway between the pelvis and knee. On the front of the thigh it communicates with the outer branch of the middle cutaneous nerve, derived from the femoral.

The **Deep Layer of the Superficial Fascia** is a very thin fibrous layer, best marked on the inner side of the long saphenous vein and below Poupart’s ligament. It is placed beneath the subcutaneous vessels and nerves, and upon the surface of the fascia lata, to which it is intimately adherent at the lower margin of Poupart’s ligament. It covers the saphenous opening in the fascia lata, is closely united to its circumference, and is connected to the sheath of the femoral vessels corresponding to its under surface. The portion of fascia covering this aperture is perforated by the internal saphenous vein and by numerous blood- and lymphatic vessels; hence it has been termed the *cribriform fascia*, the openings for these vessels having been likened to the holes in a sieve. The cribriform fascia adheres closely both to the superficial fascia and to the fascia lata, so that it is described by some anatomists as a part of the fascia lata, but it is usually considered (as in this work) as belonging to the superficial fascia. It is not till the cribriform fascia has been cleared away that the saphenous opening is seen, so that this opening does not in ordinary cases exist naturally, but is the result of dissection (p. 515). A femoral hernia in passing through the saphenous opening receives the cribriform fascia as one of its coverings.

Fig. 1139.—Femoral hernia, showing fascia lata and saphenous opening.
The deep layer of superficial fascia, together with the criciform fascia, having been removed, the fascia lata is exposed.

The Fascia Lata has been already described with the muscles of the front of the thigh (p. 515). At the upper and inner part of the thigh, a little below Poupart's ligament, a large oval-shaped aperture is observed after the superficial fascia has been cleared away; it transmits the internal saphenous vein and other smaller vessels, and is called the saphenous opening (Fig. 1130). In order the more correctly to consider the mode of formation of this aperture, the fascia lata in this part of the thigh is described as consisting of two portions, an iliac portion and a pubic portion.

The iliac portion (Fig. 1139) is all that part of the fascia lata on the outer side of the saphenous opening. It is attached externally to the crest of the ilium and its anterior superior spine; to the whole length of Poupart's ligament; and to the pectineal line in conjunction with Gimbernat's ligament. From the spine of the os pubis it is reflected downward and outward, forming an arched margin, the outer boundary or falciform process or superior cornu (cornu superius) (Fig. 1139) of the saphenous opening. This margin overlies and is adherent to the anterior layer of the sheath of the femoral vessels; to its edge is attached the criciform fascia, and below it is continuous with the pubic portion of the fascia lata.

The pubic portion of the fascia lata or the pectineal fascia (Fig. 1139) is situated at the inner side of the saphenous opening; at the lower margin of this aperture it is continuous with the iliac portion; traced upward, it covers the surface of the Pectineus, Adductor longus, and Gracilis muscles; and, passing behind the

![Image of Femoral Hernia](image-url)
sheath of the femoral vessels, to which it is loosely united, is continuous with the sheath of the Psoas and Iliacus muscles, and is attached above to the iliopsoas the fascia covering the iliopsoas muscle. From the description it may be observed that the iliac portion of the fascia lata passes in front of the femoral vessels and the pubic portion behind them, so that an apparent aperture consequently exists between the two, through which the internal saphenous vein joins the femoral vein.

The **Saphenous Opening** (fossa ovalis) (Figs. 1130, 1138, 1139, and 1140) is an oval-shaped aperture measuring about an inch and a half in length and half an inch in width. It is situated at the upper and inner parts of the front of the thigh, below Poupart’s ligament, and is directed obliquely downward and outward. It is covered by the **cribriform fascia** (fascia cribrosa), a portion of the deep layer of the superficial fascia of the thigh, and which extends from the falciform margin to the pubic portion of the fascia lata or the pectineal fascia.

The **outer margin** of the saphenous opening is of a semilunar form, thin, strong, sharply defined, and lies on a plane considerably anterior to the inner margin. If this edge is traced upward, it will be seen to form a curved elongated process, the falciform process or **superior cornu** (Fig. 1139), which ascends in front of the femoral vessels, and, curving inward, is attached to Poupart’s ligament and to the spine of the os pubis and pectineal line, where it is continuous with the pubic portion. If traced downward, it is found continuous with another curved margin, the concavity of which is directed upward and inward; this is the inferior cornu of the saphenous opening, and is blended with the pubic portion of the fascia lata covering the Pectineus muscle.

The **inner boundary of the opening** (Figs. 1130 and 1139) is on a plane posterior to the outer margin and behind the level of the femoral vessels; it is much less prominent and defined than the outer, from being stretched over the subjacent Pectineus muscle. It is through the saphenous opening that a femoral hernia passes after descending along the crural canal.

If the finger is introduced into the saphenous opening while the limb is moved in different directions, the aperture will be found to be greatly constricted on extending the limb or rotating it outward, and to be relaxed on flexing the limb and inverting it; hence the necessity for placing the limb in the latter position in employing the two for the reduction of a femoral hernia.

The iliac portion of the fascia lata, but not its falciform process, should now be removed by detaching it from the lower margin of Poupart’s ligament, carefully dissecting it from the subjacent structures, and turning it inward, when the sheath of the femoral vessels is exposed, descending beneath Poupart’s ligament (Fig. 1140).

**Poupart’s Ligament** (ligamentum inguinale [Poupart]) (Figs. 288, 1130, 1133, 1134, 1136, 1139, 1140, 1141, and 1142) is the lower border of the aponeurosis of the External oblique muscle, which extends from the anterior superior spine of the ilium to the spine of the os pubis. From this latter point it is reflected outward, to be attached to the pectineal line for about half an inch, forming **Gimbernat’s ligament**. Its general direction is curved downward toward the thigh, where it is continuous with the fascia lata. Its outer half is rounded and oblique in direction. Its inner half gradually widens at its attachment to the os pubis, is more horizontal in direction, and lies beneath the spermatic cord. Nearly the whole of the space included between Poupart’s ligament and the innominate bone is filled in by the parts which descend from the abdomen into the thigh (Figs. 296, 338, and 1141). The outer half of the space (lacuna musculorum) is occupied by the Iliacus and Psoas muscles, together with the external cutaneous and femoral nerves. The pubic half of the space (lacuna vasorum) is occupied by the femoral vessels included in their sheath, a small oval-shaped interval existing between the femoral vein and the inner wall of the sheath,
which is occupied merely by a little loose areolar tissue, a few lymphatic vessels, and occasionally by a small lymphatic gland; this is the femoral ring, through which the gut descends in femoral hernia. The part of Poupart’s ligament in front of the femoral or crural ring is called the **superficial crural arch**.

**Gimbernat’s Ligament** (ligamentum lacunare [Gimbernati]) (Figs. 296, 338, 1130, 1141, and 1142) is that part of the aponeurosis of the External oblique muscle which is reflected backward and outward from the spine of the os pubis, to be inserted into the pectineal line. It is about half an inch in length, larger in the male than in the female, almost horizontal in direction in the erect posture, and of a triangular form, with the base directed outward. Its **base or outer margin** is concave, thin, and sharp, and lies in contact with the femoral sheath. Its **apex** corresponds to the spine of the os pubis. Its **posterior margin** is attached to the pectineal line, and is continuous with the pubic portion of the fascia lata. Its **anterior margin** is continuous with Poupart’s ligament.

**Femoral Sheath** (Fig. 1141).—The femoral or **crural sheath** is a continuation downward of the fasciae that line the abdomen, the **transversalis fascia** passing down in front of the femoral vessels, and the **iliac fascia** descending behind them; these fasciae are directly continuous on the iliac side of the femoral artery, but a small space exists between the femoral vein and the point where they are continuous on the pubic side of that vessel, which constitutes the **femoral or crural canal** (Fig. 1130). The femoral sheath is closely adherent to the contained vessels about an inch below the saphenous opening, being blended with the areolar sheath of the vessels, but opposite Poupart’s ligament it is much larger than is required to contain them; hence the funnel-shaped form which it presents. The outer border of the sheath...
FEMORAL HERNIA

is perforated by the femoral nerve. Its inner border is pierced by the internal saphenous vein and numerous lymphatic vessels. In front it is covered by the iliac portion of the fascia lata; and behind it is the pubic portion of the same fascia.

If the anterior wall of the sheath is removed (Fig. 1130), the femoral artery and vein are seen lying side by side, a thin septum separating the two vessels, while another septum may be seen lying just internal to the vein, and cutting off a small space between the vein and the inner wall of the sheath. The septa are stretched between the anterior and posterior walls of the sheath, so that each vessel is enclosed in a separate compartment. The interval left between the vein and the inner wall of the sheath is not filled up by any structure, excepting a little loose areolar tissue, a few lymphatic vessels, and occasionally by a small lymphatic gland; this is the femoral or crural canal (Fig. 1130), through which the intestine descends in femoral hernia.

Deep Crural Arch.—Passing across the front of the femoral sheath on the abdominal side of Poupart's ligament, and closely connected with it, is a thickened band of fibres of the transversalis fascia, called the deep crural arch. It is apparently a thickening of the transversalis fascia, joining externally to the centre of Poupart's ligament, and arching across the front of the crural sheath, to be inserted by a broad attachment into the pectineal line behind the conjoined tendon. In some subjects this structure is not very prominently marked, and not infrequently it is altogether wanting. The superficial crural arch is the portion of Poupart's ligament in front of the femoral ring.

The Femoral or Crural Canal (canalis femoralis) (Figs. 296, 338, and 1130) is the narrow interval between the femoral vein and the inner wall of the femoral sheath. It exists as a distinct canal only when the sheath has been separated from the vein by dissection or by the pressure of a hernia or tumor. Its length is from a quarter to half an inch, and it extends from the femoral ring to the upper part of the saphenous opening.

Its anterior wall is very narrow, and formed by a continuation downward of the transversalis fascia, under Poupart's ligament, covered by the falciform process of the fascia lata.

Its posterior wall is formed by a continuation downward of the iliac fascia covering the pubic portion of the fascia lata.

Its outer wall is formed by the fibrous septum separating it from the inner side of the femoral vein.

Its inner wall is formed by the junction of the processes of the transversalis and iliac fasciae, which form the inner side of the femoral sheath, and lies in contact at its commencement with the outer edge of Gimbernat's ligament.

This canal has two orifices—an upper one, the femoral or crural ring, closed by the septum crurale; and a lower one, the saphenous opening, closed by the cribiform fascia.

The femoral or crural ring (annulus femoralis) (Figs. 1130, 1141, and 1142) is the upper opening of the femoral canal, and leads into the cavity of the abdomen. It is bounded in front by Poupart's ligament and the deep crural arch; behind, by the os pubis, covered by the Pectineus muscle and the pubic portion of the fascia lata; internally, by the base of Gimbernat's ligament, the conjoined tendon, the transversalis fascia, and the deep crural arch; externally, by the fibrous septum lying on the inner side of the femoral vein. The femoral ring is of an oval form; its long diameter, directed transversely, measures about half an inch, and it is larger in the female than in the male, which is one of the reasons of the greater frequency of femoral hernia in the former sex.

Position of Parts around the Ring.—The spermatic cord in the male and round ligament in the female lie immediately above the anterior margin of the
THE SURGICAL ANATOMY OF HERNIA

femoral ring, and may be divided in an operation for femoral hernia if the incision for the relief of the stricture is not of limited extent. In the female this is of little importance, but in the male the spermatic artery and vas deferens may be divided.

The femoral vein lies on the outer side of the ring.

The deep epigastric artery in its passage upward and inward from the external iliac artery passes across the upper and outer angle of the crural ring, and is consequently in danger of being wounded if the stricture is divided in a direction upward and outward.

The communicating branch between the deep epigastric and obturator lies in front of the ring.

The circumference of the ring is thus seen to be bounded by vessels in every part, excepting internally and behind (Fig. 1142). It is in the former position that the stricture is divided in cases of strangulated femoral hernia.

The obturator artery (p. 689), when it arises by a common trunk with the deep epigastric (p. 690), which occurs once in every three subjects and a half, bears a very important relation to the crural ring. In most cases it descends on the

inner side of the external iliac vein to the obturator foramen, and will consequently lie on the outer side of the crural ring, where there is no danger of its being wounded in the operation for dividing the stricture in femoral hernia (Fig. 429 A, p. 690). Occasionally, however, the obturator artery curves along the free margin of Gimbernat’s ligament in its passage to the obturator foramen; it would consequently skirt along the greater part of the circumference of the crural ring, and could hardly avoid being wounded in the operation (Fig. 429 B, p. 690).

The Crural Septum or Septum Crurale (septum femorale musculus) (Fig. 296).—The femoral ring is closed by a thin process of transversalis fascia containing fat and called, by J. Cloquet, the septum crurale. This serves as a barrier to the protrusion of a hernia through this part. Its upper surface is slightly concave, and supports a small lymphatic gland (Fig. 1142), by which it is separated from the subserous areolar tissue and peritoneum. Its under surface is turned toward the femoral canal. The septum crurale is perforated by numerous apertures for the passage of lymphatic vessels connecting the deep inguinal lymphatic glands with those surrounding the external iliac artery.

![Fig. 1142.—Hernia. The relations of the femoral and internal abdominal rings, seen from within the abdomen. Right side.](image-url)
The size of the femoral canal, the degree of tension of its orifices, and consequently the degree of constriction of a hernia, vary according to the position of the limb. If the leg and thigh are extended, abducted, or everted, the femoral canal and its orifices are rendered tense from the traction on these parts by Poupart's ligament and the fascia lata, as may be ascertained by passing the finger along the canal. If, on the contrary, the thigh is flexed upon the pelvis, and at the same time adducted and rotated inward, the femoral canal and its orifices become considerably relaxed; for this reason the limb should always be placed in the latter position when the application of the taxis is made in attempting the reduction of a femoral hernia.

The subperitoneal areolar tissue is continuous with the subserous areolar tissue of surrounding parts. It is usually thickest and most fibrous where the iliac vessels leave the abdominal cavity. It covers over the femoral ring, the small interval on the inner side of the femoral vein. In some subjects it contains a considerable amount of adipose tissue. In such cases, where it is protruded forward in front of the sac of a femoral hernia, it may be mistaken for a portion of omentum. The peritoneum lining the portion of the abdominal wall between Poupart's ligament and the brim of the pelvis is similar to that lining any other portion of the abdominal wall, being very thin. Here there is no natural aperture for the escape of intestine.

Descent of the Hernia.—From the preceding description it follows that the femoral ring must be a weak point in the abdominal wall; hence it is that when violent or long-continued pressure is made upon the abdominal viscera a portion of intestine may be forced into it, constituting a femoral hernia; and the changes in the tissues of the abdomen which are produced by pregnancy, together with the larger size of this aperture in the female, serve to explain the frequency of this form of hernia in women.

When a portion of the intestine passes through the femoral ring, a pouch of peritoneum lies before it, which forms what is called the hernial sac; it is covered by the subserous areolar tissue, receives an investment from the septum crurale, and descends vertically along the crural canal in the inner compartment of the sheath of the femoral vessels as far as the saphenous opening; at this point it changes its course, being prevented from extending farther down the sheath on account of the narrowing of the sheath and its close contact with the vessels, and also from the close attachment of the superficial fascia and crural sheath to the lower part of the circumference of the saphenous opening; the hernia is consequently directed forward, pushing before it the cribriform fascia, and then curves upward on to the fallopian process of the fascia lata and lower part of the tendon of the External oblique, being covered by the superficial fascia and integument. While the hernia is contained in the femoral canal it is usually of small size, owing to the resisting nature of the surrounding parts; but when it has escaped from the saphenous opening into the loose areolar tissue of the groin, it becomes considerably enlarged. The direction taken by a femoral hernia in its descent is at first downward, then forward and upward; this should be borne in mind, as in the application of the taxis for the reduction of a femoral hernia pressure should be directed in the reverse order.

Coverings of the Complete Hernia.—The coverings of a femoral hernia, from within outward, are—peritoneum, subserous areolar tissue, the septum crurale, crural sheath, cribriform fascia, superficial fascia, and integument.¹

¹ Sir Astley Cooper has described an investment for femoral hernia, under the name of "fascia propria," lying immediately external to the peritoneal sac, but frequently separated from it by more or less adipose tissue. Surgically, it is important to remember the existence (at any rate, the occasional existence) of this layer, on account of the ease with which an inexperienced operator may mistake the fascia for the peritoneal sac and the contained fat for omentum. Anatomically, this fascia appears identical with what is called in the text "subserous areolar tissue," the areolar tissue being thickened and caused to assume a membranous appearance by the pressure of the hernia.—En. of 15th English edition.
Varieties of Femoral Hernia.—If the hernia descends along the femoral canal only as far as the saphenous opening, and does not escape from this aperture, the condition is called incomplete femoral hernia. The small size of the protrusion in this form of hernia, which is due to the firm and resisting nature of the canal in which it is contained, renders it an exceedingly dangerous variety, from the extreme difficulty of detecting the existence of the swelling, especially in corpulent subjects. The coverings of an incomplete femoral hernia, named from without inward, are as follows: the integument, superficial fascia, iliac portion of fascia lata, crural sheath, septum crurale, subserous areolar tissue, and peritoneum. When, however, the hernia protrudes through the saphenous opening and directs itself forward and upward, it forms a complete femoral hernia, the coverings of which have been given (p. 1533). Occasionally the hernial sac descends on the iliac side of the femoral vessels or in front of these vessels, or even sometimes behind them.

The seat of stricture in a strangulated femoral hernia varies; it may be in the peritoneum at the neck of the hernial sac; in the greater number of cases it would appear to be at the point of junction of the falciform process of the fascia lata with the lunated edge of Gimbernat's ligament, or at the margin of the saphenous opening in the thigh. The stricture should in every case be divided in an inward direction, or upward and inward, and the extent of the necessary cut in the majority of cases is about two or three lines. By these means all vessels or other structures of importance in relation with the neck of the hernial sac will be avoided.
SURGICAL ANATOMY OF THE PERINÆUM.

Dissection.—The student should select a well-developed muscular subject, free from fat, and the dissection should be commenced early, in order that the parts may be examined in as recent a state as possible. A staff having been introduced into the bladder and the subject placed in the position shown in Fig. 1143, the scrotum should be raised upward, and retained in that position, and the rectum moderately distended with tow.

The Perinæum corresponds to the inferior aperture or outlet of the pelvis. Its deep boundaries are, in front, the pubic arch and subpubic ligament; behind, the tip of the coccyx; and on each side, the rami of the os pubis and ischium, the tuberosities of the ischium, and great sacro-sciatic ligaments. The space included by these boundaries is somewhat lozenge-shaped, and is limited on the surface of the body by the scrotum in front, by the buttocks behind, and on each side by the inner side of the thigh. A line drawn transversely between the anterior parts of the tuberosities of the ischium, on each side, in front of the anus, divides this space into two portions. The anterior portion contains the penis and urethra, and is called the perinæum proper or genito-urinary region. The posterior portion contains the termination of the rectum, and is called the ischio-rectal or anal region.

ISCHIO-RECTAL REGION.

The ischio-rectal region contains the termination of the rectum and a deep fossa, filled with fat, on each side of the intestine, between it and the tuberosity of the ischium; this is called the ischio-rectal fossa.

The ischio-rectal region presents in the middle line the aperture of the anus; around this orifice the integument is thrown into numerous folds, which are obliterated on distention of the anus. The integument is of a dark color, continuous with the mucous membrane of the rectum, and is provided with numerous
Dissection (Fig. 1143).—Make an incision through the integument, along the median line, from the base of the scrotum to the anterior extremity of the anus: carry it around the margins of this aperture to its posterior extremity, and continue it backward to about an inch behind the tip of the coccyx. A transverse incision should now be carried across the base of the scrotum, joining the anterior extremity of the preceding; a second, carried in the same direction, should be made in front of the anus; and a third at the posterior extremity of the first incision. These incisions should be sufficiently extensive to enable the dissector to raise the integument from the inner side of the thighs. The flaps of skin corresponding to the ischio-rectal region should now be removed. In dissecting the integument from this region great care is required, otherwise the Corrugator cutis ani and External sphincter will be removed, as they are intimately adherent to the skin.

The **Superficial Fascia** is exposed on the removal of the skin; it is very thick, areolar in texture, and contains much fat in its meshes. In it are found ramifying two or three branches of the perforating cutaneous nerve; these turn around the inferior border of the Gluteus maximus and are distributed to the integument around the anus.

In this region, and connected with the lower end of the rectum, are four muscles: the Corrugator cutis ani; the two Sphincters, External and Internal; and the Levator ani.

These muscles have been already described (p. 451).

The **Ischio-rectal Fossa** (fossa ischiorectalis) (Figs. 299 and 303) is situated between the end of the rectum and the ischial tuberosity. It is triangular in shape; its base, directed to the surface of the body, is formed by the integument of the ischio-rectal region; its apex, directed upward, corresponds to the point of division of the obturator fascia and the thin membrane given off from it, which covers the outer surface of the Levator ani (ischio-rectal or anal fascia). Its dimensions are about an inch in breadth at the base and about two inches in depth, being deeper behind than in front. It is bounded, internally, by the Sphincter ani, Levator ani, and Coccygeus muscles; externally, by the tuberosity of the ischium and the obturator fascia, which covers the inner surface of the Obturator internus muscle; in front, it is limited by the line of junction of the superficial fascia with the base of the triangular ligament; and behind, by the margin of the Gluteus maximus muscle and the great sacro-sciatic ligament. This space is filled with a large mass of adipose tissue, which explains the frequency with which abscesses in the neighborhood of the rectum burrow to a considerable depth.

If the subject has been injected, on placing the finger on the outer wall of this fossa the internal pudic artery, with its accompanying veins and the two divisions of the nerve, will be felt about an inch and a half above the margin of the ischial tuberosity, but approaching nearer the surface as they pass forward along the inner margin of the pubic arch. These structures are enclosed in a sheath, the [fascial canal or canal of Alcock](Figs. 303 and 1148), formed by the obturator fascia, the pudic nerve lying below the artery and the dorsal nerve of the penis above it. Crossing the space transversely, about its centre are the inferior hemorrhoidal vessels and nerves, which are distributed to the integument of the anus and to the muscles of the lower end of the rectum. These vessels are occasionally of large size, and may give rise to troublesome hemorrhage when divided in the operation of lithotomy or in that for fistula in ano. At the back part of this space, near the coccyx, may be seen a branch of the fourth sacral nerve, and at the forepart of the space the superficial perineal vessels and nerves can be seen for a short distance.
THE PERINEUM PROPER IN THE MALE.

The perineal space is of a triangular form; its deep boundaries are limited, laterally, by the rami of the pubic bones and ischia, meeting in front at the pubic arch; behind, by an imaginary transverse line extending between the anterior parts of the tuberosities of the ischia. The lateral boundaries are, in the adult, from three inches to three inches and a half in length, and the base from two to three inches and a half in breadth, the average extent of the space being two inches and three-quarters.

The variations in the diameter of this space are of extreme interest in connection with the operation of lithotomy and the extraction of a stone from the cavity of the bladder. In those cases where the tuberosities of the ischia are near together it would be necessary to make the incisions in the lateral operation of lithotomy less oblique than if the tuberosities were widely separated, and the perineal space consequently wider. The perineum is subdivided by the median raphe into two equal parts. Of these, the left is the one in which the operation of lithotomy is performed.

In the middle line the perineum is convex, and corresponds to the bulb of the urethra. The skin covering it is of a dark color, thin, freely movable upon the subjacent parts, and covered with sharp crisp hairs, which should be removed before the dissection of the part is commenced. In front of the anus a prominent line commences, the raphe, continuous in front with the raphe of the scrotum. The skin of the raphe is adherent to the deep layer of the superficial fascia.

Upon removing the skin and the superficial layer of the superficial fascia, in the manner shown in Fig. 1143, a plane of fascia will be exposed, covering in the triangular space and stretching across from one ischio-pubic ramus to the other. This is the deep layer of the superficial fascia or fascia of Colles (fascia superficialis perinaei). It has already been described (p. 458). It is a layer of considerable strength, and encloses and covers a space in which are contained muscles, vessels, and nerves. It is continuous in front with the fascia of the penis and the dartos of the scrotum; on each side it is firmly attached to the margin of the ischio-pubic ramus and to the tuberosity of the ischium; and posteriorly it curves down behind the Transversalis perinaei muscles to join the base of the triangular ligament.

It is between this layer of fascia and the triangular ligament of the urethra that extravasation of urine most frequently takes place in cases of rupture of the urethra. The triangular ligament of the urethra (p. 461) is attached to the ischio-pubic rami, and in front to the subpubic ligament. It is clear, therefore, that when extravasation of fluid takes place between these two layers, it cannot pass backward, because the two layers are continuous with each other around the Transversi perinaei muscles; it cannot extend laterally, on account of the connection of both these layers to the rami of the os pubis and ischium; it cannot find its way into the pelvis because the opening into this cavity is closed by the triangular ligament, and, therefore, so long as these two layers remain intact, the only direction in which the fluid can make its way is forward into the areolar tissue of the scrotum and penis, and then on to the anterior wall of the abdomen.

When the deep layer of the superficial fascia is removed (Fig. 1144), a space is exposed, between this fascia and the triangular ligament, in which are contained the superficial perineal vessels and nerves and some of the muscles connected with the penis and urethra—viz., in the middle line, the Accelerator urinae; on each side, the Erector penis; and behind, the transversus perinaei; together with the crura of the corpora cavernosa and the bulb of the corpus spongiosum. Here also is seen the central tendinous point of the perineum. This is a fibrous point in the middle line of the perineum between the urethra and the rectum, being about half an inch in front of the anus. At this point four muscles converge and are attached—viz., the External sphincter ani, the Accelerator urinae, and the two Transversi perinaei
muscles; so that by the contraction of these muscles, which extend in opposite directions, it serves as a fixed point of support.

The Accelerator urinae, the Erector penis, and the Superficial transversus perinaei muscles have been already described (p. 459). They form a triangular space (Fig. 1144), bounded, internally, by the Accelerator urinae; externally, by the Erector penis; and behind, by the Transversus perinaei. The floor of this space is formed by the triangular ligament of the urethra; and running from behind forward in it are the superficial perineal vessels and nerves, and the transverse perineal artery coursing along the posterior boundary of the space, on the Transversus perinaei muscle.

The Accelerator urinae and Erector penis should now be removed, when the triangular ligament of the urethra will be exposed, stretching across the front of the outlet of the pelvis. The urethra is seen perforating its centre, just behind the bulb; and on each side is the crus penis, connecting the corpus cavernosum with the rami of the ischium and os pubis.

The Triangular Ligament or the Deep Perineal Fascia (trigonum urogenitale or diaphragma urogenitale) (Figs. 308, 309, and 1145), which has been already described (p. 461), consists of two layers, the inferior anterior or superficial layer (fascia trigoni urogenitalis inferior) of which is now exposed. It is united to the superior or deep layer behind, but is separated in front by a subfascial space in which are contained certain structures.

The inferior layer of the triangular ligament (Figs. 304 and 309) consists of a strong fibrous membrane, the fibres of which are disposed transversely, which stretches across from one ischio-pubic ramus to the other and completely fills in the pubic arch; it is attached in front to the subpubic ligament, except just in the centre, where a small interspace is left for the dorsal vein of the penis. In the erect position of the body it is almost horizontal. It is perforated by the urethra in the middle line, and on each side of the urethral opening by the ducts of Cowper's glands and by the arteries of the bulb; in front, and external to this, by the artery
of the corpus cavernosum, immediately before this vessel enters the crus penis. Near its apex the ligament is perforated by the termination of the pudic artery and by the dorsal nerve of the penis. The apex of the triangular ligament is known as the transverse perineal ligament. The crura penis are exposed, lying superficial to this ligament. They will be seen to be attached by blunt-pointed processes to the rami of the os pubis and ischium, in front of the tuberosities, and passing forward and inward, joining to form the body of the penis. In the middle line the bulb and corpus spongiosum are exposed by the removal of the Accelerator urinae muscle.

If the inferior layer of the triangular ligament is detached on either side, the deep perineal interspace will be exposed and the following parts will be seen between it and the deep layer of the ligament: the subpubic ligament in front, close to the symphysis pubis; the dorsal vein of the penis; the membranous portion of the urethra and the Compressor urethrae muscle; Cowper’s glands and their ducts; the pudic vessels and the dorsal nerve of the penis; the artery and nerve of the bulb and a plexus of veins.

![Diagram](image_url)

Fig. 1145.—Deep perineal fascia. On the left side the anterior layer has been removed.

The superior, deep, or posterior layer of the triangular ligament or deep perineal fascia (fascia trigoni urogenitalis superior) (Fig. 304) is derived from the obturator fascia, and is continuous with it along the pubic arch. Behind, it joins with the inferior layer of the triangular ligament, and is continuous with the anal fascia. Above it is the prostate gland (Fig. 1146), supported by the anterior fibres of the Levator ani, which act as a sling for the gland and form the Levator prostatae muscle. The superior layer of the triangular ligament is continuous around the anterior free edge of this muscle with the layer of recto-vesical fascia covering the prostate gland. The superior layer of the triangular ligament is perforated by the urethra. Between the two layers of the triangular ligament are situated the membranous part of the urethra, enveloped by the Compressor urethrae muscle (Fig. 309); the ducts of Cowper’s glands; the arteries to the bulb; the pudic vessels and the dorsal nerve of the penis. The membranous part of the urethra is about three-quarters of an inch in length, and passes downward and
forward behind the symphysis pubis, from which it is distant about an inch. It is the narrowest part of the tube, and is enveloped, as has already been stated, by the Compressor urethrae muscle.

The Compressor urethrae has already been described (p. 460). In addition to this muscle, and immediately beneath it, circular muscular fibres surround the membranous portion of the urethra from the bulb in front to the prostate behind, and are continuous with the muscular fibres of the bladder. These fibres are involuntary.

Cowper's glands (Figs. 302, 1145, and 1146) are situated immediately below the membranous portion of the urethra, close behind the bulb, and below the artery of the bulb.

The Pudic Vessels (Figs. 1145 and 1146) and Dorsal Nerve of the Penis (Fig. 309) are placed along the inner margin of the pubic arch (p. 1548).

The Artery of the Bulb (Figs. 1145 and 1146, and p. 692) passes transversely inward, from the internal pudic artery (p. 690) along the base of the triangular ligament, between its two layers, accompanied by a branch of the pudic nerve. If the superior layer of the triangular ligament is removed and the crus penis of one side detached from the bone, the under or perineal surface of the Levator ani muscle, covered by the anal fascia, is brought fully into view (Figs. 301, 302, and 303). This muscle, with the triangular ligament in front and the Coccygeus and Pyriformis behind, closes the outlet of the pelvis.

The Levator ani and Coccygeus muscles have already been described (p. 453).

Position of the Viscera at the Outlet of the Pelvis.—Divide the central tendinous point of the perineum, separate the rectum from its connections by dividing the fibres of the Levator ani, which descend upon the sides of the prostate gland, and draw the gut backward toward the coccyx, when the under surface of the prostate gland, the neck and base of the bladder, the vesicule seminales, and the vasa deferentia will be exposed.

The Prostate Gland (p. 1141) is a pale, firm, glandular body which is placed immediately below the neck of the bladder, around the commencement of the
urethra. It is placed in the pelvic cavity, behind the lower part of the symphysis pubis, above the superior layer of the triangular ligament, and rests upon the rectum, through which it may be distinctly felt, especially when enlarged. In shape and size it resembles a chestnut. Its base is directed upward toward the neck of the bladder. Its apex is directed downward to the deeper layer of the triangular ligament, which it touches.

Its posterior surface is smooth, marked by a slight longitudinal furrow, and rests on the second part of the rectum, to which it is connected by areolar tissue. Its anterior surface is flattened, marked by a slight longitudinal furrow, and placed about three-quarters of an inch below the pubic symphysis. It measures about an inch and a half in its transverse diameter at the base, an inch in its anteroposterior diameter, and three-quarters of an inch in depth. Hence the greatest extent of incision that can be made in it without dividing its substance completely across is obliquely backward and outward. This is the direction in which the incision is made in it in the lateral operation of lithotomy. The prostate has a sheath derived from the recto-vesical fascia (p. 1459).

Above the prostate a small triangular portion of the bladder is seen (Fig. 1147), bounded, in front and below, by the prostate gland; above, by the recto-vesical fold of the peritoneum; on each side, by the seminal vesicle and the vas deferens. It is separated from direct contact with the rectum by the recto-vesical fascia. The relation of this portion of the bladder to the rectum is of extreme interest to the surgeon. In cases of retention of urine this portion of the organ is found projecting into the rectum, between three and four inches from the margin of the anus, and may be easily perforated without injury to any important parts. This portion of the bladder was consequently selected in the old days for the performance of the now obsolete operation of tapping the bladder.

**Surgical Anatomy.** **Median Lithotomy.**—As the incision is in the raphé, the hemorrhage is trivial, and there is but slight risk of injuring the pelvic fascia. But the operation gives little room for manipulation and is inadmissible in children, because in them dilatation of the wound may tear the bladder loose from the urethra. A risk of median lithotomy is division of the artery of the bulb.

In median lithotomy a grooved staff is introduced, the groove being median. The knife is introduced in the mid-line, just in front of the anal margin, and hits the staff near the apex of the prostate; the entire length of the membranous urethra is cut as the instrument is withdrawn.

**Parts Divided.**—Skin, superficial fascia, sphincter ani muscle, central tendon of the perineum, inferior leaf of the triangular ligament, membranous urethra, and the Compressor urethrae muscle.

**Lateral Lithotomy.**—The operation is performed on the left side of the perineum, as this is most convenient for the right hand of the operator. A grooved staff having been introduced into the bladder, the first incision is commenced midway between the anus and the back of the scrotum (i.e., in an ordinary adult perineum about an inch and a half in front of the anus) a little on the left side of the raphé, and is carried obliquely backward and outward to midway between the anus and tuberosity of the left ischium. The incision divides the integument and superficial fascia, the inferior hemorrhoidal vessels and nerves, and the superficial and transverse perineal vessels. If the forefinger of the left hand is thrust upward and forward into the wound, pressing at the same time the rectum inward and backward, the staff may be felt in the membranous portion of the urethra. The finger is fixed upon the staff, and the structures covering the staff are divided with the point of the knife, which must be directed along the groove toward the bladder, the edge of the knife being turned outward and backward, dividing in its course the membranous portion of the urethra and part of the left lobe of the prostate gland to the extent of about an inch. The knife is then withdrawn, and the forefinger of the left hand passed along the staff into the bladder. The position of the stone having been ascertained, the staff is to be withdrawn, and the forceps is introduced over the finger into the bladder. If the stone is very large, the opposite side of the prostate may need to be notched before the forceps is introduced; the finger is now withdrawn, and the blades of the forceps opened and made to grasp the stone, which must be extracted by slow and cautious undulating movements.

**Parts Divided in the Operation.**—The various structures divided in this operation are as follows: the integument, superficial fascia, inferior hemorrhoidal vessels and nerves, and prob-
ably the superficial perineal vessels and nerves, the posterior fibres of the Accelerator urinæ muscle, the Transversus perinæi muscle and artery, the triangular ligament, the anterior fibres of the Levator ani muscle, part of the Compressor urethrae muscle, the membranous and prostatic portions of the urethra, and part of the prostate gland.

Parts to be Avoided in the Operation.—In making the necessary incisions in the perineum for the extraction of a calculus the following parts should be avoided: The primary incision should not be made too near the middle line, for fear of wounding the bulb of the corpus spongiosum or the rectum; nor too far externally, otherwise the internal pudic artery may be implicated as it ascends along the inner border of the pubic arch. If the incisions are carried too far forward, the artery of the bulb may be divided; if carried too far backward, the entire breadth of the prostate and neck of the bladder may be cut through, which allows the urine to become infiltrated behind the pelvic fascia into the loose areolar tissue between the bladder and rectum, instead of escaping externally; diffuse inflammation is consequently set up, and peritonitis, from the close proximity of the recto-vesical peritoneal fold, is the result. If, on the contrary, only the anterior part of the prostate is divided, the urine makes its way externally, and there is less danger of infiltration taking place.

During the operation it is of great importance that the finger should be passed into the bladder before the staff is removed; if this is neglected, and if the incision made in the prostate and neck of the bladder is too small, great difficulty may be experienced in introducing the finger afterward; and in the child, where the connections of the bladder to the surrounding parts are very loose, the force made in the attempt is sufficient to displace the bladder upward into the abdomen, out of the reach of the operator. Such a proceeding has not unfrequently occurred, producing the most embarrassing results and total failure of the operation.

It is necessary to bear in mind that the arteries in the perineum occasionally take an abnormal course. Thus the artery of the bulb, when it arises, as sometimes happens, from the pudic opposite the tuber ischii, is liable in its passage forward to the bulb to be wounded in the operation of lithotomy. The accessory pudic may be divided near the posterior border of the prostate gland, if this gland is completely cut across; and if the prostatic veins are of large size, and give rise, when divided, to troublesome hemorrhage. In men advanced in years the prostatic veins are very apt to be enlarged.

Extravasation of Urine.—Extravasation most commonly occurs from urethral rupture, between Colles's fascia and the triangular ligament of the urethra (extravasation in front of the triangular ligament). The adherence of these two fascial layers posteriorly prevents the urine from passing backward. The urine cannot find a way laterally, because both layers on each side are attached to the rami of the pubes and ischium. It cannot reach the pelvis, because the triangular ligament bars the way. It can only go forward if the two fascial layers remain intact, and consequently the urine passes into the areolar tissue of the serotum beneath the superficial fascia of the penis and of the anterior abdominal wall.

Pus and blood would pursue the same course in this space. Effusions in this space causes much pain, because the space contains the three long serotum nerves.

In rupture of the urethra between the two layers of the triangular ligament, the urine remains in this situation as long as fascia remains intact. If suppuration occurs, destruction of fascia liberates the urine.

In rupture behind the superior layer of the triangular ligament (extravasation back of the triangular ligament), the urine passes into the ischio-rectal fossa and upward and backward into the pelvis.

THE FEMALE PERINÆUM.

The female perinæum presents certain differences from that of the male, in consequence of the whole of the structures which constitute it being perforated in the middle line by the vulvo-vaginal passage.

The Superficial Fascia, as in the male, consists of two layers, of which the superficial one is continuous with the superficial fascia over the rest of the body, and the deep layer, corresponding to the fascia of Colles in the male, is, like it, attached to the ischio-rectal rami, and in front is continued forward through the labia majora to the inguinal region. It is of less extent than in the male, in consequence of being perforated by the aperture of the vulva.

On removing this fascia the muscles of the female perinæum, which have already been described (p. 463), are exposed (Figs. 310 and 1147). The Sphincter vaginae, corresponding to the Accelerator urinæ in the male, consists of an atten-
uated plane of fibres, forming an orbicular muscle around the orifice of the vagina, instead of being united in a median raphé, as in the male. The Erector clitoridis is proportionately reduced in size, but differs in no other respect from the erector penis, and the Transversus perinaei is similar to the muscle of the same name in the male.

The triangular ligament (Fig. 1147) is not strongly marked as in the male. It transmits the urethra and the tube of the vagina.

The Compressor Urethrae corresponds with the Compressor urethrae in the male. It arises from the ischio-pubic ramus, and, passing inward, its anterior fibres blend with the muscle of the opposite side, in front of the urethra; its middle fibres, the most numerous, are inserted into the side of the vagina, and the posterior fibres join the central point of the perineum.

The distribution of the internal pudic artery is the same as in the male (p.1552), and the pudic nerve has also a similar arrangement, the dorsal nerve being, however, very small and supplying the clitoris.

The corpus spongiosum is divided into two lateral halves, which are represented by the bulbi vestibuli and partes intermediales.

The Perineal Body fills up the interval between the lower part of the vagina and the rectum. Its base is covered by the skin lying between the anus and
vagina on what is called the perineum. Its anterior surface lies behind the posterior vaginal wall, and its posterior surface lies in front of the anterior rectal wall and the anus. It measures about an inch and a quarter from before backward, and laterally extends from one tuberosity of the ischium to the other. In it are situated the muscles belonging to the external organs of generation. Through its centre runs the transverse perineal septum, which is of great strength in women, and forms on either side, behind the posterior commissure, a hard, ill-defined body, consisting of connective tissue, with much yellow elastic tissue and interlacing bundles of involuntary muscular fibres, in which the voluntary muscles of the perineum are inserted.

**THE PELVIC FASCIA (FASCIA PELVIS) (Figs. 303 and 1149).**

The pelvic fascia strengthens the floor of the pelvis, fastens pelvic structures together, and supports the nerves, blood-vessels, and lymphatics. It is connected above with the transversalis fascia and the iliac fascia. It is at first a thin membrane and covers the inner surface of the pelvis, being attached to the brim for a short distance at the side of the cavity and to the inner surface of the bone around the attachment of the Obturator internus. At the posterior portion of this muscle it is continued backward as a very thin membrane in front of the Pyriformis muscle to the front of the sacrum. In front, as it descends, it gives off the parietal layer of the pelvic fascia, which continues as the obturator fascia. It then becomes thicker and covers the inner and upper surface of the Diaphragm of the pelvis as far as the white line (arcus tendineus fasciae pelvis). The portion covering the superior and upper surface of the pelvic Diaphragm is the inner sheath of the Levator ani muscle and is called the visceral layer of the pelvic fascia or the recto-vesical fascia (fascia diaphragmatic pelvis superior). The white line is a rough band of fascial thickening, seen in the pelvic fascia of each side. It indicates the line of separation between the pelvic cavity and the ischio-rectal fossa. It passes from the lower
portion of the symphysis pubis outward and backward to the spine of the ischium. It makes the attachment of the Levator ani muscle to the pelvic fascia. At the white line the chief mass of the pelvic fascia passes upon the pelvic viscera and is known as the **fascia endo-pelvica**. It covers portions of the vagina, rectum, and urinary bladder, becomes thinner and thinner, and is gradually lost. Other bands of fascia begin at the white line, descend on the inner surface of the recto-vesical fascia, and in the male pass to the tip of the prostate and become the prostatic fascia. Between the anterior ends of the two white lines the level of the fascia is lower, and it forms a fossa, bounded on the sides in the male by the **pubo-prostacic ligaments** (ligamenta puboprostatica lateralia), and in the female by the **pubo-vesical ligaments** (ligamenta pubovesicalia lateralia). These ligaments are called the **lateral true ligaments of the bladder**. In the base of this fossa in the male runs the **anterior true ligament of the bladder** or the **pubo-prostacic ligament** (ligamentum puboprostaticum).

![Diagram of pelvic viscera of the male subject](image)

FIG. 1149.—Side view of the pelvic viscera of the male subject, showing the pelvic and perineal fasciae.

**medium**, and in the female the **anterior true vesical ligament** (ligamentum pubovesicale medium). These ligaments arise from the lowest portion of the symphysis and pass to the urinary bladder and prostate in the male, and urinary bladder and urethra in the female (Spalteholz). The outer surface of the pelvic Diaphragm is covered by the **anal fascia** or the **ischio-rectal fascia** (fascia diaphragmatis pelvis inferior). It is the lower or outer sheath of the Levator ani muscle, and is derived from the obturator fascia. The space between the obturator fascia and the anal fascia is pyramidal and is called the **ischio-rectal fossa** (fossa ischiorectalis).

The pelvic fascia does not completely invest the bladder, although the neck and lateral walls lie upon the Levator ani muscles, and the lateral true ligaments and the anterior ligament ascend upon the sides and front of the bladder and are lost upon the fibrous coat of that viscus. The sides and anterior wall have a fascial investment. The **sheath of the prostate** has already been discussed (p. 1459). It is
continuous with the recto-vesical fascia and the anterior true ligament of the bladder.

The pelvic fascia is composed, according to Hughes, of: 1. The fibrous capsules of the pelvic viscera. 2. The sheaths of the Levator ani and Coccygei muscles (recto-vesical and anal fasciae). 3. The sheath of the Obturator internus (obturator fascia). 4. Sheath of the Compressor urethrae muscle (the triangular ligament). 5. The sheath of the pelvic aspect of the Pyriformis muscle. The sacral plexus is outside this sheath, the internal iliac vessels inside of it. As previously stated, the pelvic fascia gives off the obturator fascia and the recto-vesical fascia.

The Obturator Fascia (fascia obturatoria) descends and covers the Obturator internus muscle. It is a direct continuation of the parietal pelvic fascia below the white line above mentioned, and is attached to the pelvic arch, the ischial tuberosities, and to the margin of the great sacro-sciatic ligaments. This fascia forms a canal for the pudic vessels and nerve in their passage forward to the perineum, and gives off a thin membrane which covers the perineal aspect of the Levator ani muscle, and is called the anal or ischio-rectal fascia. It forms the inner boundary of the ischio-rectal fossa. From its attachment to the rami of the os pubis and ischium a process is given off which is continuous with a similar process from the opposite side, so as to close the front part of the outlet of the pelvis, forming the deep layer of the triangular ligament.

The Recto-vesical Fascia or the Visceral Layer of the Pelvic Fascia (fascia endopelvica) descends into the pelvis upon the upper surface of the Levator ani muscle, and invests the prostate, bladder, and rectum. From the inner surface of the symphysis pubis a short rounded band is continued, on each side of the middle line, to the upper surface of the prostate and neck of the bladder, forming the pubo-prostatic or anterior true ligaments of the bladder. At the side this fascia is connected to the side of the prostate, enclosing this gland and the vesico-prostatic plexus of veins, and is continued on to the side of the bladder, forming the lateral true ligaments of the organ. Another prolongation invests the seminal vesicle, and passes across between the bladder and rectum, being continuous with the same fascia of the opposite side. Another thin prolongation is reflected around the surface of the lower end of the rectum. The Levator ani muscle arises from the point of division of the pelvic fascia, the visceral layer of the fascia descending upon and being intimately adherent to the upper surface of the muscle, while the under surface of the muscle is covered by a thin layer derived from the obturator fascia, called the ischio-rectal or anal fascia. In the female the vagina perforates the recto-vesical fascia and receives a prolongation from it.

1 A Manual of Practical Anatomy. By Prof. Alfred W. Hughes; edited and completed by Dr. Arthur Keith.
CHRONOLOGICAL TABLE
OF
THE DEVELOPMENT OF THE FETUS.

(FROM BEAUNIS AND BOUCHARD.)

First Week.—During this period the ovum is in the Fallopian tube. Having been fertilized in the upper part of the tube, it slowly passes down, undergoing segmentation, and reaches the uterus probably about the end of the first week. During this time it does not undergo much increase in size.

Second Week.—The ovum rapidly increases in size and becomes imbedded in the decidua, so that it is completely enclosed in the decidua reflexa by the end of this period. An ovum believed to be of the thirteenth day after conception is described by Reichert. There was no appearance of any embryonic structure. The equatorial margins of the ovum were beset with villi, but the surface in contact with the uterine wall and the one opposite to it were bare. In another ovum, described by His, believed to be of about the fourteenth day, there was a distinct indication of an embryo. There was a medullary groove bounded by folds. In front of this a slightly prominent ridge, the rudimentary heart. The amnion was formed and the embryo was attached by a stalk, the allantois, to the inner surface of the chorion. It may be said, therefore, that these parts, the amnion and the allantois, and the first rudiments of the embryo, the medullary groove, and the heart, are formed at the end of the second week.

Third Week.—By the end of the third week the flexures of the embryo have taken place, so that it is strongly curved. The protvertebral disks, which begin to be formed early in the third week, present their full complement. In the nervous system the primary divisions of the brain are visible, and the primitive ocular and auditory vesicles are already formed. The primary circulation is established. The alimentary canal presents a straight tube communicating with the yolk-sac. The branchial arches are formed. The limbs have appeared as short buds. The Wolfian bodies are visible.

Fourth Week.—The umbilical vesicle has attained its full development. The caudal extremity projects. The upper and the lower limbs and the cloacal aperture appear. The heart separates into a right and left heart. The special ganglia and anterior roots of the spinal nerves, the olfactory fossae, the lungs and the pancreas can be made out.

Fifth Week.—The allantois is vascular in its whole extent. The first traces of the hands and feet can be seen. The primitive aorta divides into aorta and pulmonary artery. The duct of Müller and genital gland are visible. The ossification of the clavicle and the lower jaw commences. The cartilage of Meckel occupies the first post-oral arch.

Sixth Week.—The activity of the umbilical vesicle ceases. The pharyngeal clefts disappear. The vertebral column, primitive cranium, and ribs assume the cartilaginous condition. The posterior roots of the nerves, the membranes of the nervous centres, the bladder, kidney, tongue, larynx, thyroid body, the germ of teeth, and the genital tubercle and folds are apparent.

Seventh Week.—The muscles begin to be perceptible. The points of ossification of the ribs, scapula, shaft of humerus, femur, tibia, patellae, and upper jaw appear.

Eighth Week.—The distinction of arm and forearm, and of thigh and leg, is apparent, as well as the interdigital clefts. The capsule of the lens and pupillary membrane, the interventricular and commencement of the interauricular septum, the salivary glands, the spleen, and suprarenal capsules are distinguishable. The larynx begins to become cartilaginous. All the vertebral bodies are cartilaginous. The points of ossification for the ulna, radius, fibula, and ilium make their appearance. The two halves of the hard palate unite. The sympathetic nerves are now for the first time to be discerned.

1 [Eternod (Anat. Anzeiger, Band xv., 1898) described an ovum which he reconstructed. It had a precise history, from which he concluded that it must have belonged to the end of the second or the beginning of the third week. Including the villi it measured 10 × 8.2 × 6 mm. It was flattened on its embryonal side, and the embryo measured 1.8 mm. The amnion was completely formed and the allantois existed as a long canal. The vitelline circulation was established and the villi of the chorion were beginning to be vascularized. The blastopore still opened into the amniotic cavity, with the primitive groove behind it and the rudimentary groove in front. The notochord was closing in and all three layers of the blastoderm were distinct, except around the blastopore, where they formed an undivided mass.—Ed. of 15th English edition.]
Ninth Week.—The corpus striatum and the pericardium are first apparent. The ovary and testicle can be distinguished from each other. The genital furrow appears. The osseous nuclei of the bodies and arches of the vertebrae, of the frontal, vomer, and malar bones of the shafts of the metacarpal and metatarsal bones, and of the phalanges appear. The union of the hard palate is completed. The gall-bladder is seen.

Third Month.—The formation of the fetal placenta advances rapidly. The projection of the caudal extremity disappears. It is possible to distinguish the male and female organs from each other. The cloacal aperture is divided into two parts. The cartilaginous arches on the dorsal region of the spine close. The points of ossification for the occipital, sphenoid, lachrymal, nasal, squamous portion of temporal and ischium appear, as well as the orbital centre of the superior maxillary. The pons Varolii and fissure of Sylvius can be made out. The eyelids, the hair, and the nails begin to form. The mammary gland, the epiglottis, and prostate are beginning to develop. The union of the testicle with the canals of the Wolffian body takes place.

Fourth Month.—The closure of the cartilaginous arches of the spine is complete. Osseous points for the first sacral vertebra and os pubis appear. The ossification of the maxilla and meus takes place. The corpus callosum, the membrana lamina spiralis, the cartilage of the Eustachian tube, and the tympanic ring are seen. Fat is first developed in the subcutaneous cellular tissue. The tonsils are seen, and the closure of the genital furrow and the formation of the scrotum and prepuce take place.

Fifth Month.—The two layers of the decidua begin to coalesce. Osseous nuclei of the axis and odontoid process, of the lateral points of the first sacral vertebra, of the median points of the second, and of the lateral masses of the ethmoid make their appearance. Ossification of the stapes and the petrous bone and ossification of the germs of the teeth take place. The germs of the permanent teeth and the organ of Corti appear. The eruption of hair on the head commences. The sudoriferous glands, Brunner’s glands, the follicles of the tonsil and base of the tongue, and the lymphatic glands appear at this period. The differentiation between the uterus and vagina becomes apparent.

Sixth Month.—The points of ossification for the anterior root of the transverse process of the seventh cervical vertebra, the lateral points of the second sacral vertebra, the median points of the third, the manubrium sterni, and the os calcis appear. The sacro-vertebral angle forms. The cerebral hemispheres cover the cerebellum. The papillae of the skin, the sebaceous glands, and Peyer’s patches make their appearance. The free border of the nail projects from the corium of the dermis. The walls of the uterus thicken.

Seventh Month.—The additional points of the first sacral vertebra, the lateral points of the third, the median point of the fourth, the first osseous point of the body of the sternum, and the osseous point for the astragalus appear. Meckel’s cartilage disappears. The cerebral convolutions, the island of Reil, and the tubercula quadrigemina are apparent. The pupillary membrane atrophies. The testicle passes into the vaginal process of the peritoneum.

Eighth Month.—Additional points for the second sacral vertebra, lateral points for the fourth and median points for the fifth sacral vertebrae, can be seen.

Ninth Month.—Additional points for the third sacral vertebra, lateral points for the fifth, osseous points for the middle turbinate bone, for the body and great cornu of the hyoid, for the second and third pieces of the body of the sternum, and for the lower end of the femur appear. Ossification of the bony lamina spiralis and axis of the cochlea takes place. The eyelids open, and the testicles are in the scrotum.

INDEX

Vertebrae, lumbar, 56
fifth, 57
process of, articular, 49
spinous, 49
transverse, 49
prominens, 53
sacral, 61
structure of, 58
thoracic, 53
peculiar, 55

Vertebral apanurosis, 413, 418
artery, 639
surgical anatomy of, 641
border of seapula, 176
canal 49
column, 48
articulations of, 271
surface form of, 69
surgical anatomy of, 69
foramen, 49
groove, 156
ligaments, 272
plexus of nerves, 1086
region, muscles of, anterior, 408, 411
lateral, 410
ribs, 161
vein, 732, 751
Vertebral arterial foramen, 50
Vertebro-echondral ribs, 161
Vertebro-pericardial ligaments, 590
Vertebr-pleural ligament, 1309
Vertebral-ternal ribs, 161
Vertex of skull, 129, 150
Vertical linguial muscle, 401
plate of palate bone, 117
Verumontanum, 1451
Vesical arteries, 657, 688
plexus of nerves, 1095
of veins, inferior, 762
superior, 761
trigone, 1447
Vesicle, prostatic, 1451
Vesicles of brain, 864
optic, 865
Gratiolet, 1514
seminal, 1486
Vesico-uterine ligament, 1502
Vesicula prostatica, 1450
Vestibular artery, 1186
ganglion, 1065
terminus, 1065
branches of, 1065
nuclei of, 893
window, 1182
Vestibule, aortic, of Sibson, 574
of ear, 1174
of mouth, 1204
of nose, 1100

Vestibule of vagina, 1491
Vestibulo-spinal tract, of cord, lateral, 853
ventral, 854
Vestigial fold of pericardium, 563
Vibrisso, 1106
Vieq d'Azayr, band of, 989
bundle of, 914, 916
Vidian artery, 617
canal, 96, 135
terminus, 1049
veins, 750
Vieusens, ansa of, 1086
Villi of small intestine, 1300
sinoval, 264
Viscera, development of, 1245
Visceral cranium, 71
layer of pleura, 1391
lymphatics, 808
peritoneum, 1257
portion of tunica vaginalis, 1481
surface of liver, 1336
of stomach, 1278
Visual axis, 1116
purple, 1130
Vitreous body, 1130
humor of eye, 1139
table of skull, 34
Vocal cords, false, 1378
terminus, 1378
process, 1373
Voice, organs of, 1389
Volar intersosseous nerve, 1004
Volkmann's canals, 38
Voluntary muscles, 363
Vomer, 120
alse of, 121, 143
articulations of, 122
development of, 122
surfaces of, 121
Vomerine cartilage, 1107
Vortex of heart, 578
Vulvo-vaginal gland, 1495

W

Waldeyer, germinal epithelium of, 1513
odontoblasts of, 1211
Wedge bodies, 249
Wharton's duct, 1226
White commissure of cord, 584
fibrous tissue, 263
line of Hilton, 1327
substance of cord, 545, 556
Wilder, post-oblongata of, 874
Willis, circle of, 631, 642
Winslow, necessary anterior cranial nerve of, 1020

Winslow, ligament of, posterior, 337
uncinate process of, 1357
Wirsung, canal of, 1359
Womb, 1498
Worm of cerebellum, 895
Wormian bones, 108
development of, 104
Wrisberg, cardiac ganglion of, 1000
cartilages of, 1373
cuneiform tubercle of, 1376
ligament of, 341
nerve of, 1003
pars intermedia of, 1059
Wrist, articulations of, 319
bursa of, 494
Wrist-joint, 319
ligament of, 320
surface form of, 320
surgical anatomy of, 320

X

Xipho-pericardial ligament, 561
Xiphoipoid appendix, 159
surfaces of, 159
cartilage, 157

Y

Y-ligament, 330
Yellow elastic tissue, 264
spot of Sommering, 1131

Z

Zinn, ligament of, 375
zonule of, 1139
Zona arcuata, 1183
fasciulata, 1439
glomerulosa, 1439
orbicularis, 329
peptinata, 1183
reticularis, 1439
tecta, 1183
Zones of brain, longitudinal, 870
Zonula ciliaris, 1139
Zonule of Zinn, 1139
Zygoma, 84
Zygomatic arch, 138
fossa, 138
lymphatic glands, 781
process of malar, 115
of temporal bone, 84
Zygomaticus major muscle, 379
minor muscle, 379
Zymogen granules, 1352
